If a loudspeaker is excited with an impulse, the signal from a suitably well-behaved test microphone placed in front of the speaker will represent the loudspeaker’s impulse response at that point. This signal may be digitized and post processed to yield the frequency-domain transfer function, as well as a number of other functions. The sampling process takes place over a fixed amount of time (the time window), and its initiation may be delayed to remove the effect of time required for sound to travel from the loudspeaker to the test microphone (propagation delay). Additionally, the length of the time window may be chosen so as to reject reflections from the room in which the measurement is being made. This is termed a quasianechoic measurement, and its availability has made it possible to acquire accurate direct-field response data on loudspeakers without an anechoic chamber.

The mathematics of Fourier series requires that the signal value be zero at the beginning and end of the time window. Since this condition is not generally satisfied, a window function is applied to the sampled data to force the endpoints of the window to zero. The effect of the window function is to create inaccuracies in the calculated transfer function, but these are generally much less than the spectral inaccuracies that would result from unwindowed (truncated) data. Various types of window functions may be used, including square (equivalent to unwindowed data), Gaussian, Hamming, and Hanning. Each has its advantages and drawbacks.

Among the disadvantages of impulse excitation is that of SNR. Because the impulse is of short duration, quiescent noise in the test environment can easily corrupt the test data. One means of reducing the effect of background noise is to average the results of multiple tests. If the noise is random, and therefore uncorrelated with the test signal, each doubling of the number of averages has the potential of reducing the relative noise level by 3 dB. Averaging increases the amount of time required to acquire the data.

Another disadvantage of impulse excitation is that it provides no means of identifying nonlinearities (distortion) in the loudspeaker. Distortion products appear no differently to the analyzer than the linear portion of the device’s response.

17.11.4.2 Maximum Length Sequence Measurements

A variation on the method of impulse excitation is called maximum length sequence, or MLS, testing. In this form of measurement, the excitation signal is a series of pulses that repeats itself. The loudspeaker’s impulse response is derived by calculating the cross-correlation between the input and output signals. This excitation signal has the advantage of producing higher average signal levels than an impulse, therefore improving the signal/noise performance of the test.

Additionally, the effects of certain types of distortion can be reduced substantially by running a series of tests employing a strategically chosen set of signal sequence lengths. To be accurate, an MLS test must be configured such that the duration of the signal sequence exceeds the length of the impulse response of the device under test. In the case of loudspeaker measurements, the impulse response of the acoustic environment must be accounted for in order to satisfy the requirement.

17.11.4.3 Other FFT-Based Measurements

Yet another variation on the FFT technique is a type of measurement that can use an arbitrary signal as the excitation signal. This form of measurement is a dual-channel FFT measurement, and the variations on
this technique have several common elements. The technique involves sampling the signal at a point in the chain prior to the input of the loudspeaker (input), as well as the signal from a test microphone (output). The output may be sampled at a later time in order to account for the time required for sound to propagate from the loudspeaker to the test microphone. As with MLS testing, cross-correlation between input and output signals will yield the impulse response of the loudspeaker. It is also possible to perform an FFT on both input and output signals and obtain the transfer function of the loudspeaker by complex division.

The dual-channel approach has the advantage of allowing a wide range of signals, including music, to be employed as excitation. The commercially available implementations of this technique incorporate several refinements of the basic procedure described above, and these systems offer the possibility of measuring the response of a sound system while it is in operation.

SNR is a possible issue with this form of measurement, so averaging is generally performed to improve the accuracy of the results. Additionally, the spectrum of the input signal may not contain sufficient energy at all frequencies to sufficiently excite the system under test. For this reason, a coherence function is used to indicate those frequency ranges where the signal energy is insufficient to yield good results.

17.11.5 Swept Sine Measurements

Although the chart recorder is a swept sine measurement, it fails to take advantage of all the possibilities offered by the use of a sweep (also known as a chirp) as a test signal. Dick Heyser developed and patented a technique known as time delay spectrometry, or TDS. In TDS, the analyzer’s receiving circuitry employs a band-pass filter, the center frequency of which is swept in synchronicity with the frequency of the signal applied to the loudspeaker. A delay may be applied to the sweep of the bandpass filter to account for the amount of time required for sound to propagate from the device under test to the microphone, hence the name of the technique.

The bandpass filter will reject frequencies that are displaced by some amount from its center frequency. If the receive delay for the filter is chosen appropriately, the analyzer will admit the direct signal from the loudspeaker, while simultaneously rejecting signals that have been reflected from environmental surfaces, thereby traveling a longer path and arriving later than the direct signal. The effect of this ability to reject unwanted reflections is the creation of a time window, even though the data is taken in the frequency domain. Additionally, the bandpass filter attenuates broadband noise by a much greater amount than it does the direct signal from the loudspeaker.

Due to the inherently high SNR of TDS, averaging of multiple tests is usually unnecessary. The number of samples analyzed is also not a function of the time window, as it is with an FFT-based analyzer. Furthermore, the bandpass filter removes distortion products, so TDS is intrinsically more capable of separating the linear transfer function from distortion products. It is also possible to use the technique to track specific harmonics while rejecting the fundamental.

Loudspeaker test instrumentation is more powerful and less expensive now than at any other time in the history of loudspeakers. While the current situation makes it possible to gather ever more detailed information about the behavior of loudspeakers, it is important to keep in mind the basics of instrumentation and spectrum analysis. This awareness will assist in identifying loudspeaker data that is suspect or incomplete.

18.1 Why Array?

For the purposes of this discussion we can define a loudspeaker array as a group of two or more full-range loudspeaker systems, arranged so their enclosures are in contact. System designers use arrays of multiple enclosures when a single enclosure cannot produce adequate sound pressure levels, when a single enclosure cannot cover the entire listening area, or both. These problems can also be dealt with by distributing single loudspeaker systems around the listening area, but most designers prefer to use arrays whenever possible because it is easier to maintain intelligibility using a sound source that approximates a point source than by using many widely separated sources.

18.2 Array Problems and Partial Solutions: A Condensed History

First-generation portable sound systems designed for music used a very primitive form of array: they simply piled up lots of rectangular full range speaker systems together, with all sources aimed in the same direction, in order to produce the desired SPL. This type of array produced substantial interference, because each listener heard the output of several speakers, each at a different distance. The difference in arrival times produced peaks and nulls in the acoustic pressure wave at each location, and these reinforcements and cancellations varied in frequency depending on the distances involved. So although the system produced the desired SPL, the frequency response was very inconsistent across the coverage area. Even where adequate high frequency energy was available, intelligibility was compromised by multiple arrivals at each listening location.

Second-generation systems incorporated compression drivers and horn-loading techniques derived from cinema sound reinforcement and used for large-scale speech-only systems (the original meaning of public address). When two or three of these horns were incorporated in a single enclosure with trapezoidal sides that splayed the horns away from each other, the first arrayable systems were introduced to the marketplace. These products promised to eliminate lobing and dead spots (peaks and nulls) and to drastically reduce comb filtering (interference). They did improve performance over the stack of rectangular enclosures loaded mainly with direct radiating cones. But frequency response across the coverage area remained inconsistent. In addition to the midrange and high frequency variations across the coverage area of the array, low frequency output varied from the front to the rear and side to side. Low frequency energy was focused along the longitudinal axis of the array and close to it, producing a “power alley” that gave the seats with the best views the worst sound, Fig. 18-1.

18.3 Conventional Array Shortcomings

As we said in the first paragraph, the performance advantages of the array (whether horizontal or vertical) derive from its ability to approximate a perfect acoustical point source. But even the smallest arrays typically including three or more loudspeaker enclosures,
each with two or three separate acoustic centers of its own. It’s easy to appreciate that getting all those discrete sources to behave like a theoretical point source is difficult in practice. Signal processing solutions attempt to compensate for the difference between theory and reality by sacrificing the coherency of the electronic signal. They apply frequency shading and/or micro-delays to the signals sent to different enclosures, in order to ameliorate the acoustic problems. These approaches are costly, complicated and often meet with limited success.

A rigorous analysis of the acoustical physics can point the way toward a practical, physical solution. First, consider what is probably the most common arrayable system in use today: $60^\circ \times 40^\circ$ horns in enclosures with $15^\circ$ trapezoidal sides, Fig. 18-2.

Figure 18-2. A very common array uses three $60^\circ \times 40^\circ$ horns in enclosures with $15^\circ$ trapezoidal sides; tightpacked, this array produces substantial overlap and interference between adjacent horns.

Tight-packing three of these systems with their $15^\circ$ sides touching produces a $30^\circ$ splay between the horns, for a total included angle of $120^\circ$. At first glance, this seems like an ideal alignment. But the EASE interference predictions in Fig. 18-3 show the familiar and clearly audible problems with this configuration: significant interference above $1 \text{ kHz}$, with variations of $8 \text{ dB} - 9 \text{ dB}$ depending on the angle. On axis, there is about $10 \text{ dB}$ of gain at frequencies below $1 \text{ kHz}$. Where maximum SPL is the main consideration, this type of array will deliver acceptable performance. When the front-of-house mix position can be located on the axis of left and right arrays, they can usually be tweaked to deliver acceptable reproduction in this limited area. Other areas of the house, including the high roller seats up front, will suffer.

The interference patterns displayed in Fig. 18-3 can be reduced by widening the splay between cabinets to $30^\circ$, as illustrated in Fig. 18-4. This array will not look as pretty as the first, but it does have much more even response across the coverage area, Fig. 18-5. At $2 \text{ kHz}$ and $4 \text{ kHz}$, the individual horns are clearly discernible in the ALS-1 predictions. Also note that the seams between the horns become deeper with increasing frequency.

Figure 18-3. The interference patterns shown above were produced by tight-packing three arrayable loudspeakers using $60^\circ \times 40^\circ$ constant directivity horns in enclosures with $15^\circ$ trapezoidal sides. While this is an improvement over a pile of direct radiating transducers, it is far from the ideal point source array.

Figure 18-4. Widening the splay between horns reduces interference and widens the coverage angle to $180^\circ$, but reduces forward gain. As always, energy is conserved.
Fig. 18-6 shows why there will always be interference with conventional horn arrays (whether they are enclosed in arrayable cabinets with trapezoidal sides or mounted in free air). As the wavefronts radiate from points of origin that are separated in space, they will always create some interference at the coverage boundaries.

Fig. 18-6. The acoustic pressure wave expands as a sphere, and multiple spherical sections will always overlap unless they originate from a common center.

18.4 Conventional Array Shortcoming Analysis

For an array in far field, dependence on angle is

\[ SPL(\theta) = 10\log P_0^2 \text{ dB} \]  

(18-1)

For a distance to the listening area very much larger than the array dimensions, let the sound pressure \( P \) be the real part of

\[ P(\theta) = A_i(\theta) e^{j(\omega \tau - kS_i)} \]  

where,

\( P \) is the sound pressure,
\( \omega \) is the angular frequency,
\( A_i(\theta) \) is a function of the angle between the array longitudinal axis and the direction of the distant listening point. It gives the ratio of the sound pressure due to the source as a ratio of its on-axis value at the same distance.

For the \( i \)th source shown in Fig. 18-7, assuming identical sources, the pressure contribution is given by:

\[ P_i = A_i(\theta) e^{j(\omega \tau - kS_i)} \]  

where,

\( k = 2\pi/\lambda = 2\lambda f/c \),
\( \lambda \) is the wavelength,
\( f \) is the frequency,
\( c \) is the speed of sound,
\( S_i \) is the distance by which the path length from the \( i \)th source to the distant point exceeds the distance from the origin to that point.

Fig. 18-7. For a circular arc array, the additional path length \( S_j \) is as shown.

For an array of \( n \) sources, the total pressure \( P \) is given by:
The square of the pressure amplitude is given by:

\[
P(\theta) = \sum_{i=1}^{n} A_i q e^{j\omega_t - kS_i}
\]

\[
= e^{j\omega_t} \sum_{i=1}^{n} A(\theta) e^{j\omega_t kS_i}
\]

The square of the pressure amplitude is given by:

\[
P_0^2(\theta) = \left[ \sum_{i=1}^{n} A_i 0 kS_i \right]^2 + [A_i(q\theta)\sin(kS_i)]^2 \tag{18-5}
\]

where,

\[A_i(\theta) = A_i(\theta - \alpha_i)\]

For a circular arc array, the additional path length \(S_i\) as shown in Fig. 18-7, for the \(i\)th source at radius \(R\) and angle \(\alpha\) is given by:

\[-S_i(\theta) = R_i \cos(\theta - \alpha_i) \tag{18-6}\]

Therefore, the smaller \(R_i\) is, the smaller the \(S_i\) differences, and the less the interference between sources. Ideally, \(R = 0\) for all sources. As \(R\) approaches 0, the interference will become less audible and frequency response across the array’s intended coverage area will become more uniform.

18.5 Coincident Acoustical Centers: A Practical Approach

Clearly, the ideal solution is to collocate all the acoustic points of origin, as shown in Fig. 18-8. We could achieve this by stacking the horns vertically, but this would solve the problem in the horizontal plane by creating a worse situation in the vertical (front to back) direction. Fig. 18-9 shows a more realistic approximation that takes into account the physical constraints of loudspeaker design (the dimensions of the transducers, horns, enclosure walls, etc.). Because the acoustic sources are real physical objects, we cannot reduce \(R_i\) to 0. But we can get close enough to make measurable, audible improvements in the performance of the multi-enclosure array.

18.5.1 TRAP Horns: A New Approach

Fig. 18-9 implies that the way to minimize \(R_i\)—and the resultant interference—is to move the acoustic centers as far to the rear of the enclosure as possible. We can attempt to minimize the size of the drivers, for instance by using high-output magnetic materials such as neodymium. But the biggest obstacle to coincident acoustic centers is the horn itself. This is because typical constant directivity horns exhibit astigmatism: their apparent points of origin are different in the horizontal and vertical planes. In order to create a wider coverage pattern in the horizontal plane, the apparent apex is moved forward, while the vertical apex is farther to the rear because its coverage pattern is usually narrower. This is certainly the case with the most popular horn patterns in use today: \(60^\circ \times 40^\circ\) and \(90^\circ \times 40^\circ\). One approach to a solution, then, is to rotate the horn and use the vertical apex of the horn in the horizontal plane. By doing so, we are effectively moving the acoustic center as far to the rear of the cabinet as possible. This technique when combined with cabinet design that minimizes the space between adjacent drivers in an array,
while matching the trapezoidal sides with the opening angle of the horn, creates a system capable of minimal interference in the frequency range where the horn is effective. This forms the basis for what I call the True Array Principle by Renkus Heinz.

Subsequent refinements to the horn flare itself have been awarded U.S. Patent #5,750,943. This Arrayguide topology goes even farther in locating the apparent acoustic origin toward the rear of the enclosure. To repeat, moving the acoustic centers to the rear minimizes $R$, the distance between acoustic points of origin within the array, and the resulting interference between array elements.

Fig. 18-10 shows the ALS-1 predictions for the first generation of TRAP horns. It is clear that interference has almost disappeared.

**Figure 18-10.** TRAP design produces truly arrayable systems with minimal destructive interference in the horns’ passband.

Fig. 18-11 shows measured EASE data for a three-wide array of TRAP40 enclosures. Frequency response is consistent in both vertical and horizontal planes within ±4 dB. This is an out of the box array, using no frequency shading or micro-delay to improve performance. Measured results don’t track the predictions 100% because the actual pattern of the horns varies somewhat with frequency: first generation TRAP horns maintain nominal coverage ±10° from 1 kHz to 4 kHz.

**Figure 18-11.** The TRAP array produces almost no measurable interference from a tight-packed three-wide cluster. This is because the three spherical wave-fronts produced by the three horns originate from a common acoustical center. Therefore they behave as a single acoustic unit, without overlap or interference.

Coverage varies less than ±5° down to the frequency at which mutual coupling between adjacent cabinets ceases. TRAP systems are designed so that the enclosures provide optimum splay angles of 40° between the horns: the trapezoidal sides are therefore steeper than many other designs at 20° per side. The combination of symmetrical horns and steeper sidewall angles maintains coincident acoustic centers for all the elements in the array.

Note that moving the horizontal apex to the same location as the vertical results in a symmetrical 40° × 40° coverage pattern. This in turn requires the use of four enclosures to cover 160° with almost no variation in frequency response in the horizontal (side to side) plane. With 60° × 40° cabinets we could deliver sound to 180° of coverage, albeit with some quite audible variations.

There are other commercially available systems offering similar array performance to that described above. The ARC’s system from French loudspeaker...
manufacturer L-Acoustic uses a type of path length equalizer to force the emerging wavefront to conform to the opening angle of their horn and also puts the acoustic center behind the cabinet. In the case of ARC, the cabinet’s trapezoidal side walls also serve as the waveguide for the high frequencies. As the waveguides opening angle matches that of the cabinet, this is certainly an elegant solution to creating minimum interference arrays at the frequency where the horn is effective.

In the KF900 series from EAW, simple phase horns for the mid and high frequencies put the acoustic center as close to the rear of the cabinet as possible, while their opening angles also match the trapezoidal sides of the enclosure. The relatively large size of the KF900 series enclosures and horns brings minimum interference performance to frequencies lower than those based on smaller waveguides. Remember, that this technique for minimum interference arrays, including the True Array Principle, only holds true for those frequencies where the horn is effective.

In the preceding paragraphs, I outlined the parameters necessary to minimize destructive acoustic interference between adjacent cabinets or horns in an array. But these techniques are only beneficial at the frequencies where the horns are effective. Yet these very systems or horns are used at frequencies well below their directivity cutoff and lower, down to frequencies where the woofers piston size offers no directional control at all.

### 18.6.1 Horizontal Woofer Arrays: Maintaining Wide Dispersion

For our first example, let’s look at the additional problems and opportunities we create when arraying small (12 inch woofer, 1 inch compression driver) full range loudspeaker enclosures as in Fig. 18-12. For a full range array module, there are three frequency zones that exhibit different wavelength related behavior. At the lowest frequencies, or longest wavelengths, these modules exhibit only beneficial interference or mutual coupling. Each additional module creates additional on axis acoustic output. The opportunity here, is that less equalization is required to make the array’s frequency response flat down to these lower frequencies as compared to a single cabinet.

A potential problem is created when the array becomes too wide however. Four or five element arrays are wide enough as to become quite directional in the forward plane at those lower frequencies (20 Hz to roughly 500 Hz or more, dependant on the module). Without a signal processing scheme, this array cannot be equalized to have the same frequency response throughout its intended coverage. It will sound boomy in the middle and thin at its coverage extremes. A solution is to taper the length of the array in the horizontal plane in order to maximize horizontal dispersion of the lower frequencies. The entire array can be used for the lowest frequencies as the wavelengths are longest (20 Hz up to about 200 Hz), but at higher frequencies, as the wavelengths get shorter, the array length must also get shorter to maintain wide dispersion. This is achieved by low passing the outermost woofers of the array, such that only two or three max woofers are used at frequencies higher than this.

The second frequency zone that can be problematic in arrays based on full range modules, occurs at wavelengths where cabinet spacing no longer supports mutual coupling, and the horn has yet to attain its directivity cutoff. This typically applies to a small half octave range where adjacent cabinet spacing approaches a wavelength. Here we observe combinations of destructive and constructive interference at various observation points around the array intended coverage, causing frequency response variations greater than ±6 dB. Fortunately there is a signal processing technique that can minimize this effect. By simply notching this frequency range from every other cabinet with a cut equal to the greatest amount a variance (typically 6 dB

18.6.1 Horizontal Woofer Arrays: Maintaining Wide Dispersion
of attenuation), and width equal to the bandwidth of the aberrations (typically half an octave), the frequency response variations throughout the arrays coverage can minimized.

The third frequency zone of wavelength related behavior for arrays based on full range modules, is then at the frequencies above which the horn is effective. Let us assume that the horns depicted in Fig. 18-12 place the acoustic center towards the rear of the cabinets, and that their opening angle also matches that of the trapezoidal sides of the cabinet. Based on these assumptions, the array performance will exhibit minimum interference for frequencies above 1–2 kHz which happens to be the effective directivity cutoff of the horn. Each additional module simply adds additional coverage to the array.

18.6.2 Vertical Woofer Arrays

18.6.2.1 Directivity at Frequencies Where Size Makes Horns Impractical

Benificial destructive interference sounds like an oxymoron, but there are several commercially available woofer arrays that take advantage of this very technique. By applying the fundamental physics described by Harry Olson, directional woofer arrays are now available that out perform large woofer horns.

When two point sources are superimposed on one another, their outputs simply add up in all directions. As the two point sources are spread apart, the output diminishes along the plane of separation due to phase cancellation. At exactly ½ wavelength, a pure null occurs, and we achieve the classic figure eight, dipole polar pattern. The current commercially available systems take advantage of this phenomena, directivity through off axis attenuation, by placing woofers in a vertical array and spacing them to create this dipolar pattern at frequencies below which horns become too large.

Fig. 18-13 is an example of one such array. Termed Tri-Polar by its designer Vance Breshears, it uses the vertical spacing between the three woofers with appropriate signal processing to maintain consistent low frequency pattern control from 400 Hz down to below 100 Hz. One of the first systems available was developed by Craig Janssen, termed Tuned Dipolar, it uses two separate arrays. With drivers, spacing and signal processing appropriate for their respective passbands Tuned Dipolar offer exceptional low frequency pattern control over an extended bandwidth. Even subwoofers are now benefitting from this type of technology. Meyer Sound is achieving cardioid patterns at lowest frequencies from its PSW-6, providing significant attenuation of those frequencies directly behind the enclosures.

18.7 Line Arrays and Digitally-Steerable Loudspeaker Column Arrays

For the communication between a source and a listener to be effective, it is important that the listener receive and comprehend the message. In large spaces where people gather, including auditoria, houses of worship, sports venues, transit terminals and classrooms, often the acoustic requirements that enable effective speech are in conflict with the architectural needs of the spaces. When the acoustics of a venue cannot be altered to enable effective speech communication, designing a sound reinforcement system to do so, can be a challenge. Recent advances in efficient amplification and digital signal processing have enabled a new class of loudspeaker; the digitally steerable column or line array as its often called. The acoustical and architectural benefits of these
loudspeakers for sound reinforcement in highly reverberant or reflective environments will be shown.

We will discuss effective communications and define intelligibility and how to measure it both subjectively and objectively. We will look at architecture and acoustics and at reverberation and its effect on intelligibility in large public spaces. Finally we’ll look at digitally steerable column arrays, their design considerations, and their performance and benefits when used in large reverberant spaces.

Some of the basic principles involved in voice communications are:

- In voice communications intelligibility is the capability of being understood.
- It assumes the existence of a communication process between a talker and a listener, or between a source and a listener.
- For the conveyance of meaning, the English language is highly dependant upon the effective receipt and comprehension of consonants. This is how we differentiate words based on similar vowels. For example, Zoo, Two, New.
- In terms of frequency response, speech ranges between 100 Hz and 8 kHz, with maximum energy around 250 Hz.
- In speech, the frequency range that conveys the most consonant information is the octave around 2 KHz.

18.7.1 What Affects Intelligibility

Major Influences that affect intelligibility are:

- Elocution and pronunciation of the talker. It’s hard to understand someone who mumbles under any condition.
- Hearing acuity of listener. An often overlooked influence, those with a hearing loss have trouble understanding what’s being said.
- SNR. We’ve all been places where it was so noisy we couldn’t understand what was being said.
- Direct to reverberant ratio. The higher the reverberation level, the more difficult it is to understand what’s being said.
- Directivity of the loudspeaker or loudspeakers. Highly directional loudspeakers direct more of the sound onto the audience and less onto the reflective walls and ceilings.
- The number of loudspeakers. Larger numbers of loudspeakers translate into more acoustic energy being transmitted into the room and higher reverberation levels.
- Reverberation time. The longer the reverberation time, the more likely it will interfere with intelligibility.
- Distance of source to listener. The closer the listener is to the loudspeaker, the less likely reverberation will interfere.

Secondary Influences are:

- Gender of talker.
- Microphone technique.
- Vocabulary and context of speech information.
- Direction of main sound to listener and/or direction of reflections and echoes.
- System fidelity, equalization, and distortion.
- Uniformity of coverage.

18.7.2 Measuring Intelligibility

18.7.2.1 Subjectively

Statistical tests with trained talkers and listeners can be the most reliable metric for determining the intelligibility of a system. To ensure that all speech sounds are represented in a test, Phonemically Balanced (PB) word lists are commonly used. These word list can be a long as 1000 words. Tests using nonsense syllables or logos, and Modified Rhyme Tests are also used. These tests are very time consuming and are difficult to set up.

18.7.2.2 Objectively

Articulation Index. Articulation Index or AI was one of the first attempts to quantify intelligibility with measurements. AI is primarily concerned with the affect of noise on speech. The index ranges from 0 to 1 with 0 representing no intelligibility.

%ALcons. %ALcons or the articulation loss of consonants was developed by Peutz in Holland during the 1970’s. %ALcons takes both noise and reverberation into account and is based the importance of the octave around 2000 Hz in conveying consonant information. %ALcons uses a scale running downwards from 0 where 0 is perfect intelligibility, or 0% articulation loss.

Although Peutz used 2000 Hz as the center frequency and 2000 Hz is still the European standard, many acousticians in the USA prefer using 1000 Hz. As a general rule, %ALcons calculated at 1000 Hz show a higher articulation loss than ones calculated at 2000 Hz.

STI. STI or Speech Transmission Index considers the source/room/listener as a transmission channel and
measures the reduction in modulation depth of a specialized test signal which replicates the burst nature of real speech. The STI scale ranges from 0 to 1, where 1 represents perfect intelligibility. STI is considered the most accurate of the intelligibility measures.

18.7.3 Architecture and Room Acoustics

18.7.3.1 Reverberation

Reverberation is the persistence of sound in a space after the original sound has been removed.

RT60 is the measure for reverberation, and it is defined as the amount of time required for the average sound energy density in a space to decrease from its original value by 60 dB after the original sound has stopped.

The Sabine equation relates RT60 to the volume of a room with its surface area and the absorption coefficients of the materials applied to the surfaces.

As room volume increases relative to surface area and absorption coefficients, the RT60 increases.

As surface area and absorption increase relative to room volume, RT60 decreases. It is this persistence of sound that interferes with our comprehension of consonants and contributes towards degrading intelligibility.

18.7.4 Line Arrays

Figs. 18-14 to 18-16 show the direct sound coverage of various loudspeakers in a sanctuary 100 ft × 65 ft. The chancel adds 20 ft to its length. The roof peaks at 52 ft. The room volume is roughly 250,000 ft³. The room has plaster walls, wood ceiling, terrazzo floors, and empty wooden pews. This produces a RT60 of about 3.5 s.

Notice the high SPL levels on the walls and ceiling in the flown-horn array simulation. The high frequency beaming of the mechanically tilted column array prevents good coverage of the front of the audience area. The digitally steerable column array covers only the audience area and has very little coverage on the walls and no coverage of the ceiling. Only the steered column array has acceptable (good to fair) intelligi-
bility throughout the audience areas. Digitally steerable column arrays can offer superior coverage and they can provide improved D/R. They can provide improved intelligibility in highly reverberant spaces, plus they blend better with their surrounding architecture and are nearly invisible in use.

18.7.4.1 Digitally Steered Column Arrays

When the room size and volume are fixed and adding absorption to reduce the RT times is not an option, digitally steerable column arrays offer a new solution:

- They have the ability to be much more directional than the largest horns.
- The idea is not new; the concepts for these column arrays were described by Harry Olson in 1957. Only the implementation is new.
- The hardware required to implement these ideas is now available.
- Digital Signal Processing required is now a mature technology, very powerful and relatively inexpensive.
- Compact, highly efficient Class D amplifiers are capable of high-fidelity performance.

Line Arrays are not a new idea. Harry F. Olson did the math and described the directional characteristics of a continuous line source in his classic *Acoustical Engineering*, first published in 1940. Traditional column loudspeakers have always made use of line source directivity.

Simple line arrays (column arrays) are basically a number of drivers stacked closely together in a line, Fig. 18-17. Simple line arrays become increasingly directional in the vertical plane as the frequency increases. The spacing between drivers controls the high frequency limits. The height (length) of the line array determines the low frequency control limit. Fig. 18-18 shows the line source directivity as described by Harry Olson in 1957.

The directivity of a line array is a function of the line length and the wavelength. As the wavelength approaches the line length, the array becomes omnidirectional, Fig. 18-19. Fig. 18-20 shows the vertical dispersion pattern of a typical line array.

18.7.4.2 Controlling High Frequency Beaming

Simple line arrays become increasingly directional as the frequency increases, in fact, at higher frequencies they become too directional. The vertical directivity can be made more consistent by making the array shorter as the frequency increases by using fewer drivers. One amplifier channel and one DSP channel per driver make this possible.

17.7.4.3 Beam Steering

The beam can be steered up or down by delaying the signal to adjacent drivers. DSP control also allows us to develop multiple beams from a single line array and individually steer these beams.

DSP control also allows us to move each beam acoustic center up and down the column allowing us to
create multiple beams and also steer the beam, Figs. 18-21 and 18-22.

18.7.5 DSP-Driven Vertical Arrays

18.7.5.1 Acoustical, Electronic & Mechanical Considerations

Practical examples are taken from the new Renkus-Heinz IC Series Iconyx steerable column arrays. Iconyx is a steerable column array that combines very high directivity with accurate reproduction of source material in a compact and architecturally pleasing package, Fig. 18-23.

Like every loudspeaker system, Iconyx is designed to meet the challenges of a specific range of applications. Many of the critical design parameters are, of course, determined by the nature of these target applications. To understand the decisions that have been made during the design process we must start with the particular problems posed by the intended applications.

The function of individual driver control and DSP is to make more effective use of this phenomenon. No amount of silicon can get around the laws of acoustical physics. The acoustical properties of first-generation column loudspeakers are set by the acoustical characteristics of the transducers and the physical characteristics of the package:

1. The height of the column determines the lowest frequency at which it exerts any control over the vertical dispersion.
2. The inter-driver spacing determines the highest frequency at which the array acts as a line source rather than a collection of separate sources.

3. Horizontal dispersion is fixed and is typically set when the drivers are selected, because column loudspeakers do not have waveguides.

4. Other driver characteristics such as bandwidth, power handling and sensitivity will determine the equivalent performance characteristics of the system.

One unfortunate corollary of these characteristics is that the power response of a conventional column loudspeaker is not smooth. It will deliver much more low-frequency energy into the room and this energy will tend to have a wider vertical dispersion. This can make the critical distance even shorter because the reverberant field contains more low-frequency energy, making it harder for the listener to recognize higher-frequency sounds such as consonants or instrumental attack transients.

18.7.5.2 Point Source Interactions

17.7.5.3 Doublet Source Directivity

Doublet source cancels each other’s output directly above and below, because they are spaced ½ wavelength apart in the vertical plane. In the horizontal plane, both sources sum. The overall output looks like Fig. 18-24.

When two sources are ¼ wavelength apart or less, they behave almost like a single source. There is very slight narrowing in the vertical plane, Fig. 18-25.

There is significant narrowing in the vertical plane at ½ wavelength spacing, because the waveforms cancel each other in the vertical plane, where they are 180° out of phase, Fig. 18-26.

At one wavelength spacing the two sources reinforce each other in both the vertical and horizontal directions. This creates two lobes, one vertical and the other horizontal, Fig. 18-27.

As the ratio of wavelength to inter-driver spacing increases, so do the number of lobes. With fixed drivers as used in line arrays, the ratio increases as frequency increases (\( \lambda = \frac{c}{f} \) where \( f \) is the frequency and \( c \) is the speed of sound), Fig. 18-28.
18.7.5.4 Array Height versus Wavelength (λ)

Driver-to-driver spacing sets the highest frequency at which the array operates as a line source. The total height of the array sets the lowest frequency at which it has any vertical directivity.

Figs. 18-29 though Fig. 18-32 show the effect of array height versus wavelength.

At wavelengths of twice the array height, there is no pattern control, the output is that of a single source with very high power handling, Fig. 18-29.

As the frequency rises, wavelength approaches the height of the line. At this point there is substantial control in the vertical plane, Fig. 18-30.

At higher frequencies the vertical beamwidth continues to narrow. Some side lobes appear but the energy radiated in this direction is not significant compared to the front and back lobes, Fig. 18-31.

Still further vertical narrowing, with side lobes becoming more complex and somewhat greater in energy, Fig. 18-32.

18.7.5.5 Inter-Driver Spacing versus Wavelength (λ)

The distinction between side lobes and grating lobes should to be maintained. Side lobes are adjacent to and radiate in the same direction as the primary lobe. Grating lobes are the strong summations tangential to the primary lobe. Side lobes will be present in any realizable line array, grating lobes form when the inter driver spacing becomes less than ½ wavelength. It
might also be good to point out that all of the graphics for this section are done using theoretical point sources.

Figs. 18-33 though Fig. 18-36 show the effect of inter-driver spacing versus wavelength.

When the drivers are spaced no more than \( \frac{1}{2} \) wavelength apart, the array produces a tightly directional beam with minimal side lobes, Fig. 18-33.

As the frequency rises, wavelength approaches the spacing between drivers. At this point, grating lobes become significant in the measurement. They may not be a problem, if most or all of the audience is located outside these vertical lobes, Fig. 18-34.

At still higher frequencies, lobes multiply and it becomes harder to isolate the audience from the lobes or...
As inter-driver spacing approaches four times the wavelength, the array is generating so many grating lobes of such significant energy that its output closely approximates a single point source, Fig. 18-36. We have come full circle to where the array’s radiated energy is about the same as it was when array height was \( \frac{1}{2} \lambda \). As shown in Fig. 18-32, this is the high frequency limit of line array directivity.

As real drivers are considerably more directional than point sources at the frequencies where grating lobes are generated, the grating lobes are much lower in level than the primary lobe, Figs. 18-37 and 18-38.

18.7.6 Multichannel DSP Can Control Array Height

The upper limit of a vertical array’s pattern control is always set by the inter-driver spacing. The design challenge is to minimize this dimension while optimizing frequency response and maximum output and do it without imposing excessive cost. Line arrays become increasingly directional as frequency increases, in fact, at high frequencies they are too directional to be acoustically useful. However, if we have individual DSP available for each driver, we can use it to make the array acoustically shorter as frequency increases—this will keep the vertical directivity more consistent. The technique is conceptually simple—use low-pass filters to attenuate drive level to the transducers at the top and bottom of the array, with steeper filter slopes on the extreme ends and more gradual slopes as we progress to the center. As basic as this technique is, it is practically impossible without devoting one amplifier channel and one DSP channel to each driver in the array.

A simplified schematic shows how multichannel DSP can shorten the array as frequency increases. For clarity, only half the processing channels are shown and delays are not diagrammed, Fig. 18-39.

18.7.7 Steerable Arrays May Look Like Columns But They are not

Simple column loudspeakers provide vertical directivity, but the height of the beam changes with frequency. The overall Q of these loudspeakers is there-
fore lower than required. Many early designs used small-cone full range transducers, and the poor high-frequency response of these drivers certainly did nothing to enhance their reputation.

18.7.7.1 Beam-Steering: Further Proof that Everything Old is New Again

As Don Davis famously quotes Vern Knudsen, “The ancients keep stealing our ideas.” Here is another illustration from Harry F. Olson’s *Acoustical Engineering*. This one shows how digital delay, applied to a line of individual sound sources, can produce the same effect as tilting the line source. It would be long after 1957 before the cost of this relatively straightforward system became low enough for commercially viable solutions to come to market, Fig. 18-40.

18.7.7.2 DSP-Driven Arrays Solve Both Acoustical and Architectural Problems

17.7.7.3 Variable Q

DSP-driven line arrays have variable Q because we can use controlled interference to change the opening angle of the vertical beam. The Renkus Heinz IC Series can produce 5°, 10°, 15° or 20° opening angles if the array is sufficiently tall (an IC24 is the minimum required for a 5° vertical beam). This vertically narrow beam minimizes excitation of the reverberant field because very little energy is reflected off the ceiling and floor.

17.7.7.4 Consistent Q with Frequency

By controlling each driver individually with DSP and independent amplifier channels, we can use signal processing to keep directivity constant over a wide operating band. This not only minimizes the reverberant energy in the room, but delivers constant power response. The combination of variable Q, which is much higher than that of an unprocessed vertical array, with consistent Q over a relatively wide operating band, is the reason that DSP-driven Iconyx arrays give acoustical results that are so much more useful.

17.7.7.5 Ability to Steer the Acoustic Beam Independently of the Enclosure Mounting Angle

Although beam-steering is relatively trivial from a signal-processing point of view, it is important for the architectural component of the solution. A column mounted flush to the wall can be made nearly invisible, but a down-tilted column is an intrusion on the architectural design. Any DSP-driven array can be steered. Iconyx also has the ability to change the acoustic center of the array in the vertical plane which can be very useful at times.

17.7.7.6 Design Criteria: Meeting Application Challenges

The previous figures make it clear that any line source, even with very sophisticated DSP, can control only a limited range of frequencies. However, by using full range coaxial drivers as the line source elements could make the overall sound of the system more accurate and natural without seriously compromising the benefits of beam-shaping and steering. In typical program material, most of the energy is within the range of controllable frequencies. Earlier designs radiate only slightly above and below the frequencies that are controllable. Thus much of the program source is sacrificed, without a significant increase in intelligibility.
To maximize the effectiveness of a digitally controlled line source, it’s not enough to start with high quality transducers. The Renkus Heinz Iconyx loudspeaker system uses a compact multichannel amplifier with integral DSP capability. The D2 audio module has the required output, full DSP control, and the added advantage of a purely digital signal path option. When PCM data is delivered to the channel via an AES/EBU or CobraNet input, the D2 audio processor/amplifier converts it directly into PWM data that can drive the output stage.

17.7.7.7 Horizontal Directivity is Determined by the Array Elements

Vertical arrays, including Iconyx, can be steered only in the vertical plane. Horizontal coverage is fixed and is determined by the choice of array elements. The transducers used in Iconyx modules have a horizontal dispersion that is consistent over a wide operating band, varying between 140° and 150° from 100 Hz to 16 kHz.

17.7.7.8 Steering is Simple—Just Progressively Delay Drivers

If we tilt an array, we move the drivers in time as well as in space. Consider a line array of drivers that is hinged at the top and tilted downward. Tilting moves the bottom drivers further away from the listener in time as well as in space. We can produce the same acoustical effect by applying progressively longer delays to each driver as we move from top to bottom of the array.

Again, steering is not a new idea. It is different from mechanical aiming–front and rear lobes steer the same direction.

18.7.7.9 BeamWare: The Software That Controls Iconyx Linear Array Systems

A series of low-pass filters can maintain constant beamwidth over the widest possible frequency range. The ideas are simple, but for the most basic Iconyx array, the IC16, we must calculate and apply 16 sets of FIR filters, and 16 separate delay times. If we intend to take advantage of constant inter-driver spacing to move the acoustical center of the main lobe above or below the physical center of the array, we must calculate and apply a different set of filters and delays. Theoretical models are necessary, but the behavior of real transducers is more complex than the model. Each of the complex calculations underlying the Iconyx beam-shaping filters were simulated, then verified by measuring actual arrays in our robotic test and measurement facility. Fortunately, the current generation of laptop and desktop CPUs are up to the task. BeamWare takes user input in graphic form (side section of the audience area, location and mounting angle of the physical array) and provides both a simulation of the array output that can be imported into EASE v4.0 or higher, and a set of FIR filters that can be downloaded to the Iconyx system via RS422 serial control. The result is a graphical user interface that delivers precise, predictable and repeatable results in real-world acoustical environments.

19.1 Power-Supply Terminology

**Power Supply.** A device that supplies electrical power to another unit. Power supplies obtain their prime power from the ac power line or from special power systems such as motor generators, inverters, and converters.

**Rectifier.** A device that passes current in only one direction. The rectifier consists of a positive anode and a negative cathode. When a positive voltage is applied to the anode of the rectifier, that voltage minus the voltage across the rectifier will appear on the cathode and current will flow. When a negative voltage is applied to the anode with respect to the cathode, the rectifier is turned off and only the rectifier leakage current will flow.

**Forward Resistance.** The resistance of an individual cell measured at a specified forward voltage drop or current.

**Forward Voltage Drop.** The internal voltage drop of a rectifier resulting from the current flow through the cell in the forward direction. The forward voltage drop is usually between 0.4 Vdc and 1.25 Vdc.

**Reverse Resistance.** The resistance of the rectifier measured at a specified reverse voltage or current. Reverse resistance is in megohms (MΩ).

**Reverse Current.** The current flow in the reverse direction, usually in microamperes (μA).

**Maximum Peak Current.** The highest instantaneous anode current a rectifier can safely carry recurrently in the direction of the normal current flow.

The value of the peak current is determined by the constants of the filter sections. With a choke filter input, the peak current is less than the load current. With a large capacitor filter input, the peak current may be many times the load current. The current is measured with a peak-indicating meter or oscilloscope.

**Maximum Peak Inverse Voltage.** The maximum instantaneous voltage that the rectifier can withstand in the direction opposite to which it is designed to pass current. Referring to Fig. 19-1, when anode A of a full-wave rectifier is positive, current flows from A to C, but not from B to C because B is negative. At the instant anode A is positive, the cathodes C of A and B are positive with respect to anode B. The voltage between the positive cathode and the negative anode B is inversely related to the voltage causing the current flow. The peak value of this voltage is limited by the resistance and nature of the path between the anode B and the cathode C. The maximum value of voltage between these points, at which there is no danger of breakdown, is termed maximum peak inverse voltage.

The relationship between peak inverse voltage, rms value of ac input voltage and dc output voltage depends largely on the individual characteristics of the rectifier circuit. Line surges, or any other transient or waveform distortion, may raise the actual peak voltage to a value higher than that calculated for a sine-wave voltage. The actual inverse voltage (and not the calculated value) should be such as not to exceed the rated maximum peak inverse voltage for a given rectifier. A peak-reading meter or oscilloscope is useful in determining the actual peak inverse voltage.

The peak inverse voltage is approximately 1.4 times the rms value of the anode voltage for single-phase, full-wave circuits with a sine-wave input and no capacitance at the input of the filter section. For a single half-wave circuit, with a capacitor input to the filter section, the peak inverse voltage may reach 2.8 times the rms value of the anode voltage.

**Ripple Voltage.** The alternating component (ac) riding on the dc output voltage of a rectifier-type power supply. The frequency of the ripple voltage will depend on the line frequency and the configuration of the rectifier. The effectiveness of the filter system is a function of the load current and the values of the filter components.

The ripple factor is the measure of quality of a power supply. It is the ratio of the rms value of the ac component of the output voltage to the dc component of the output voltage or

\[
\text{ripple factor} = \frac{V_{rms}}{V_{dc}}
\]  

(19-1)

where,

- \(V_{rms}\) is the alternating current voltage at the output terminals,
- \(V_{dc}\) is the direct current output voltage at the output terminals.

Internal Output Impedance. The impedance presented to the equipment receiving the power supply voltage. In the operation of many devices, it is necessary that the internal power supply impedance be as near to zero as possible. Since most load devices consist of both passive and active elements, the current drawn from the supply consists of an ac component superimposed on the dc output of the supply. The ac component is generally of a nonsinusoidal nature. The output impedance in ohms over a wide range of frequencies is used to determine the regulation of output voltage of a power supply with respect to load variations. Power supply output impedance ($Z_o$) may be defined as

\[
Z_o = \frac{E_{ac}}{I_{ac}}
\]  

(19-2)

where,

$E_{ac}$ is the sinusoidal voltage across the power supply terminals,

$I_{ac}$ is the sinusoidal current flowing through a series loop consisting of the power supply and load equipment.

Static Line Regulation. The variation in output voltage as the input voltage is varied slowly from rated minimum to rated maximum with the load current held at the nominal value.

Dynamic Load Regulation. The variation in output when the load change is sudden. The power supply may be unable to respond instantaneously, and an additional momentary excursion in the output voltage may result, subsiding afterward to the static load regulation level. The positive and negative excursion limits are superimposed on the static line and load regulation region. The positive and negative components are not necessarily equal or symmetrical. The most stringent rating is for a change from no load to full load or from full load to no load.

Dynamic Line Regulation. The momentary additional excursion of output voltage as a result of a rapid change in input voltage.

Thermal Regulation. Variations in the output voltage over the rated operating temperature range due to ambient temperature variations influencing various components of the power supply. This is also known as thermal drift.

19.2 Power Supplies

19.2.1 Simple dc Power Supplies

The simplest type of dc power supply is a rectifier in series with the load. As more rectifiers are installed into the circuit, along with filters, the power supply becomes more sophisticated. The rectifier in series with the load supply will always remain simple and have poor regulation and transient response. Table 19-1 shows various power supplies and their characteristics. To determine the value of the parameter in the left column, multiply the factor shown in any of the center columns by the value in the right column.

19.2.2 One-Half Wave Supplies

A one-half wave unit can be connected directly off the ac mains, Fig. 19-2A, or off the mains through a transformer, Fig. 19-2B. Since a rectifier only passes a current when the anode is more positive than the cathode, the output waveform will be one-half of a sine wave, Fig. 19-2C. The dc voltage output will be 0.45 of the ac voltage input, and the rectifier current will be the full dc current; the peak inverse voltage ($piv$) across the rectifier will be 1.414 Vac, and the ripple will be 121%. In the transformerless power supply, the 115 Vac power line is connected directly to the rectifier system. This type of power supply is dangerous to both operating personnel and to grounded equipment. Also, power supplies of this type will cause hum problems that can only be solved by the use of an isolating transformer between the line and power supply.

19.2.3 Full-Wave Supplies

The full-wave supply is normally used in electronic circuits because it is simple and has a good ripple factor and voltage output. A full-wave supply is always used with a transformer. Full-wave supplies may be either a single-phase center tap design or a full-wave bridge. In either case, both the positive and negative cycles are rectified and mixed to produce the dc output.

The center tap configuration, Fig. 19-2D, uses two rectifiers and a center-tapped transformer. The $V_{dc}$ is approximately equal to Vac where Vac is from one side of the transformer to the center tap. Because the output is from each half wave, ripple is only 48% of the output voltage and at twice the input frequency. Each rectifier carries one-half of the load current. The $piv/rectifier$ is 2.828 Vac.
A full-wave bridge rectifier supplies full-wave rectification without a center tap on the transformer. The bridge rectifier is not a true single-ended circuit, since it has no terminal common to both the input and output circuits.

A full-wave bridge rectifier consists of four rectifier elements, as shown in Fig. 19-2E. This circuit is the most familiar and is the type most commonly employed in the electronics industry.

With the full-wave bridge circuit, the dc output voltage is equal to 0.9 of the rms value of the ac input voltage.

Full-wave bridge rectifier circuits may be grounded by three methods shown in Fig. 19-3A, B, C. Either the input (ac source) or output (dc load) may be grounded, but not both simultaneously. If an isolation transformer is used between the ac source and the input to the rectifier, as shown in Fig. 19-3C, both ac and dc sides may be grounded permanently. A method of grounding a bridge rectifier is shown in Fig. 19-3D where the center tap of an isolation transformer is grounded.

When designing rectifier circuits, dc load current, dc load voltage, peak inverse voltage, maximum ambient temperature, cooling requirements, and overload current must be analyzed. For example, assume a full-wave rectifier using silicon rectifiers is to be designed as in Fig. 19-3D and the dc load voltage $V_{dc}$ under load is 25 V at 1 A.

Using Table 19-1, determine the current per rectifier using the equation

---

**Figure 19-2.** Two one-half wave and two full-wave power supplies.

**Figure 19-3.** Methods of grounding a power supply.
\[ I_{\text{rect}} = 0.5 \times I_{dc} \]
\[ = 0.5 \times 1 \]
\[ = 0.5 \text{A} \]  \hspace{2cm} (19-3)

where,
\( I_{\text{rect}} \) is the current per rectifier,
0.5 is a constant from Table 19-1,
\( I_{dc} \) is the rectified ac current, which is the dc current.

This is the current each rectifier must carry. Next, the ac voltage required from the transformer is determined by the equation
\[ V_{ac} = 1.11 \times V_{dc} \]
\[ = 1.11 \times 25 \]
\[ = 27.75 \text{ Vrms} \]  \hspace{2cm} (19-4)

where,
\( V_{ac} \) is the transformer voltage,
1.11 is a constant from Table 19-1.

This is the voltage as measured from each side of the transformer center tap; the total voltage across the secondary is 55.50 Vrms.

The peak inverse voltage is
\[ piv = 2.82 \times V_{ac} \]
\[ = 2.82 \times 27.75 \]
\[ = 78.4 \text{ Vrms} \]  \hspace{2cm} (19-5)

where,
\( V_{ac} \) is the secondary ac voltage per leg,
2.82 is found in Table 19-1.

If a rectifier with the required \( piv \) rating is not available, two or more may be connected in series to obtain the desired \( piv \) rating. Unequal values of \( piv \) ratings may be used, provided the lowest rating is greater than half of the total \( piv \) rating needed.

Parallel operation of rectifiers can be used obtain higher current ratings. However, because of a possible imbalance between the units due to the forward voltage drop and effective series resistance, one unit may carry more current than the other and could conceivably fail. To prevent this, small equal value resistors must be connected in series with each individual rectifier to balance the load currents, as shown in Fig. 19-4.

**19.2.4 Three-Phase Power Supplies**

Three-phase power supplies are common in the industry but are seldom used to power audio circuits directly.

**19.3 Filters**

A power-supply filter is a series of resistors, capacitors, and/or inductors connected either passively or actively to reduce the ac or ripple component of the dc power supply.

**19.3.1 Capacitor Filters**

A capacitor filter employs a capacitor at its input, as shown in Fig. 19-5A. Power supplies with an input capacitor filter have a higher output voltage than one without a capacitor because the peak value of the rectifier output voltage appears across the input filter. As the rectified ac pulses from the rectifier are applied across capacitor \( C \), the voltage across the capacitor rises nearly as fast as the pulse. As the rectifier output drops, the voltage across the capacitor does not fall to zero but gradually diminishes until another pulse from the rectifier is applied to it. It again charges to the peak voltage. The capacitor may be considered a storage tank, storing up energy to the load between pulses. In a half-wave circuit, this action occurs 60 times per second, and in a full-wave circuit, it occurs 120 times per second.

For a single-phase circuit with a sine-wave input and without a filter, the peak inverse voltage at the rectifier is 1.414 times the rms value of the voltage applied to the rectifier. With a capacitor input to the filter, the peak inverse voltage may reach 2.8 times the rms value of the applied voltage. This data may be obtained by referring to Table 19-1.
When a dc voltmeter is connected across the unfiltered output of a rectifier, it will read the average voltage. As an example, assume a dc voltmeter is connected across a half-wave rectifier. Because of the inertia of the meter pointer movement, the meter cannot respond to the rapidly changing pulses of the half-wave rectified current but acts as a mechanical integrator. The pointer will be displaced an amount proportional to the time average of the applied voltage waveform.

The average voltage \( V_{av} \), as read by the dc voltmeter, is

\[ V_{av} = \frac{V_p}{\pi} \]  \hspace{1cm} (19-6)

where,

\( V_p \) is the peak voltage,
\( \pi \) is 3.1416….

The ripple factor is

\[ \gamma = \frac{I_{dc}}{4\pi\sqrt{3}fCV_{dc}} \]  \hspace{1cm} (19-7)

where,

\( I_{dc} \) is the output dc current,
\( f \) is the ripple frequency,
\( C \) is the filter capacitor in farads,
\( R_L \) is the load resistance in ohms.

Capacitor filters operate best with large filter capacitors and high-resistance loads. As the load resistance is lowered, the ripple increases and regulation decreases.

Filtering efficiency is reduced, and the internal leakage is increased when the capacitor’s power factor increases. Electrolytic capacitors should be removed when their power factor reaches an excessive value. In an ideal capacitor, the current would lead the voltage by 90°. Capacitors are never ideal because a small amount of leakage current always exists through the dielectric. Also, a certain amount of power is dissipated by the dielectric, the leads, and their connections. All this adds up to power loss. This power loss is termed phase difference and is expressed in terms of power factor (PF). The smaller the power factor value, the more effective the capacitor. Since most service capacitor analyzers indicate these losses directly in terms of power factor, capacitors with large power factors may be readily identified. Generally speaking, when an electrolytic capacitor reaches a power factor of 15%, it should be replaced. The filtering efficiency for different values of power factor can be read directly from Table 19-2.

### 19.3.2 Inductive Filters

An inductive filter employs a choke rather than a capacitor at the input of the filter, as shown in Fig. 19-5B. Although the output voltage from this type of filter is lower, the voltage regulation is better.
A choke filter operates best with maximum current flow. It has no effect on a circuit when no current is flowing. The critical inductance is the inductance required to assure that current flows to the load at all times. An inductor filter depends on the property of an inductor to oppose any change of current.

To assure that current flows continuously, the peak current of the ac component of the current must not exceed the direct current \( I_{dc} = \frac{I_{dc}}{R_L} \). Therefore,

\[
X_L \geq \frac{\sqrt{2}}{3R_L} 
\]

(19-8)

and

\[
L_C = \frac{R_L}{3 \times 2\pi f} 
\]

(19-9)

where,

- \( L_C \) is the critical inductance,
- \( R_L \) is the load resistance.

Filter chokes should be selected for the lowest possible dc resistance commensurate with the value of inductance.

The ripple factor (\( \gamma \)) for an inductive filter is

\[
\gamma = \frac{R_L + R_C}{3 \sqrt{2} \times 2\pi f} 
\]

(19-10)

where,

- \( R_L \) is the load resistance in ohms,
- \( R_C \) is the choke resistance in ohms,
- \( f \) is the ripple frequency.

19.3.3 Combination Filters

Combination filters use a combination of resistors, capacitors, and inductors to improve the filtering. The simplest is a resistor-capacitor filter and the more complicated is a series of inductance-capacitor (LC) circuits.

19.3.3.1 Inductance-Capacitance Filters (LC)

Inductance-capacitance filters, sometimes called L filters, use an inductor as an input filter and a capacitor as the second stage of the filter, Fig. 19-5C. LC filters operate well under varying load conditions.

The inductive reactance of the choke in an LC filter section tends to oppose any change in the current flowing through the winding, creating a smoothing action on the pulsating current of the rectifier. The capacitor stores and releases electrical energy, also smoothing out the ripple voltage, resulting in a fairly smooth output current.

The ripple factor for an LC filter is

\[
\gamma = \frac{\sqrt{2}X_C}{3X_L} 
\]

\[
= \frac{\sqrt{2}}{3 \times 2\pi f/C \times 2\pi f/L} 
\]

(19-11)

\[
= 0.01 \frac{f^2 CL}{2} 
\]

where,

- \( X_C \) is the capacitance reactance in ohms,
- \( X_L \) is the inductive reactance in ohms,
- \( f \) is the frequency of ripple,
- \( C \) is the capacitance in farads,
- \( L \) is the inductance in henrys.

When multiple LC filters are connected together, the ripple factor is

\[
\gamma = \frac{\sqrt{2}}{3} \left( \frac{16\pi f^2 LC} {n} \right) 
\]

(19-12)

\[
= \frac{0.47}{157.9f^2 LC} 
\]

where,

- \( L \) is the inductance in henrys,
- \( f \) is the ripple frequency,
- \( C \) is the capacitance in farads,
- \( n \) is the number of sections.

19.3.3.2 Resistance-Capacitance Filters

Resistance-capacitance filters, RC, Fig. 19-5D, employ a resistor and capacitor rather than an inductor and capacitor. The advantages of such a filter are its low cost, light weight, and the reduction of magnetic fields. The disadvantage of such a filter is that the series resistance induces a voltage drop that varies with current and could be detrimental to the circuit operation. An RC filter system is generally used only where the current demands are low. RC filters are not as efficient as the LC type, and they may require two or more sections to provide sufficient filtering.

19.3.3.3 π Filters

A π (pi) filter has a capacitor input followed by an LC
section filter, Fig. 19-5E. π filters have a smooth output and poor regulation. They are often used where the transformer voltage is not high enough and low ripple is required. By using the input capacitor, the dc voltage is boosted to the peak voltage. The ripple factor for a π filter is

\[
\gamma = \sqrt{2} \frac{X_{c1}X_{c2}}{R_LX_{L1}} \quad (19-13)
\]

where,

- \(X_{c1}\) is the capacitive reactance of the first capacitor,
- \(X_{c2}\) is the capacitive reactance of the second capacitor,
- \(R_L\) is the load resistance,
- \(X_{L1}\) is the inductive reactance of the choke.

When the choke is replaced with a resistor, the ripple factor becomes

\[
\gamma = \sqrt{2} \frac{X_{c1}X_{c2}}{R_LR} \quad (19-14)
\]

where,

- \(R\) is the filter resistor.

### 19.3.4 Resistance Voltage Dividers

A resistance voltage divider is shown in Fig. 19-6. In this system of voltage division, the resistors are connected in series with the particular load they feed. The resistors are calculated by means of Ohm’s law

\[
R = \frac{V}{I} \quad (19-15)
\]

The wattage is computed by

\[
P = \frac{V^2}{R} = I^2R \quad (19-16)
\]

Generally, when a series-resistance voltage divider is used, a separate bleeder resistor is also used to secure better regulation. Each section should have a separate bypass capacitor of 10 μF or more to ground. The bypass capacitors stabilize and improve the filtering and decouple the various levels. This is particularly true for the series-type voltage divider.

There are two common types of voltage dividers, the shunt and the series types. The shunt type shown in Fig. 19-6 is designed to supply three different voltages to external devices. The upper circuit supplies load \(L_1\), the second circuit supplies \(L_2\), and the third circuit supplies \(L_3\). All circuits are common to ground.

The total current required is the total current of the three external circuits, or \(I_{L1} + I_{L2} + I_{L3}\), plus an additional current called the bleeder current. This bleeder current flows only through the resistors and not through the external circuits. It is generally 10% of the total current.

Resistor \(R_1\) is calculated first, because only bleeder current flows through this resistor,

\[
R_1 = \frac{V}{I} \quad (19-17)
\]

where,

- \(V\) is the \(L_1\) voltage also across \(R_1\),
- \(I\) is the bleeder current.

The voltage at the top of \(R_2\) is the \(L_2\) voltage to ground. Subtracting the voltage drop across \(R_1\) results in a voltage across \(R_2\). The current through \(R_2\) is the current of load \(L_1\) plus the bleeder current

\[
R_2 = \frac{V_{L2} - V_{L1}}{I_{R1} + I_{L1}} \quad (19-18)
\]

Resistor \(R_3\) has the current of loads \(L_1\) and \(L_2\) plus the bleeder current flowing through it or

\[
R_3 = \frac{V_{L3} - V_{L2}}{I_{R1} + I_{L1} + I_{L2}} \quad (19-19)
\]

The current of load \(L_3\) does not flow through any part of the voltage-divider system; therefore, it requires no further considerations.

### 19.4 Regulated Power Supplies

A regulated power supply holds the output constant with variations in load, current, or input voltage. Regu-
lated supplies may be simple shunt or series regulators with 1–3% regulation or high gain supplies with 0.001% regulation and 0.001% ripple.

Power supplies may be connected in parallel, but to protect the supplies, diodes are connected in the positive lead of each power supply. When the diode is in its normal conducting mode, it must be capable of withstanding the short-circuit current of its regulator. The pi rating of the diode must be equal to or greater than the maximum open-circuit potential of the highest-rated power supply.

Regulated power supplies can also be connected in series if certain precautions are observed. The isolation voltage rating of the individual power supplies must not be exceeded, and the power supplies must be protected against reverse potential. Diodes are connected in the nonconducting direction across the output of each supply unit. These diodes will start to conduct the instant a reverse potential appears, providing a path for short-circuit current. If possible, the regulating circuit for one supply should be connected as a master and the other as slaves. The voltages of the supplies do not have to be the same.

All regulated supplies have a reference element and a control element. The amount of electronics between the two elements determines the quality and regulation of the supply, Fig. 19-7.

The reference element is the unit that forms the foundation of all voltage regulators. The output of the regulated power supply is equal to or a multiple of the reference. Any variation in the reference voltage will cause the output voltage to vary; therefore, the reference voltage must be maintained as stable as possible.

The control element is that unit that maintains the output voltage constant. The regulator type is named after the control element—namely, series, shunt, or switching, Fig. 19-7A, B, C. The control element is an electronic variable resistor that drops voltage either in series with the load or across the load. Control element configurations are shown in Fig. 19-8.

All regulated supplies draw standby current, which is the current drawn by the power supply with no output load. The input voltage to regulated supplies is filtered dc. The smoother the input voltage is, the smoother the output will be. The capacitor \( C_1 \) shown in Fig. 19-7A is used to smooth the output or reduce ripple.

The comparison amplifier constantly monitors the output, reducing ripple because the reference voltage is smooth dc and the output ripple voltage appears to the comparator like a varying load. The regulator or pass transistor attempts to follow it, reducing ripple.

A constant-voltage regulated power supply is designed to keep its output voltage constant, regardless of the changes in load current, line voltage, or temperature. For a change in the load resistance, the output voltage remains constant to a first approximation, while the output current changes by whatever amount is
The actual impedance is a function of the load and the type of equipment being fed by the supply.

A constant-current regulated power supply is designed to keep its output current constant, regardless of the changes in load impedance, line voltage, or temperature. For a change in the load resistance, the output current remains constant to a first approximation, although the output voltage changes by whatever amount is necessary to accomplish this, Fig. 19-7B. Its impedance characteristics are given in Fig. 19-9B.

A constant-current supply would have infinite impedance at all frequencies. However, these ideals are not achieved. Therefore, a practical power supply has a very low impedance at the lower frequencies, and the impedance rises with frequency. The constant-current supply has a rather high impedance at the lower frequencies and decreases at the higher frequencies.

A constant-voltage, constant-current regulated power supply, Fig. 19-7C, acts as a constant-voltage source for comparatively large values of load resistance and as a constant-current source for comparatively small values of load resistance. An automatic crossover (or transition) between these two modes of operation occurs at a critical or crossover value of load resistance \( R_C \) where

\[
R_C = \frac{V_s}{I_s} \quad \text{(19-20)}
\]

where,

- \( V_s \) is the voltage-control setting,
- \( I_s \) is the current-control setting.

### 19.4.1 Simple Regulated Supplies

A simple supply consists of only the control element and the reference element. The solid-state zener diode has almost replaced the gaseous tube reference element because it is smaller and has better regulation, wide voltage range, and wide power range. Referring to the basic design in Fig. 19-10A, the zener diode is connected in series with the limiting resistor \( R_1 \) and in parallel with the output. As a rule, the zener diode current \( I_Z \) is chosen for a value of 10% of the load current \( I_L \).

The value of the series resistance \( R_1 \) can be calculated using the equation

\[
R_1 = \frac{V_s - V_{out}}{I_L + I_Z} \quad \text{(19-21)}
\]

where,

- \( V_s \) is the voltage source,
- \( V_{out} \) is the output voltage,
$I_L$ is the load current, 
$I_Z$ is the zener current, (normally 10% of $I_L$.)

The power dissipated in $R_1$ is $I^2R$. The dissipation is only for a condition where the load current remains constant at its design current. If the load current is completely removed, the current through the diode increases to the design load current plus the design zener current.

Two additional voltage-regulating circuits are shown in Fig. 19-10B and C. Zener diodes can be connected in series across the output of a dc supply, provided the power-handling capabilities and the current-operating ranges are similar.

A cascade shunt regulator is given in Fig. 19-10D. The zener diode controls the base potential of transistor $Q_1$, which functions as an emitter follower and circuit amplifier. This circuit is used where large current variations are encountered.

If only a small voltage drop is required, i.e., 5–6 V, the configuration in Fig. 19-10E might be employed. In this instance, the entire load current plus the current through $R_1$ must flow through the diode, and it could be easily damaged.

A current-regulator circuit is shown in Fig. 19-10F. The load current remains essentially constant until $R_L$ increases to where the average voltage drop across $R_L$ is as large as the voltage drop across $R_3$.

### 19.4.2 Complex Power Supplies

Complex supplies include a pass element, a sampling element, and a comparator element, and they may include a preregulator, current limiting, undervoltage and overvoltage protection, and remote sensing.

**Pass Elements.** A transistor or group of transistors connected in parallel and placed in series with the output of a regulated power supply to control the flow of the output current. A *pass element* is another name for control element.

**Reference Elements.** The unit that forms the foundation of all voltage regulators. The output of the regulated power supply is equal to or a multiple of the reference. Any variation in the reference voltage will cause the output voltage to vary; therefore, the reference voltage must be maintained as stable as possible.

**Sampling Elements.** The device that monitors the output voltage and translates it into a level comparable to the reference voltage. The variations in the sampling voltage versus the reference voltage is the error voltage.

---

**Figure 19-10.** Various regulator circuits using zener diodes.
that ultimately controls the regulator output.

**Comparator Elements.** Compares the feedback voltage from the sampling element with the reference and provides gain for the detected error level. This signal controls the control circuit.

**Preregulator.** Monitors the voltage across the series regulator and adjusts the input $V_{in}$ to maintain the regulator voltage at approximately 3 volts. This regulator voltage is held relatively constant regardless of input or output conditions. This reduces the power dissipated and the number of transistors in the series regulator, Fig. 19-11.

![Figure 19-11. Simplified block diagram of a preregulated power supply.](image)

**Current Limiting.** A method used to protect the pass transistor by limiting the current within the safe operating range. The simplest current-limiting device is a resistor in series with the load. This, however, affects regulation by the IR drop across the resistor.

To overcome this, constant current limiting is used. With constant current limiting, the voltage drop across the series resistor is sampled. The output voltage remains constant up to a predetermined current at which time the voltage decreases to limit the output current.

A third current limiting is foldback current limiting in which the load current actually decreases as the load continues to increase beyond $I_{max}$. This is usually only used in high current supplies.

The conventional current-limiting power supply of Fig. 19-12A is protected from instantaneous short circuits but long duration shorts can overheat $Q_2$, leading to its eventual failure. In Fig. 19-12B this circuit is modified to produce foldback by adding two voltage feedback resistors, $R_3$ and $R_4$. The control transistor $Q_1$ emitter voltage depends on the power supply output voltage as sampled by the $R_3, R_4$ voltage divider. If $R_1$ senses a current overload, the drop across it decreases the output voltage and lowers the emitter voltage of $Q_1$. Then $Q_1$ turns on at reduced current through $R_1$, which limits current flow through $Q_2$, as shown in the current-foldback characteristic of Fig. 19-12B. The foldback ratio can be adjusted by changing $R_3, R_4, R_1$, or all three.

![Figure 19-12. Current limiting circuits.](image)

**Overvoltage Protection.** Protects the load from overvoltage. This may be accomplished internally or as an add-on to the power supply. A crowbar circuit is a typical overvoltage protector.

The circuit monitors the output voltage of a power supply and instantaneously throws a short circuit across the output terminals when a preset voltage is reached. This is generally accomplished by the use of a silicon controlled rectifier (SCR) connected across the output terminals of the supply unit.

**Remote Sensing.** Adding two extra wires between the supply and the load produces a remote sensing circuit that permits the supply to achieve its optimum regulation at the load terminals, rather than at the power supply output terminals. In this manner, the circuit compensates for the IR drop in the line from the power supply to the equipment receiving its voltage. The sensing lines are high impedance and have almost no current flowing. Therefore, the voltage drop is negligible.

The wire size and voltage drop for regulated power supplies can be determined by Ohm’s Law or with the
use of the nomograph in Tables 14-2 and 14-3. Since regulated power supplies are designed to control the output at the power supply output terminals, the conductors used for the supply line must be considered as a part of the power supply load.

19.4.3 Switching Regulators

In a switching regulator, the pass transistor operates in an on-off mode, increasing efficiency and reducing heat. The simple switching regulator shown in Fig. 19-13 incorporates a pulse generator circuit that pulses on the pass transistor as the output voltage decreases. As the output voltage increases, the comparator circuit reduces the pulse generator, reducing the on time of the pass transistor and, therefore, reducing the average output voltage. Since the output voltage is a series of pulses, a filter is required to smooth the dc output. An inductance-capacitance filter is commonly used. Switching regulators normally operate at 20 kHz or higher and have the following advantages:

- Switching regulators are on-off devices, so they avoid the higher power dissipation associated with the rheostat like action of a series regulator. Transistors dissipate very little power when either saturated (on) or nonconducting (off); most of the power losses occur elsewhere in the supply. Efficiency to 85% is typical for switching supplies, as compared to 30–45% for linear supplies. Less wasted power means switching supplies run cooler, cost less to operate, and have smaller regulator heat sinks.
- Size and weight reductions for switching supplies are achieved because of their high switching rate. Typically, a switching supply is less than one-third the size and weight of a comparable series-regulated supply.
- Switching supplies can operate under low ac input voltage (brownout) conditions and sustain a relatively long carryover (or holdup) of its output if input power is lost momentarily because more energy is stored in its input filter capacitors. In a switching supply, the input ac voltage is rectified directly, and the filter capacitor charges to the ac voltage peaks. The ac voltage input of the standard linear supply is stepped down through a power transformer and then rectified, resulting in a lower voltage across its filter capacitor. Since the energy stored in a capacitor is proportional to \( CV^2 \) and \( V \) is higher in switching supplies, their storage capability (and thus their holdup time) is better.

Switching disadvantages include the following:

- A switching supply transient recovery time (dynamic load regulation) is slower than that of a series-regulated supply. In a linear supply, recovery time is limited only by the speeds of the semiconductors used in the series regulator and control circuitry. In a switching supply, recovery is limited mainly by the inductance in the output filter.
- Electromagnetic interference (emi) is a natural by-product of the on-off switching. This interference can be conducted to the load (resulting in higher output ripple and noise), it can be conducted back into the ac line, and it can be radiated into the surrounding atmosphere.

![Figure 19-13. Basic switching regulator.](image-url)

High-Power Regulated Supply. Regulation of a high-power switching regulator is accomplished by push-pull switching transistors operating under control of a feedback network consisting of a pulse-width modulator and a voltage comparison amplifier, Fig. 19-14. The feedback elements control the onperiods of the switching transistors to adjust the duty cycle of the bipolar waveform (E) delivered to the output rectifier filter. Here the waveform is rectified and averaged to provide a dc output level that is proportional to the duty cycle of the waveform, varying the on times of the switches.

The waveforms of Fig. 19-14 provide a more detailed picture of circuit operation. The voltage comparison amplifier continuously compares a fraction of the output voltage with a stable reference voltage, \( V_{\text{ref}} \), to produce the \( V_{\text{control}} \) level for the turn-on comparator. This device compares the \( V_{\text{control}} \) input with a triangular ramp waveform \( A \), occurring at a fixed 40 kHz rate. When the ramp voltage is more positive than the control level, a turn-on signal (B) is generated. Notice that an increase or decrease in the \( V_{\text{control}} \) voltage varies the width of the output pulses at B and thus the on time of the switches.

Steering logic within the modulator chip causes switching transistors \( Q_1 \) and \( Q_2 \) to turn on alternately so
that each switch operates at one-half the ramp frequency or 20 kHz.

The addition of a triac preregulator and associated control circuit improves regulation and ripple. The triac is a bidirectional device and is usually connected in series with one side of the input primary. Whenever a gating pulse is received, the triac conducts current in a direction that is dependent on the polarity of the voltage across it. The goal is to control the triac so that the bridge rectifier output (dc input to the switches) is held relatively constant. This is accomplished by a control circuit that issues a phase-adjusted firing pulse to the triac once during each half-cycle of the input ac. The control circuit compares a ramp function to a rectified ac sine wave to compute the proper firing time for the triac.

Although the addition of the preregulator circuitry increases complexity, it provides three important benefits:

1. By keeping the dc input to the switches constant, it permits the use of more readily available lower voltage switching transistors.
2. The coarse preregulation it provides allows the main regulator to achieve a finer regulation.
3. Through the use of slow-start circuits, the initial conduction of the triac is controlled, providing an effective means of limiting input surge current.

19.4.4 Phase-Controlled Regulated Power Supplies

In the phase-controlled supply, the pass element is switched on and off at line frequency and controls the output voltage by a varying pulse width. This is most often accomplished by using an SCR as the pass element. By delaying the firing point of the SCR in each cycle, the output voltage can be varied. Fig. 19-15. SCR is fired by applying a voltage to the gate. The voltage is obtained by C1 charging through R2 and the ballast lamp. When the gate firing voltage is reached across C1, SCR fires. Once the SCR is on, it remains on until its anode voltage goes to zero, which is during the second half of the cycle. When SCR is on, C1 discharges and remains discharged until the phase of the
line voltage returns to zero. The rate that the $C_1$ charges is controlled by $Q_1$. When $Q_1$ is turned on, much of the $C_1$ charging current is shunted around $C_1$, requiring a longer time to charge $C_1$, thus delaying the firing of $SCR_1$. As the line voltage increases, the resistance of $VDR_1$ and $VDR_2$ decreases, turning $Q_1$ on more and thus slowing the charging rate of $C_1$. Since the output is a series of pulses with a high rise time of the leading edge, a filter is required on the output to smooth the dc.

![Figure 19-15. Phase controlled regulated supply.](image)

### 19.5 Single IC, Power Factor Corrected, Off-Line Supply

Many off-line power supplies now include power factor correction (PFC) which reduces input current and meets regulatory requirements. Normal switching power supplies that incorporate a bridge rectifier followed by bulk capacitance create harmonic currents, increasing the supply’s rms input current, while contributing nothing to real power. To solve this problem a PFC preregulator and a separate controller was added to an existing design.

The Linear Technology Corporation LT®1508 (voltage mode) and LT1509 (current mode) power supply eliminate combine the PFC and a pulse width modulator (PWM) function in a single 20-pin IC.

PFC is achieved by programming the input current of a boost regulator to follow the input line voltage, resulting in a near-unity power factor compared to 0.5–0.7 for a typical capacitive input switcher. The architecture maintains 0.99 power factor over a 20:1 load range. Start-up is controlled by separate PFC and PWM soft start pins. The PWM Soft Start pin is held low, disabling the PWM output until the PFC stage is in regulation. The PWM will remain enabled as long as the PFC output voltage stays above 73% of its preset value (typically 280 V out of 383 V for universal input). A separate overvoltage protection pin can be connected to the output through an independent resistor divider. This ensures overvoltage protection during safety agency abnormal testing conditions, such as opening the main feedback path. The two stages are synchronized and the PWM turn-on is delayed for 50% of the oscillator cycle. This minimizes noise and conducted emission problems. A peak current gate drivers and a 1.2 V optoisolator offset on the VC pin further simplify the design.

A universal input, 24 Vdc, 300 W converter using the LT1508 is shown in Fig. 19-16. Following the PFC boost preregulator is a 2-transistor forward converter that features low voltage (500 Vdc) switches, low peak currents and automatic nondissipative core reset. Under worst case conditions (low line, full power), the PFC and PWM stages have efficiencies of 90% and 92% respectively. The LT1508’s low start-up current of 250 $\mu$A minimizes start-up resistor power dissipation. An overwinding on T1 provides the bootstrapped chip supply. The intermediate bus voltage of 382 V is well controlled, simplifying the post regulator and increasing capacitor holdup time compared to a typical off-line converter.

### 19.6 Synchronous Rectification Low-Voltage Power Supplies

Synchronous rectifiers can improve switching-power-supply efficiency, particularly in low-voltage low-power applications compared to Schottky-diode types of supplies. A synchronous rectifier is an electronic switch that improves power-conversion efficiency by placing a low resistance conduction path across the diode rectifier in a switch-mode regulator. MOSFETs or bipolar transistors and other semiconductor switches can be used.

The forward-voltage drop across a switch-mode rectifier is in series with the output voltage, so losses in the rectifier determine efficiency.

Even at 3.3 V, rectifier loss is significant. For step-down regulators with a 3.3 V output and a 12 V input, the 0.4 V forward voltage of a Schottky diode represents a typical efficiency penalty of about 12%. The losses are less at lower input voltages because the recti-
fier has a lower duty cycle and thus a shorter conduction time. However, the Schottky rectifier’s forward drop is usually the dominant loss mechanism.

For an input voltage of 7.2 V and an output of 3.3 V, a synchronous rectifier improves on the Schottky diode rectifier’s efficiency by around 4%. As output voltage decreases, the synchronous rectifier provides even larger gains in efficiency, Fig. 19-17.

19.6.1 Diode versus Synchronous Rectifiers

In the absence of a parallel synchronous rectifier, the drop across the rectifier diode in a switching regulator, Fig. 19-18A causes an efficiency loss that worsens as the output voltage falls. The Schottky diode simple buck converter clamps the switching node, the inductor’s swinging terminal, as the inductor discharges.

In the synchronous-rectifier version of Fig. 19-18B, a large N-channel MOSFET switch replaces the diode

![Figure 19-16. 24 V, 300 W off-line PFC supply. Courtesy Linear Technology Corporation.](image)

![Figure 19-17. Data based on a high-performance buck switch-mode regulator and powered from a standard 7.2 V notebook-computer battery shows that the synchronous rectifier has little effect on efficiency at 5 V, but offers significant improvements at 3.3 V and below. Courtesy Maxim Integrated Products.](image)
and forms a half-bridge configuration that clamps the switching node to 0.1 V or less. The diode in Fig. 19-18A clamps the node to 0.35 V. Intuitively, losses in either type of rectifier increase with reduced output voltage. At $V_{IN} \leq V_{OUT}$, the rectifier voltage drop is in series with the load voltage for about half the switching period. As the output voltage falls, power lost in the rectifier becomes a greater fraction of the load power.

The basic trade-off between using diode or MOSFET rectifiers is whether the power needed to drive the MOSFET gate cancels the efficiency gained from a reduced forward-voltage drop. The synchronous rectifier’s efficiency gain depends strongly on load current, battery voltage, output voltage, switching frequency, and other application parameters. Higher battery voltage and lighter load current enhance the value of a synchronous rectifier. The duty factor, which equals $1 - D$, where $D$ equals $t_{on}/(t_{on} + t_{off})$, for the main switch, increases with the battery voltage. Also, the forward drop decreases with the load current.

The gate-drive signal is a key factor in calculating a synchronous rectifier’s efficiency gain. For example, the gate loss can be reduced by using a gate drive of 5 V (as for logic-level MOSFETs) instead of the input (battery) voltage. Simply supply the gate drive from a 5 V linear regulator powered from the battery. Another method is to bootstrap the gate driver’s power-supply rails from the regulator’s output voltage. (This approach adds complexity in the form of a bypass switch for the initial power-up.) One must weigh the lower loss associated with reduced gate voltage against the higher $R_{DS(ON)}$, resulting from a less-enhanced MOSFET.

When comparing diode and synchronous rectifiers, note that the synchronous rectifier MOSFET doesn’t always replace the usual Schottky diode. To prevent switching overlap of the high-side and low-side MOSFETs that might cause destructive cross-conduction currents, most switching regulators include a dead-time delay. The synchronous rectifier MOSFET contains an integral, parasitic body diode that can act as a clamp and catches the negative inductor voltage swing during this dead time. This diode is lossy, is slow to turn off, and can cause a 1–2% efficiency drop.

To squeeze the last percent of efficiency out of a power supply, a Schottky diode can be placed in parallel with the synchronous rectifier MOSFET. This diode conducts only during the dead time. A Schottky diode in parallel with the silicon body diode turns on at a lower voltage, ensuring that the body diode never conducts. Generally, a Schottky diode used in this way can be smaller and cheaper than the type the simple buck circuit requires, because the average diode current is low. (Schottky diodes usually have peak current ratings much greater than their dc current ratings.) It’s important to note that conduction losses during the dead time can become significant at high switching frequencies. For example, in a 300 kHz converter with a 100 ns dead time, the extra power dissipated is equal to

$$I_{LOAD} \times V_{FWD} \times td \times f = 6 \text{ mW}$$

(19-22)

where,
- $f$ is the switching frequency
- $td$ is the dead time)

for a 2.5 V, 1 W supply, which represents an efficiency loss of about 0.5%.

Light-load efficiency is a key parameter when the load spends a long time in a nearly dormant suspend mode. For the buck-type switch-mode regulators, the synchronous rectifier’s control circuit has a strong influence on light-load efficiency and noise performance. The key issue for light-load or no-load conditions is the timing of the MOSFET’s turn-off signal.

When load current is light, the inductor current discharges to zero, becoming discontinuous or reversing direction. There are at least three options in dealing with this problem:

- **Figure 19-18.** A synchronous rectifier replaces the Schottky diode in A with a low $R_{DS(ON)}$ MOSFET in B. The lower-resistance conduction path improves efficiency for the 5–3.3 V 3 A converter by 3–4%. Courtesy Maxim Integrated Products.
1. Continue to hold the synchronous switch on until the beginning of the next cycle, allowing the inductor to reverse.

2. Completely disable the synchronous rectifier at light loads.

3. Sense the inductor current’s zero crossing and shut off the synchronous rectifier on a cycle-by-cycle basis.

Each approach involves a trade-off in different areas. In the past, the option that designers widely used was holding the inductor switch on until the beginning of the next cycle which requires driving the MOSFET gates with complementary waveforms. This approach produces lower noise and allows a simple control scheme. The gate-drive signal is simply an inverted, opposite phase version of the drive signal for the high-side switch. Noise is lower because the absence of pulse skipping ensures a constant switching frequency, regardless of load. A constant, fundamental switching frequency ensures that output ripple and EMI at the harmonic frequencies won’t cause havoc in the IF bands of an audio or radio system. This approach also eliminates the dead time during which a resonant-tank circuit comprising the inductor and stray capacitance at the switching node can introduce ringing.

Unfortunately when the inductor current reverses, the synchronous rectifier pulls current from the output. The circuit replaces this lost output energy during the next half cycle. However, at the beginning of the cycle when the high-side switch turns on, the circuit transfers the inductor energy stored during the earlier current reversal to the input-bypass capacitor.

This action resembles perpetual motion, in which energy shuttles between the input and output capacitors. As energy shuttles back and forth, the circuit dissipates power in all its parasitic resistances and switching inefficiencies, so additional energy is necessary to maintain the shuttling action. The most obvious consequence is a high no-load supply current of typically 5 mA for the 2.5 V, 1 W circuit.

The second option, turning off the synchronous rectifier entirely at light loads, offers simplicity and low quiescent supply current. This method can be implemented in conjunction with a pulse-skipping operation, governed by a light-load pulse-frequency-modulation (PFM) control scheme. Whenever the circuit goes into its light-load pulse skipping mode, the circuit disables the synchronous rectifier that lets an accompanying parallel Schottky diode do all the work. Disabling the synchronous rectifier prevents the reversal of inductor current, and the problem of shuttling energy back and forth does not arise.

The final option, sensing the inductor current’s zero crossing and quickly latching the synchronous rectifier off, turns off the synchronous rectifier on a cycle-by-cycle basis. This method provides the highest light-load efficiency, because the synchronous rectifier does its job without allowing the inductor current to reverse. But, to be effective, the switching-regulator IC’s current-sense amplifier that monitors the inductor current must combine high speed with low power consumption.

A logic-control input can shift the synchronous-rectifier operation from the complementary-drive option to the off-at-zero option, Fig. 19-19. When low, “SKIP” allows normal operation: The circuit employs pulse-width modulation (PWM) for heavy loads and automatically switches to a low-quiescent-current pulse-skipping mode for light loads. When high, “SKIP” forces the IC to a low-noise fixed-frequency PWM mode, regardless of the load. Also, applying a high level to “SKIP” disables the IC’s zero-crossing detector, allowing the inductor current to reverse direction, which suppresses the parasitic resonant LC tank circuit.

Another issue related to a synchronous rectifier’s gate-drive timing is the cross regulation of multiple outputs obtained using flyback windings. Placing an extra winding or a coupled inductor on a buck regulator’s inductor core can provide an auxiliary output.
voltage for the cost of a diode, a capacitor, and a little wire, Fig. 19-20.

Normally, the coupled-inductor flyback trick in Fig. 19-20 stores energy in the core when the high-side switch is on and discharges some of it through the secondary winding to an auxiliary 15 V output when the synchronous rectifier’s low-side switch is on. During discharge, the voltage across the primary is equal to \( V_{OUT} + V_{SAT} \), where \( V_{OUT} \) is the main output and \( V_{SAT} \) is the synchronous rectifier’s saturation voltage. Therefore, the secondary output voltage equals the primary output times the turns ratio.

Unfortunately, if the synchronous rectifier turns off at zero current and the primary load is light or nonexistent, the 15 V output sags to ground because the core stores no energy at this time. If the synchronous rectifier remains on, the primary current can reverse and let the transformer operate in the forward mode, providing a theoretically infinite output-current capability that prevents the 15 V output from sagging. Unfortunately, quiescent supply current suffers a great deal.

However, the circuit in Fig. 19-20 achieves excellent cross regulation with no penalty in quiescent supply current. A second, extra feedback loop senses the 15 V output. If this output is in regulation, the synchronous rectifier turns off at zero current as usual. If the output drops below 13 V, the synchronous rectifier remains on for an extra microsecond after the primary current reaches zero, so the 15 V output can deliver hundreds of milliamps even with no load on the main 5 V output. This scheme also provides a better 15 V load capability at low values of \( V_{IN} - V_{OUT} \), which becomes important if the input voltage drops.

19.6.2 Secondary-Side Synchronous Rectifiers

Multiple synchronous rectifiers on the secondary windings can replace the usual high-voltage rectifier diodes in multiple-output nonisolated applications, Fig. 19-21. This substitution can dramatically improve load regulation on the auxiliary outputs and often eliminates the need for linear regulators, which are otherwise added to increase the output accuracy. The MOSFET must be selected with a breakdown rating high enough to withstand the flyback voltage, which can be much higher than the input voltage. Tying the gates of the secondary-side MOSFETs directly to the gate of the main synchronous MOSFET (the DL terminal) provides the necessary gate drive.

Another neat trick enables a synchronous rectifier to provide gate drive for the high-side switching MOSFET. Tapping the external switching node to generate a gate-drive signal higher than the supply voltage enables the use of N-channel MOSFETs for both switches in a synchronous-rectifier buck converter. Compared to P-channel types, N-channel MOSFETs have many advantages, because their superior carrier
mobility confers a near 2:1 improvement in gate capacitance and on-resistance.

A flying-capacitor boost circuit provides the high-side gate drive, Fig. 19-22. The flying capacitor is in parallel with the high-side MOSFET’s gate-source terminals. The circuit alternatively charges this capacitor from an external 5 V supply through the diode and places the capacitor in parallel with the high-side MOSFET’s gate-source terminals. The charged capacitor then acts as supply voltage for the internal gate-drive inverter, which is comparable to several 74HC04 sections in parallel. Biased by the switching node, the inverter’s negative rail rides on the power-switching waveform at the LX terminal.

A flying capacitor then acts as supply voltage for the internal gate-drive inverter, which is comparable to several 74HC04 sections in parallel. Biased by the switching node, the inverter’s negative rail rides on the power-switching waveform at the LX terminal.

The synchronous rectifier is indispensable to the Fig. 19-22 gate-drive boost supply. Without this low-side switch, the circuit may not start at initial power-up. When power is first applied, the low-side MOSFET forces the switching node to 0 V and charges the boost capacitor to 5 V.

Synchronous rectifiers can be incorporated in the boost and inverting topologies. The boost regulator in Fig. 19-23 employs an internal pnp synchronous rectifier in the active rectifier block. Boost topologies require the rectifier in series with $V_{OUT}$, so the IC connects the pnp collector to the output and the emitter to the switching node. The rectifier control block’s fast comparator detects whether the rectifier is forward- or reverse-biased and drives the pnp transistor on or off accordingly. When the transistor is on, an adaptive basecurrent control circuit keeps the transistor on the edge of saturation. This condition minimizes the efficiency loss due to base current and maintains high switching speed by minimizing the delay due to stored base charge.

An interesting side benefit of the pnp synchronous rectifier is its ability to provide both step-up and step-down action. For ordinary boost regulators, the input voltage range is limited by an input-to-output path through the inductor and the diode. (This unwanted path is inherent in the simple boost topology.) Thus, if $V_{IN}$ exceeds $V_{OUT}$, the conduction path through the rectifier can drag the output upward, possibly damaging the load with overvoltage.

The pnp-rectifier circuit in Fig. 19-23 operates in switch mode, even when $V_{IN}$ exceeds $V_{OUT}$, the conduction path through the rectifier can drag the output upward, possibly damaging the load with overvoltage.

The pnp-rectifier circuit in Fig. 19-23 operates in switch mode, even when $V_{IN}$ exceeds $V_{OUT}$, the conduction path through the rectifier can drag the output upward, possibly damaging the load with overvoltage.

Inverting-topology regulators that generate negative voltages, sometimes called buck-boost regulators, are useful applications for synchronous rectification. Like the boost topology, the inverting topology connects the synchronous rectifier in series with the output rather than to ground, Fig. 19-24. In this example, the synchronous switch is an N-channel MOSFET with its
source tied to the negative output and its drain tied to the switching node.

The circuit tricks the resulting 300 kHz buck regulator into performing as an inverting-topology switcher by connecting the IC’s GND pin to the negative output voltage instead of circuit ground. This switching regulator’s efficiency of about 88% exceeds that of comparable asynchronous-rectifier supplies by 4%.

19.7 Converters

A converter changes low-voltage dc to high-voltage dc. Basically, a dc-to-dc converter consists of a dc source of potential (generally a battery) applied to a pair of switching transistors. The transistors convert the applied dc voltage to a high-frequency ac voltage. The ac voltage is then transformed to a high voltage that is rectified to dc again and filtered in the conventional manner. Power supplies of this nature are often used for a source of high voltage, where the usual ac line voltage is not available.

19.8 Inverters

An inverter converts direct current to alternating current. Inverters are used in applications where the primary source of power is direct current. Because direct current cannot be transformed, it is converted to alternating current so that alternating current output from the inverter may be applied to a transformer to supply the desired voltage.

An inverter operates much like the switching circuit and transformer section of a converter. In Fig. 19-25, \( R_1 \) and \( R_2 \) assure that the oscillator (switch) will start. \( T_1 \) is a saturable base-drive transformer that determines the drive current to turn on \( Q_1 \) or \( Q_2 \). \( T_2 \) is a non-saturable transformer; therefore, collector current through \( Q_1 \) and \( Q_2 \) is dependent upon load. Base resistors \( R_b \) are current limiting resistors. By adding a rectifier and filter section, this inverter can be changed to a converter.

19.9 Ultra Capacitor (UPS)

A backup power supply for medical computers manufactured by Ram Technologies utilizes ultra capacitor technology. The model 8000 Ultra UPS module contains the charge and discharge circuitry to ensure high-efficiency energy transfer, Fig. 19-26. The proprietary patent pending module is designed to directly interface with RAM Technologies line of ATX/SFX medical-grade power supplies. The unit can be modified by Ram Technologies to operate with other sensitive and/or life-threatening devices. The module may be expanded by adding additional ultra capacitor modules. The base module contains 8000 J of energy; expansion modules also contain 8000 J of energy. Any number of additional modules can be added to increase load capabilities. Fig. 19-27 shows a typical installation in a computer.

The module’s input voltage is +12 Vdc and has an efficiency of >90%. Charge time is 2 minutes for each 8 kJ module.

The maximum output current is 30 A at 12 Vdc. Run time is

\[
\text{Run time} = \frac{\text{number of modules} \times 133}{\text{dc load}} \tag{19-23}
\]
where,

Run time is in minutes,

dc load is in watts.

Ultra Capacitors do not degrade in time as batteries do so reliability is high.

UCs have a capacity one million times that of a standard electrolytic capacitors. This is accomplished by depositing carbon on an aluminum substrate which can be etched it give dramatically increased surface area and low impedance. A typical UC 30 mm × 50 mm can have up to 400 F of capacitance with a working voltage of 2.5 V.

The energy stored in a capacitor is CV^2/2. To have the same energy density as current Lithium Ion batteries, the working voltage for a given size would have to be increased to 5 V. This would yield 4 times the energy density of current UC technology and make UCs the ultimate energy storage device. It is just a matter of time before technology reveals materials capable of having dielectrics in the 5 V or higher range and making batteries as we know them today obsolete.

Charging. Ultra Capacitors have extremely low internal impedance so power limited charging must be used to avoid overloading the charger. UCs are also sensitive to voltage. They must be operated below their rating to avoid destruction. Designers tend to charge them as close as possible to their maximum voltage to extract the maximum energy from them.
Discharging: Unlike batteries Ultra Capacitors store their energy over their entire voltage range which makes the design of the boost complex due to the wide input voltage range and overall efficiency.

19.10 Batteries

Batteries offer a means of producing a smooth, ripple-free, hum-free, portable power supply. A battery’s capacity is rated in ampere-hours (Ah). Three facts about batteries are:

1. An ampere-hour can be a 1 A drain for 1 h, 0.5 A drain for 2 h, or 2 A drain for 0.5 h.
2. A 12 V liquid battery is generally considered completely discharged when its voltage reaches 10.5 V.
3. Batteries for cycling service—i.e. powering amplifiers etc.—are normally rated with:
   • A 20 h discharge rate, which means a 20 Ah battery will deliver 1 A for 20 h and a 100 Ah battery will deliver 5 A for 20 h.
   • A reserve capacity stated in minutes for a 25 A discharge rate.
   • Discharging batteries below 50% shortens their life.

A cell or battery is an electrochemical system that converts chemical energy into electrical energy. When the chemical action is reversible, the battery is a secondary or rechargeable system.

To be rechargeable, the positive and negative electrodes of a battery must be capable of being converted back to their original state following a discharge. Thus, the battery must be electrically recharged by reversing the process that occurred during its discharge cycle.

19.10.1 Temperature Effects

The standard rating for batteries is at 25°C (77°F). Battery capacity is reduced at lower temperature. At freezing, Ah capacity is reduced to 80%. At −27°C (−22°F), Ah capacity drops to 50%. At 122°F, capacity is increased by 12%.

Battery charging voltage is also affected by temperature. It will vary from about 2.74 V/cell (16.4 V) at −40°C (−40°F) to 2.3 volts per cell (13.8 V) at 50°C (122°F).

Temperature also affects battery life. While battery capacity is reduced by 50% at −22°F, battery life increases about 60%. Battery life is reduced at higher temperatures. In fact, for every 8.3°C (15°F) over 25°C (77°F), battery life is cut in half. This holds true for all types of lead-acid batteries, sealed, gelled, and AGM.

19.10.2 Cycles versus Battery Life

A battery cycle is one complete discharge and recharge cycle and is often considered a discharge from 100% to 20%, and then recharged back to 100%. Other ratings for depth of discharge (DOD) cycles are 10%, 20%, and 50%.

Battery life is directly related to how deep the battery is cycled each time. If a battery DOD is 50% every cycle, it will last twice as long as if the DOD is 80%. If the DOD cycle is only 10%, it will last about five times as long as one cycled to 50%. A 50% DOD is usually recommended. A battery that has a DOD cycle of 5% or less usually does not last as long as one cycled down 10% because at very shallow cycles, the lead dioxide tends to build up in clumps on the positive plates rather than a film.

19.10.3 Battery Voltage

All lead-acid batteries supply about 2.14 volts per cell (V/cell), or 12.6–12.8 V for a 12 volt battery when fully charged. Batteries that are stored for long periods will eventually self-discharge. This varies with battery type, age, and temperature. Self-discharge can range from 1–15% per month. Batteries should never be stored in a partly discharged state for a long period of time. A float charge should be maintained if they are not used.

19.10.4 State of Charge

State of charge, or conversely, the depth of discharge (DOD), can be determined by measuring the voltage and/or the specific gravity of the acid with a hydrometer. Voltage on a fully charged battery is 2.12–2.15 V/cell, or 12.7 V for a 12 volt battery when fully charged. At 50% DOD the voltage is 2.03 V/cell, and at 0% DOD it is 1.75 V/cell or less. Specific gravity is 1.265 for a fully charged cell and 1.13 or less for a totally discharged cell. Many batteries are sealed, therefore, hydrometer reading cannot be taken.

19.10.5 False Capacity

A battery can meet all the tests for being at full charge, yet be lower than its original capacity because the plates are damaged, sulfated, or partially gone from long use.
In this case it acts like a battery of much smaller size.

**19.10.6 Ampere-Hour Capacity**

Deep cycle batteries are rated in ampere hours (Ah). An Ah is a 1 A drain for 1 h, 10 A for 0.1 h, etc. It is calculated with the equation $A \times h$. Drawing 20 A for 20 min would be $20 \times 0.333 = 6.67$ Ah. The accepted Ah rating time period for batteries used in solar electric and backup power systems and for nearly all deep cycle batteries is the 20 hour rate. This is defined as the battery being discharged to 10.5 V over a 20 h period while the total actual Ah it supplies is measured.

Amp-hours are specified at a particular rate because of the Peukert effect. The Peukert value is directly related to the internal resistance of the battery. The higher the internal resistance, the higher the losses while charging and discharging, especially at higher currents. The faster a battery is discharged, the lower the Ah capacity. Conversely, if it is drained more slowly, the Ah capacity is higher.

**19.10.7 Battery Charging**

Batteries can be charged by constant current or constant voltage. When charged by the constant-current method, care must be taken to eliminate the possibility of overcharging; therefore, the condition of the battery should be known before charging so that the charger can be removed when the ampere-hour rate of the battery is met.

Charging with the constant voltage method reduces the possibility of overcharging. With the constant voltage method, charge current is high initially and tapers off to a trickle charge when the battery is fully charged. Two requirements must be met when using the constant-voltage method:

- The charging voltage must be stable and set to 2.4 V per cell for a lead-acid battery and 2.30 V per cell for a gel cell battery. Gel cell open-circuit voltage is 2.12 V per cell.
- A current-limiting circuit must be employed to limit charge current when the battery is fully discharged.

A good battery charger charges in three steps. In the first stage, charge current is at the maximum safe rate the batteries will accept until the voltage rises to 80–90% of full charge level. Voltages at this stage typically range from 10.5–15 V. There is no correct voltage for bulk or charge charging, but there may be limits on the maximum current that the battery and/or wiring can accept.

In the second stage, accept, the voltage remains constant and current gradually tapers off as internal resistance increases during charging. Voltages are typically 14.2–15.5 V.

After batteries reach full charge, the third stage charging voltage is reduced to a lower level, 12.8–13.2 V, to reduce gassing and prolong battery life. This is often referred to as a maintenance, float, or trickle charge, since its main purpose is to keep an already charged battery from discharging, Fig. 19-28. An ideal charging state table is shown in Table 19-4.

![Ideal charge curve](image)

PWM, or pulse width modulation is sometimes used as a float or trickle charge. In PWM chargers, the controller circuit senses small voltage drops in the battery and delivers short charging cycles (pulses) to the battery. This may occur several hundred times per minute and is called pulse width because the width of the pulses varies from a few microseconds to several seconds.

Most flooded batteries should be charged at no more than the C/8 rate for any sustained period. C/8 is the battery capacity at the 20 hour rate divided by 8. For a 220 Ah battery, this would equal 26 A. Gelled cells should be charged at no more than the C/20 rate, or 5% of their amp-hour capacity. AGM batteries can be charged at up the C × 4 rate, or 400% of the capacity for the bulk charge cycle.

Lead acid batteries require 15.5 V for 100% charge. When the charging voltage reaches 2.583 V/cell, charging should be stopped or reduced to a trickle
charge. Flooded batteries must bubble (gas) to insure a full charge, and to mix the electrolyte. Float voltage for flooded batteries should be 2.15–2.23 V/cell, or 12.9–13.4 V for a 12 volt battery. At higher temperatures, over 85°F, charge voltage should be reduced to 2.10 V/cell. Float and charging voltages for gelled batteries are usually about 0.2 V less than for flooded batteries.

19.10.7.1 Equalizing

The equalize cycle puts a controlled overcharge to remove lead sulfate from the plates that is not removed during the normal charging of the battery. Flooded battery life can be extended if an equalizing charge is applied every 10 to 40 days. This is a charge that is about 10% higher than the normal full charge voltage, and is applied for 2–16 h to be sure that all cells are equally charged and the gas bubbles mix the electrolyte. If the liquid in the cells is not mixed, the electrolyte becomes stratified, creating a strong solution at the top and weak solution at the bottom of the cell. AGM and gelled batteries should be equalized a maximum of two to four times a year.

19.10.7.2 Charging Voltage versus Temperature

Battery charging is sensitive to temperature. As the ambient temperature decreases, the charging voltage must be increased, Table 19-4.

19.10.7.4 Internal Resistance

All batteries have internal resistance that causes the battery voltage to fluctuate with the load. To calculate the internal resistance of a single cell or battery, the open-circuit voltage $V_1$ is measured using a voltmeter with an internal resistance of at least 1000 Ω/V. The battery or cell is then loaded with resistor $R_1$, and the voltage $V_2$ across the resistor is measured. $R_1$ should be at least 10 times the battery resistance. The current through the resistor $R_1$ is

$$I = \frac{V_2}{R_1}. \quad (19-24)$$

The internal resistance, $R_i$, of the battery may now be calculated using

$$R_i = \frac{V_1}{I} - R_1. \quad (19-25)$$

19.10.8 Lead-Acid Batteries

The lead-acid storage battery was invented by Gaston Planté in 1860 and is one of the most widely used forms of battery power. The principal drawback to this type of battery has been the liquid electrolyte and the fumes given off when charging and discharging. Today the sealed lead-acid battery may take its place with other rechargeable batteries such as the nickel-cadmium battery. Since small amounts of gas may be generated in any battery during the charge or discharge cycle, lead-
acid batteries are vented so that the gas but not the electrolyte escapes.

Lead-acid cells are normally 2.1 V and are easily connected in series to produce 6 V and 12 V automotive types, 24 V aircraft types and 36 V types for golf carts, etc. Lead-acid batteries, because of their availability, high Ah ratings, and ability to be connected in series, work well powering sound systems in the field.

The type and amount of charge determine the condition of the cell. If a lead-acid battery is overcharged, excessive water consumption and hydrogen evolution result, while constant undercharging results in a battery with less and less capacity.

The recharge factor (RF) is defined as the charge Ah divided by the previous discharge Ah. The RF must always be greater than 1 to bring the battery back to capacity. The actual RF is between 1.04 and 1.20, with the sealed lead acid batteries requiring less than the standard vented type. Fig. 19-29A shows the state of charge (SOC) achieved versus the RF for a lead-acid battery. Fig. 19-29B shows the SOC versus the RF after a number of cycles. Note that the battery rapidly loses its capacity if it is not overcharged—i.e., more is put in than is taken out.

The use of a trickle charger with a storage battery shortens the life of the battery because of overcharging. Trickle chargers should only be used when it is impractical to charge a battery by other means. A practical approach to the problem is to adjust the charging voltage to a value between 2.15 V and 2.17 V per cell.

A better, but more elaborate, method is to check the specific gravity of the cells over a period of several months and adjust the charging voltage to a value where the specific gravity is maintained at 1.250. Compensation must be made for temperature changes when reading the specific gravity. Four gravity points are added to the reading for every 10°F (5°C) the electrolyte is above a temperature of 80°F (27°C).

The freezing point of a battery electrolyte depends on the specific gravity of the electrolyte, Table 19-6. Lead acid batteries freeze when in a discharged state, so it is imperative that they be kept fully charged when in subfreezing temperatures. If a storage battery is left in a discharged condition for any length of time, the plates may be damaged due to sulfation.

19.10.9 Lead-Dioxide Batteries

A lead-dioxide battery is a gelled electrolyte, maintenance-free type that exhibits high capacity and long life when properly applied and charged. To prevent electrolyte movement in the battery, the electrolyte in sealed batteries is immobilized by the use of a gelling agent that stores the electrolyte in highly porous separators. With this construction, the loss of water is minimized.

The terminal voltage of each cell is approximately 2.12 V. The cell voltage is higher for a battery that has...
just been taken off charge, but in all instances it should adjust to about 2.12 V after a period of time.

Gel/Cells comes as a type A or type B. The type A Gel/Cell is conservatively designed for 4–6 years of continuous charging in standby power applications. During this period over 100 normal discharge/charge cycles can be expected. Even more are obtained if only minor discharges are experienced. The end of life is actually determined by when the equipment will no longer perform its required function. Since the battery may still have 40–60% of its initial capacity, the service life may be much longer.

The type A Gel/Cell has near its full nominal capacity upon shipment from the factory. Type A cells are used for alarm systems, memory standby, etc. where they are normally in a standby mode.

The type B Gel/Cell is designed to provide 3–5 years of service in standby power applications or 300–500 normal discharge-charge cycles in portable power applications.

As the battery is discharged, the terminal voltage will slowly decrease. For instance, when the rated capacity of the battery is removed over a 20 h period, the terminal voltage would decrease to 1.75 V per cell. These batteries are rated at a 20 h current rate and room temperature. This means a 2.6 Ah battery would put out 0.13 A for 20 h. This does not mean, however, that it will put out 2.6 A for 1 h (it would put out about 1.7 A for 1 h).

Lead-dioxide batteries can be charged by the constant-current or constant-voltage method. The constant-current method is used when charger cost is the primary consideration. The battery is forced to receive a constant amount of current regardless of its needs. While charger component economy is achieved, it is sometimes done at the expense of recharge time or service life if the current is not properly set. Trickle charging current ranges from 0.5–2.0 mA per rated Ah capacity of the battery.

When charging with the constant-voltage method, a voltage of 2.25–2.30 V per cell should be used. To maintain the battery at 100°F (38°C), a voltage of 2.2 V/cell is required, while at 30°F (0°C), 2.4 V/cell is required.

19.10.10 Absorbed Glass Mat Batteries

Absorbed glass mat batteries (AGM) are sealed batteries that can be operated in any position. AGM was developed to provide increased safety, efficiency, and durability. In AGM batteries the acid is absorbed into a very fine glass mat that is not free to slosh around. The plates are kept only moist with electrolyte, so gas recombination is more efficient (99%). The AGM material has an extremely low electrical resistance so the battery delivers high power and efficiency. AGM batteries offer exceptional life cycles.

The plates in an AGM battery may be flat like wet cell lead-acid batteries, or they may be wound in a tight spiral. Their construction also allows for the lead in their plates to be purer as they no longer need to support their own weight. AGM batteries have a pressure relief valve that activates when the battery is recharged at voltage greater than 2.30 V/cell. In cylindrical AGM batteries, the plates are thin and wound into spirals so they are sometimes referred to as spiral wound.

AGM batteries have several advantages over both gelled and flooded, at about the same cost as gelled:

- All the electrolyte (acid) is contained in the glass mats so they cannot spill or leak, even if broken. Since there is no liquid to freeze and expand, they are practically immune from freezing damage.
- Most AGM batteries are recombinant—i.e., the oxygen and hydrogen recombine inside the battery. Using the gas phase transfer of oxygen to the negative plates to recombine them back into water while charging prevents the loss of water through electrolysis. The recombining is typically 99+% efficient.
- AGM batteries have a self-discharge of 1–3% per month.
- AGM batteries do not have any liquid to spill, and even under severe overcharge conditions, hydrogen emission is far below the 4% max, specified for aircraft and enclosed spaces.
- The plates in AGM’s are tightly packed and rigidly mounted so they withstand shock and vibration.

19.10.10.1 A Comparison of the Three Types of Deep Cycle Batteries

Safety. Batteries can be dangerous. They store a tremendous amount of energy, create explosive gas during charge and discharge, and contain dangerous chemicals. Both gel and AGM batteries are sealed batteries that use recombinant gas technology. AGM is more efficient in the AGM process and completes its gas recombination near the plates. Gel recombinant gas batteries should incorporate automatic temperature-compensated voltage regulators to prevent explosions associated with their overcharging. Flooded batteries will spew acid, will definitely spill and leak if tipped over, and they generate dangerous and noxious explosive gases. AGM batteries are best at protecting both equipment and passengers.
Longevity. All batteries die. The number of cycles it takes to kill them is a function of the type and quality of the battery. When cycled between 25% and 50% depth of discharge (recommended deep cycle use), AGM batteries will normally outlast the other two types.

Durability. Some battery designs are simply more durable than others are. They are more forgiving in abusive conditions — i.e., they are less susceptible to vibration and shock damage, over-charging, and deeper discharge damage. Gel acid batteries are the most likely to suffer irreversible damage from overcharging. Flooded acid batteries are the most likely to suffer from internal shorting and vibration damage. AGM batteries are usually more durable and can withstand severe vibration, shocks, and fast charging.

Efficiency. Internal resistance of a battery denotes its overall charge/discharge efficiency and its ability to deliver high cranking currents without significant drops in voltage and is a measure of how well it has been designed and manufactured. Internal resistance in NiCad batteries is approximately 40%—i.e., you need to charge a NiCad battery 140% of its rated capacity to have it fully charged. The flooded wet battery’s internal resistance can be as high as 26%, which is the charging current lost to gassing, or breaking up of water. Gel acid batteries are better at approximately 16% internal resistance and require roughly 116% of rated capacity to be fully charged. AGM batteries have an internal resistance of 2%, allowing them to be charged faster and deliver higher power.

19.10.11 LeClanche (Zinc-Carbon) Batteries

LeClanche batteries consist of a carbon anode, zinc cathode, and electrolyte solution of ammonium chloride, zinc chloride, and mercury chloride in water (called a mix). The nominal voltage is 1.5 V. This type of cell is quite inefficient at heavy loads, and its capacity depends considerably on the duty cycle. Less power is available when it is used without a rest period. Maximum power is produced when it is given frequent rest periods, since the voltage drops continuously under load. Shelf life is limited by the drying out of the electrolyte. A typical discharge curve is given in Fig. 19-30.

Zinc-carbon cells may be recharged for a limited number of cycles. The following information is extracted from the National Bureau of Standards Circular 965:

The cell voltage for recharge must not be less than 1 V and should be recharged within a short time after removing from service. The ampere

Figure 19-30. Typical discharge curves for three different types of penlight cells discharged continuously into a 50 Ω load.

hours of charge should be within 120–180% of the discharge rate. The charging rate is to be low enough to distribute the recharge over 12–16 h. Cells must be put into service soon after recharging as the shelf life is poor.

19.10.12 Nickel-Cadmium Batteries

For optimum performance, many battery-operated items require a relative constant voltage supply. In most applications, nickel-cadmium cells hold an almost constant voltage throughout most of the discharge period, and the voltage level varies only slightly with different discharge rates. Nominal discharge voltage is 1.25 V at room temperature.

Nickel-cadmium cells are especially suited to high discharge or pulse currents because of their low internal resistance and maintenance of discharge voltage. They are also capable of recharge at high rates under controlled conditions. Many cells can be rapidly charged in 3–5 h without special controls, and all can be recharged at a 14 h rate.

Nickel-cadmium cells are designed to operate with a wide temperature range and can be discharged from –40°F to +140°F (–40°C to +60°C).

These cells can be continuously overcharged at recommended rates and temperature. This will not noticeably affect life unless the charge rate exceeds design limitations of the cell.

The cell construction eliminates the need to add water or electrolyte, and, under certain conditions, the cell will operate on overcharge for an indefinite period. A typical discharge curve for a cell, rated at 25 Ah and weighing approximately 2 lb, is given in Fig. 19-31.

The charge retention varies from 75% for 1 month to as low as 15% for 5 months. Storage at high temperatures will reduce high retention. Cells should be charged
prior to use to restore full capacity. Nickel cadmium eventually fails due to permanent or reversible cell failure. A reversible failure is usually due to shallow charge and discharge cycles and the battery appears to have lost capacity. This is often called the *memory effect*. This problem can be removed by deep discharge and a full recharge. A loss of capacity can also come from extended overcharging. If this should occur, full capacity can be restored by a discharge followed by a full recharge.

The capacity of a nickel-cadmium cell is the total amount of electrical energy that can be obtained from a fully charged cell. The capacity of a cell is expressed in ampere-hours (Ah) or milliampere-hours (mAh), which are a current-time product. The capacity value is dependent on the discharge current, the temperature of the cell during discharge, the final cutoff voltage, and the cell’s general history.

The nominal capacity of the nickel-cadmium cell is that which will be obtained from a fully charged cell discharged at 68°F (20°C) for 5 h to a 1.0 V cut off. This is called the C/5 rate.

Discharges at the 20, 15, 10, and 1 h rates are called C/20, C/15, C/10, and C, respectively. Higher rates are designated as 2C, 3C, etc.

When three or more cells are series connected for higher voltages, the possibility exists that during discharge, one of the cells, which may be slightly lower in capacity than the others, will be driven to a zero potential and then into reverse. At discharge rates (C) in the vicinity of C/10, cells can be driven into reverse without permanently damaging the cell. Prolonged, frequent, or deep reversals should be avoided since they shorten cell life or cause it to vent. Cell voltage should never be allowed to go below –0.2 V.

Nickel-cadmium batteries may be charged using either a constant-current or constant-voltage charger. There are four major factors that determine the charge rates, which can be used on nickel-cadmium batteries. They are charge acceptance, voltage, cell pressure, and cell temperature.

No charge control is required for *charge rates* up to C/3. This allows the use of the least expensive charger design. When charging rates equal or exceed 1.0 C, the charging current must be regulated to prevent overcharge.

</table>

In Table 19-3, the notation that includes the letter C is used to describe current rates in terms of a fraction of the capacity rating of the battery. A comparison of cells from different manufacturers requires rationalization to a common standard for capacity rating at the same discharge rate.

In general, discharge times will be shorter than those for C rates greater than 1 and longer than those for C rates less than 1. The charge input must always be more than discharged output. For example, to ensure full recharge of a completely discharged battery, the constant-current charge time at the 10 h rate must be longer than 10 hours due to charge acceptance characteristics.

**19.10.13 Alkaline-Manganese Batteries**

The *alkaline-manganese battery* is gaining considerable importance in the electronic field since it is a primary battery and is rechargeable.

The polarity of this cell is reversed from the conventional zinc-carbon cell, in which the can is negative.
However, because of packaging, the outward appearance is similar to the zinc-carbon cell, with the same terminal arrangement. Although this cell has an open-circuit voltage of approximately 1.5 V, it discharges at a lower voltage than the zinc-carbon cell. Also, the discharge voltage decreases steadily but more slowly. Alkaline-manganese batteries have 50–100% more capacity than their zinc counterparts. Zinc-carbon cells yield most of their energy above 1.25 V and are virtually exhausted at 1 V, while the alkaline cell yields most of its energy below 1.25 V with a considerable portion released at less than 1 V.

If the discharge rate is limited to 40% of the nominal capacity of the cell and recharge is carried out over a period of 10–20 h, alkaline-manganese cells can be cycled 50–150 times. A typical discharge curve is shown in Fig. 19-32.

The 1.35 V cell has a pure mercuric-oxide cathode. On discharge its voltage drops only slightly until close to the end of the cell life when it then drops rapidly. The 1.4 V cell has a cathode of mercuric oxide and manganese dioxide. On discharge, its voltage is not quite as well regulated as the 1.35 V cell, but it is considerably better than the manganese-alkaline or zinc-carbon cell.

Mercury cells have excellent storage stability. A typical cell will indicate a voltage of 1.3569 V, with a cell-to-cell variation of only 150 μV. Variation due to temperature is 42 μV/°F, ranging from −70°F to +70°F (−56°C to +21°C), with a slight increase of voltage with temperature. The internal resistance is approximately 0.75 Ω. Voltage loss during storage is about 360 μV per month; therefore, a single cell can be used as a reference voltage of 1.3544 V, ±0.17%. The voltage is defined under a load condition of 5% of the maximum current capacity of the cell. Normal shelf life is on the order of 3 years.

Recharging of mercury cells is not recommended because of the danger of explosion. A typical stability curve for a single cell over a period of 36 months is shown in Fig. 19-33. The drop in voltage over this period is 13 mV.

This page intentionally left blank
20.1 The Necessity for Amplifiers

The necessity for amplification becomes apparent from an analysis of the unlikely arrangement depicted in Fig. 20-1 wherein a dynamic microphone is connected directly to a loudspeaker.

![Figure 20-1. The impossible sound reinforcement system.](image)

The microphone typically, with moderate excitation, would generate an open circuit voltage of 10 mV and possess an internal impedance of 200 $\Omega$. The loudspeaker typically would have an impedance of 8 $\Omega$ and an efficiency of 10%. The electrical power delivered to the loudspeaker assuming that the microphone and loudspeaker impedances are predominantly resistive would be $1.8 \times 10^{-8}$ W while the acoustical output of the loudspeaker would only be $1.8 \times 10^{-9}$ W. Even if a matching transformer is interposed between the microphone and the loudspeaker, the improvement is hardly significant. The acoustical output in this event becomes only $1.25 \times 10^{-8}$ W which is several orders of magnitude below the acoustical power requirements of most applications.

20.2 Types and Descriptions of Amplifiers

The initial description for an amplifier is based on the nature of the active elements involved such as vacuum tube, bipolar transistor, field effect transistor, integrated circuit, magnetic field, or a mixture of two or more of these technologies, in which case it is called a hybrid. The second descriptor is associated with the principal quantity being amplified and indirectly with the input output relationships exhibited by the amplifier.

For example, a voltage amplifier is excited at its input by a signal in the form of a voltage and responds by producing a related voltage at its output. In this instance, it is desirable that the input impedance of a voltage amplifier be large compared with the impedance of the signal source and that the output impedance of the amplifier be small compared with the load impedance connected at its output. As a result, the signal source impresses a maximum voltage across the amplifier’s input and the amplifier subsequently produces a maximum voltage across its associated load.

A current amplifier is excited at its input by a signal in the form of a current and responds by producing a related current in its associated load. Current amplifiers have low input impedances and high output impedances.

A transconductance amplifier is excited at its input by a voltage and responds by producing a related current in its associated load. Transconductance amplifiers have high input impedances and high output impedances.

Transresistance amplifiers are excited at the input by a signal current and respond by producing a related voltage at the output. A transresistance amplifier has a low input impedance as well as a low output impedance.

Another useful amplifier descriptor describes the functional relationship, in a mathematical sense, which exists between the input and output signals. For example, in linear amplifiers the output signal is a linear function of the input signal whereas in logarithmic amplifiers, the output signal is proportional to the logarithm of the input signal. The majority of the amplifiers employed in audio are linear but a significant number of logarithmic or other special function amplifiers find use in signal processing applications.

Additional descriptions are associated with the physical location of an amplifier in the overall amplification chain. For example, a preamplifier is usually placed immediately after a transducer where the signal levels are quite low and noise characteristics are of considerable importance. Certain preamplifiers will incorporate special equalization circuitry; for instance, a phono preamplifier provides the required RIAA playback characteristic.

Preamplifiers are followed by mixing amplifiers that can combine and individually control the signals from several different sources. Although there may exist several other intermediate steps, the power amplifier is the last step.

Power amplifiers in audio work have the input-output impedance characteristics of a voltage amplifier along with the ability to deliver large amounts of electrical power. Fig. 20-2 illustrates a typical arrangement in a reinforcement chain.

The final descriptor to be discussed concerns amplifier terminal connections. Amplifiers are essentially two port devices, i.e., they are constituted with a pair of input terminals and a pair of output terminals as indicated in Fig. 20-3.

If neither of the input terminals is connected directly to ground and if both of the input terminals are electrically symmetric with respect to ground, the input is said to be balanced. If one of the input terminals is connected to ground, the input is unbalanced and is described as being single ended. Similar statements are applicable to the output pair of terminals. All possible combinations are encountered in practice. The input
may be balanced while the output is unbalanced, the input may be unbalanced while the output is balanced, both input and output may be balanced, or both input and output may be unbalanced. The balanced configuration is preferable when dealing with long lines and low signal levels or where ground isolation is required. This preference is based on the common mode rejection properties of the balanced arrangement. For example, consider the signal leads in Fig. 20-3 to be a long twisted pair contained within an electrostatic shield with the shield grounded. The electrostatic shield offers no noise immunity from external time-varying magnetic fields. When such varying magnetic fields exist, a noise signal will be induced between each of the signal conductors and ground. The amplifier, however, amplifies the difference that appears between its input terminals and hence any common signal between the input terminals, and ground is rejected.

20.2.1 Amplifier Transfer Function

The relationship that exists in the steady state between the output signal and the input signal of a two-port device such as an amplifier or filter is called the *transfer function*. The transfer function has a magnitude and an angle with each being dependent on the steady state signal frequency. Mathematically, the transfer function is expressed concisely in the form of a complex function that has both real and imaginary parts. The magnitude of the transfer function at any particular frequency is the square root of the sum of the squares of the real and imaginary parts and physically corresponds to the ratio of the output signal amplitude to the input signal amplitude. The angle of the transfer function at any particular frequency is the angle whose tangent is the ratio of the imaginary and real parts and physically corresponds to the phase difference between the output signal and the input signal. These ideas are best expressed by a simple example. Consider a dc-coupled voltage amplifier that offers an amplification of 10 volts per volt (V/V) at dc or zero frequency and an amplification of $10/\sqrt{2}$ V/V at a frequency $f_0$ while having introduced a phase shift of $-\pi/4$ radian, or $-45^\circ$. Upon denoting the transfer function by the symbol $A$ and the independent frequency variable by the symbol $f$, the following statements can be made:

\[
A = \frac{10}{1 + \left(\frac{f}{f_0}\right)^2} + j \frac{-10\frac{f}{f_0}}{1 + \left(\frac{f}{f_0}\right)^2}
\]

or more compactly

\[
A = Ge^{j\phi}
\]

where,

- $G$ is the magnitude of the transfer function or gain function,
- $e$ is the base of the natural logarithm,
- $\phi$ is the angle of the transfer function or phase function, the angle whose tangent is the imaginary part divided by the real part of Eq. 20-1,
- $G$ is the square root of the sum of the squares of the real and imaginary parts of Eq. 20-1,
- $j$ is $\sqrt{-1}$.

\[
G = \frac{10}{\sqrt{1 + \left(\frac{f}{f_0}\right)^2}}
\]
An elegant form in which to express Eq. 20-1 is obtained by letting \( S = jZ \) with \( Z \) equal to \( 2Sf \) and \( Z_0 \) equal to \( 2Sf_0 \). Eq. 20-1 after substitution and simplification becomes

\[
A = \frac{10\omega_0}{S + \omega_0} \quad (20-5)
\]

Eq. 20-5 is the statement of Eq. 20-1 in the language of the Laplace transform, which is really the basis for transfer function analysis. It is worthwhile at this point to note that Eqs. 20-1, 20-2, and 20-5 are alternative ways of expressing the transfer function of the simple amplifier under discussion. The form in Eq. 20-5 is that which is used most often in practice because of its simplicity.

If \( S \) were allowed to assume any possible value, whether it be real, imaginary, or complex, such that all points in a two-dimensional complex plane were accessible, there would be only one value of \( S \) in Eq. 20-5 for which the denominator would become zero and \( A \) would become infinite. That value of \( S \) is when \( S = -j\omega_0 \). It is said then that Eq. 20-5 has a single pole located at \( S = -\omega_0 \). The pole order of a transfer function is determined by the power of \( S \) appearing in the denominator. A two-pole amplifier would have an \( S^2 \), a three-pole an \( S^3 \), etc., appearing in the denominator of the transfer function. In the steady state as opposed to transient state recall that \( S \) is restricted to the values \( S = j\omega \) and the only accessible points lie on the positive imaginary axis because the physical frequency values must be positive. In the steady state even though the value of \( S \) never coincides with the location of our example pole, the pole location nevertheless influences the operation of the amplifier. Changing the pole location in effect changes the value of \( \omega_0 \) and hence changes the value of the transfer function at all frequencies other than zero frequency.

A further study of the Laplace transform and the inverse Laplace transform indicates that the transfer function is a description also of the device’s impulse response in the complex frequency plane while the inverse Laplace transform of the transfer function is the description of the device’s response to an impulse described in the time domain—i.e., it is the device’s transient response to an impulse expressed as a function of time. An important consequence of this is that in order for a device to exhibit a transient response that decays with increasing time, all of the poles of the device’s transfer function must have negative real parts.

The amplifier under discussion satisfies this criterion with a pole at \(-\omega_0\) and hence its transient response decays with time which allows the amplifier to exhibit a stable steady-state response. If this were not true, the device would not be useful as an amplifier.

The information contained in the amplifier’s transfer function may be depicted in a variety of ways, the two most popular of which are the Bode and Nyquist diagrams. The Bode diagram displays Eqs. 20-3 and 20-4 in the form of a graph of 20 dB per log of \( \omega \) and a graph of \( \phi \) plotted versus log of \( \omega \). Fig. 20-4 is the Bode diagram for the amplifier of the example.

![Figure 20-4. Gain and phase graphs for the example amplifier.](image-url)

An examination of the Bode diagram of Fig. 20-4 leads to the conclusion that this amplifier is in essence a low-pass filter having a reference gain of 20 dB, a single pole, and a half power point at \( \omega = \omega_0 \). The pole order is deduced from the fact that even though the response is low pass in nature its asymptotic slope is \(-20\, \text{dB per decade}\) or equivalently \(-6\, \text{dB per octave}\). A two-pole low pass would produce \(-12\, \text{dB per octave}\), a three-pole \(-18\, \text{dB per octave}\), etc., in the asymptotic slope.

This same information is displayed in a different form by means of a Nyquist diagram. A Nyquist diagram is a graph in the complex plane of Eq. 20-1 plotted under the condition that \( \omega \) is allowed to take on all values from zero to infinity. Fig. 20-5 is the Nyquist diagram for the amplifier of the example.
A second example will serve to further explore the properties of transfer functions. Consider that the amplifier of the previous example had an input resistance of amount \( R \). The input circuit is now to be modified by connecting a capacitor of size \( C \) in series with this input resistance to form a simple ac-coupled amplifier. Upon denoting \( Z_0c = 1/RC \) the transfer function for this new amplifier is given by

\[
A = \frac{10S\omega_o}{(S + \omega'_o)(S + \omega_o)} \tag{20-6}
\]

Eq. 20-6 indicates that the amplifier now has two poles, the original one at \( S = -\omega_0 \) and a new one located at \( S = -\omega'_o \). In addition, an examination of the numerator of the transfer function indicates that there is now a value of \( S \) for which the numerator becomes zero namely at \( S = 0 \). Values of \( S \) that make the numerator zero are called the zeros of the transfer function. The present amplifier has a single zero and a pair of poles that can be displayed in a pole-zero diagram. A pole-zero diagram is a drawing of the complex frequency plane in which the pole locations are denoted by \( X \) and the zero locations by \( 0 \). The pole-zero diagram for the ac-coupled amplifier appears as Fig. 20-6.

Fig. 20-6 is a relatively simple pole-zero diagram as the amplifier upon which it is based is simple. A few conclusions based on more general amplifiers are worth noting. Real poles may be singular while complex poles always appear as conjugate pairs. The poles for amplifiers that exhibit stable steady-state behavior may be real or complex but must have negative real parts. The zeros may appear anywhere in the \( S \) plane, but any zeros with positive real parts are associated with nonminimum phase behavior.

The Bode diagram for this example is arrived at by the following steps. First, reform Eq. 20-6.

\[
A = \left( \frac{S}{S + \omega'_o} \right) \left( \frac{10\omega_o}{S + \omega_o} \right)
\]

Substitute for \( \omega'_o \) in terms of \( \omega_o \) by examining the pole-zero diagram, \( \omega'_o = 1/4\omega_o \) therefore

\[
A = \left( \frac{S}{S + \omega_o/4} \right) \left( \frac{10\omega_o}{S + \omega_o} \right)
\]

Substitute \( S = j\omega \) and find the absolute magnitude of the resulting expression to obtain the gain function as indicated here

\[
G = |A| = \frac{\omega}{\omega^2 + \omega_o^2} \times \frac{10\omega_o}{\sqrt{\omega^2 + \omega_o^2}}
\]

\[
= \frac{\omega}{\omega_o} \times \frac{10}{\sqrt{\omega^2 / \omega_o^2 + 1}}
\]

Make a graph of 20 dB \( \log G \) versus \( \log(\omega/\omega_o) \). This graph appears in Fig. 20-7. Next determine the phase function \( \phi \).
The angle of the first factor is
\[ \frac{\pi}{2} - \tan^{-1}\left(\frac{4\omega}{\omega_0}\right) \]
while the angle of the second factor is
\[ -\tan^{-1}\left(\frac{\omega}{\omega_0}\right) \]
therefore, the total phase shift is
\[ \phi = \frac{\pi}{2} - \tan^{-1}\left(\frac{4\omega}{\omega_0}\right) - \tan^{-1}\left(\frac{\omega}{\omega_0}\right) \]

Make a graph of \( \phi \) versus \( \log(\omega/\omega_0) \) in order to complete the Bode diagram. This graph also appears in Fig. 20-7.

### 20.2.2 Feedback Theory

Fig. 20-8 represents a generalized feedback loop based on a voltage amplifier. In the absence of feedback, with the loop open, the amplifier has a transfer function \( A \).

The feedback path has a transfer function \( B \), the input signal from the outside world is \( V_{in} \) and the signal supplied as an output is \( V_0 \). When the loop is closed, the input signal is combined with the feedback signal in the indicated junction to form an error signal \( V_e \). The process that occurs in the junction may be either addition or subtraction, depending on the nature of \( A, B \), and the type of feedback (positive or negative) desired. In any event the signal actually supplied to the amplifier when the loop is closed is \( V_e \).

\[ V_e = V_{in} + BV_0 \]  \hspace{1cm} (20-7)
\[ V_0 = AV_e \]  \hspace{1cm} (20-8)
\[ = AV_{in} + ABV_0 \]
\[ A' = \frac{V_0}{V_{in}} \]  \hspace{1cm} (20-9)

\[ A \] and \( B \), in general, are complex functions of the steady-state frequency of operation. The absolute magnitude of the denominator of Eq. 20-9 is called the gain reduction factor. The feedback is called negative when
\[ |1 - AB| > 1 \]  \hspace{1cm} (20-10)
and is positive when

![Figure 20-8. Generalized feedback loop.](image-url)
The nature of the feedback is best explored by studying the quantity $AB$ as a function of the frequency as displayed in a Nyquist diagram. The quantity $AB$ is called the loop gain of the hypothetical amplifier. Included in the diagram is a circle of unit radius centered on the point $1, j0$.

The perimeter of the unit circle divides the plane into two regions. For all of the points outside of the circle $|1 - AB| > 1$, the feedback is negative, whereas for any point on the curve within the unit circle, $|1 - AB| < 1$, the feedback is positive. The hypothetical amplifier for which Fig. 20-9 was drawn thus has negative feedback at low frequencies but exhibits positive feedback over a range of high frequencies. Note that $AB$ is negative, real, and has its maximum absolute value at $Z = 0$. This is characteristic of a dc-coupled amplifier having a loop gain transfer function that has poles but no zeros. Furthermore, $AB$ resides in the second quadrant until $\omega$ exceeds $\omega_1$ for $\omega_1 < \omega < \omega_2$, $AB$ is in the first quadrant but the feedback is still negative. Whenever the frequency is such that $\omega > \omega_2$, $AB$ falls within the unit circle and the feedback becomes positive. This region must be handled with extreme care.

As will presently be discussed in detail, negative feedback is a stabilizing influence on amplifier performance but positive feedback is a destabilizing influence and can, in fact, lead to an uncontrolled oscillatory condition. The final conclusion to be drawn from Fig. 20-9 is that for $\omega > \omega_3$, $AB$ is in the fourth quadrant and finally approaches zero as the operating frequency becomes very large. As $\omega$ is allowed to vary from zero to infinity, the angle associated with $AB$ undergoes a change of $-270^\circ$, which is characteristic of a transfer function that, in the absence of zeros, possesses three poles. If $AB$ for the hypothetical amplifier had possessed just a single pole, the entire Nyquist diagram would have been restricted to the second quadrant and the feedback would have been negative for all frequencies. On the other hand, if $AB$ had possessed just two poles, the Nyquist diagram would enter the first quadrant at high frequencies but would approach zero without ever crossing the real axis. The feedback would be positive at high frequencies but not to an excessive degree.

The critical point to be avoided for stable operation is the point $1, j0$ on the positive real axis. If the Nyquist curve passes through this point under any condition, the loop gain becomes one with an angle of zero. As a consequence, $|1 - AB|$ becomes zero and $A'$ becomes infinite. Physically this implies that the amplifier will produce an output even in the absence of an input signal from the outside world. That is, what was intended to be an amplifier has become an oscillator. The type of Nyquist diagram that is to be avoided is one that encircles the critical point such as displayed in Fig. 20-10.

Fig. 20-10 was obtained by a modification of the amplifier described by Fig. 20-9. This modification amounted to changing $AB$ at zero frequency from its former value of $-6$ to a new value of $-10$ with all other factors remaining the same.

Unlike Fig. 20-9, Fig. 20-10 is the Nyquist curve for an unstable amplifier. The curve does not pass through the critical point but it does encircle the critical point. Consider for the moment that the amplifier is initially off. Under such a circumstance, $A$ is zero and, consequently, $AB$ is also zero. Under these conditions the Nyquist curve is collapsed into a single point at the origin. Following turn-on, there is a period of time in which $A$ and $AB$ are growing toward their final values. In this interval, the Nyquist curve is in effect growing outward from the origin. At some instant during this growth period, the Nyquist curve will intersect the critical point $1, j0$ and the amplifier will break into oscillation. Precaution must be taken, therefore, when dealing with feedback loops in which the loop gain transfer function has three or more poles.

It was mentioned earlier that negative feedback can be a stabilizing influence on amplifier operation. A
negative feedback loop is in essence a type of quality control wherein the system output is compared with what is desired for it to be. Any difference as a result of this comparison is injected back into the system in such a way as to force a correction of system behavior. A highly simplified example is as follows. Consider a dc voltage-amplifier for which it is desired that the voltage gain be $-10$; that is, an output voltage ten times as large as the input signal but with the opposite polarity. One might proceed on good faith and employ the latest electronic design techniques, consult manufacturer’s specifications on the best available active devices, design, and finally construct an amplifier that, according to the best available information, possesses an open loop transfer function at low frequencies of $-10$. In fact, in order to be on the safe side, one may follow the same procedure yielding a value of $-20$ and precede the device by an adjustable attenuator set at an absolute value of $\frac{1}{2}$ or whatever is required to obtain an overall transfer function of $-10$ when the system is first tested. Unfortunately, the active devices employed are at the mercy of the operating voltages supplied to them (line voltage variations, etc.), ambient temperature variations, age, and weather elements in general. To a lesser degree, the same may be said of the passive elements involved. $A$, the open loop transfer function may possess a nominal value of $-10$ but it is constantly changing from moment to moment being at times larger and at other instants smaller than the intended value. There exists nothing in the system to monitor its overall operation. Alternatively, one might, following the same procedures outlined before, design an amplifier having an open loop transfer function whose nominal value is $-100$ and enclose this with a negative feedback loop to obtain a nominal closed loop transfer function, $A'$, of $-10$. Mathematically,

$$A' = \frac{A}{1 - AB}$$

By substituting nominal values, one can solve for $B$:

$$-10 = \frac{-100}{1 + 100B}$$

$$1 + 100B = 10$$

$$100B = 9$$

$$B = \frac{9}{100}$$

$B$ is found to require the properties of a simple attenuator or voltage divider. The next step would be to construct this divider from precision resistors possessing very small voltage and temperature coefficients of resistance. The feedback loop is then closed, making use of this stable attenuator. The resulting system has a nominal closed loop transfer function, $A' = -10$, a nominal loop gain, $AB = -9$, and a nominal gain reduction factor of 10. What has been accomplished? Suppose that the original open loop amplifier whose nominal transfer function was $-10$ had variations or changes in $A$ that were about $\pm 20\%$ and the new amplifier that was constructed employing the same technology has similar variations under open loop conditions. Now compare the ratio of the variations to the nominal values with and without feedback; that is, $\Delta A/A$ is to be compared with $\Delta A'/A'$. Knowing that $A' = A/(1 - AB)$ and by employing the techniques of differential calculus one finds that

$$\Delta A' = \frac{\Delta A}{(1 - AB)^2}$$

Consequently,

$$\frac{\Delta A'}{A'} = \frac{\Delta A}{(1 - AB)^2} \times \frac{1}{A} \times \frac{1}{1 - AB}$$

$$= \pm 20\% \times \frac{1}{10}$$

$$= \pm 2\%$$

The application of negative feedback has produced a system that has a nominal transfer function of $-10$ with a variation of $\pm 2\%$; whereas before, in the absence of feedback, there existed a system having a nominal transfer function of $-10$ with a variation of $\pm 20\%$ under the same conditions. The price paid for this improvement amounted to trading off a higher open loop gain for the sake of a more stable value of gain.

Negative feedback affects many amplifier properties other than gain stability. Negative feedback increases amplifier bandwidth, reduces most but not all forms of distortion, modifies amplifier input and output impedances, and can be beneficially employed in shaping frequency response characteristics. Examples of these features are given in the next section.

Negative feedback is not, however, a panacea. It can not turn a bad amplifier into a good one. It may make a good amplifier into a better one. It should always be remembered that the derivations and conclusions obtained above are based on linear or nearly linear oper-
ating conditions of the active devices. Negative feedback loops lose control under clipping conditions and recovery from such conditions may be poorer with negative feedback than without it.

20.2.3 Operational Amplifiers

Operational amplifiers derive the name as a result of their first employment in analog computing systems. In this role, with suitable feedback, they were employed to accomplish the mathematical operations of addition, subtraction, integration, and differentiation. In their current form of integrated circuits, operational amplifiers have become the fundamental building blocks of electronic analog circuits with notable uses in power supply regulation, voltage and current amplification, and active filters, as well as other forms of signal processors.

Operational amplifiers are dc-coupled voltage amplifiers possessing, under open loop conditions, very high gain, wide bandwidth, high input impedance, low output impedance, balanced or difference inputs accompanied usually by a single-ended output, and provisions for accomplishing a dc voltage balance at the output.

Fig. 20-11 displays the configurations commonly employed for operational amplifiers where signal inversion (polarity change) is required or desirable. In each instance the open loop transfer function, \( A \), is negative and real at low frequencies.

In Fig. 20-11A through 20-11D expressions are given for the respective closed loop transfer functions \( A' \). These expressions are valid without correction provided that the input impedance of the operational amplifier under open loop conditions is much larger than the impedances used in structuring the loop and that the output impedance of the operational amplifier is low.

![Operational Amplifiers Diagram](image-url)
under open loop conditions is much smaller than any of
the impedances used in structuring the loop. These
requirements are easily met in practice as input impe-
dances of commercial devices range upward from several
megohms while the output impedances range downward
from several tens of ohms throughout the audio
frequency range. The approximate values given for
\( V_o/V_i \) are valid if, in addition to the requirements stated
above, the magnitude of \( A \) is large throughout the
frequency range being employed. Fig. 20-11A is an
inverting voltage amplifier having an unbalanced input
as well as output. Fig. 20-11B is an inverting voltage
amplifier with a balanced input. Fig. 20-11C (unbal-
anced) and Fig. 20-11D (balanced) are examples of
more versatile configurations. The impedances \( Z_1 \) and
\( Z_2 \) can be any two terminal configurations of imped-
ance elements. These circuits find applications as low-pass
filters or integrators, high-pass filters or differentiators,
phase compensators, shelving filters, and tone controls
among a myriad of other possibilities. Fig. 20-11E is a
combining amplifier that combines or adds signals from
several sources with different weighting or gain factors
for each signal.

Fig. 20-12A is an example of a noninverting voltage
amplifier and Fig. 20-12B is a noninverting unity gain
voltage follower that is often employed as a buffer
because of its extremely high input impedance and
exceptionally low output impedance. In each instance
the open loop transfer function, \( A \), is positive and real at
low frequencies.

Most of the wideband low noise operational ampli-
fiers currently available for audio applications are inter-
nally structured so as to exhibit dominant pole
characteristics. This means that the open loop transfer
function of such an amplifier exhibits the behavior of a
single-pole amplifier over the frequency range for
which it is useful. Such an amplifier is easily employed
in the majority of feedback arrangements without fear
of violating the conditions necessary for stability. Fig.
20-13 is a Bode diagram typical of such amplifiers, both
when operated open loop as well as when operated with
a closed loop noninverting voltage gain of 20 dB.

An examination of Fig. 20-13 reveals that under open
loop conditions this amplifier exhibits a gain of 90 dB or
\( \sqrt{10} \times 10^4 \ V/V \) at dc with the gain being down by 3 dB
at a frequency of \( \sqrt{10} \times 10^7 \ Hz \) attended by a phase
shift of \(-45^\circ\). The bandwidth of this amplifier is then
\( \sqrt{10} \times 10^7 \ Hz \) and the product of the gain at dc with
the bandwidth or the gain bandwidth product is \( 10^7 \ Hz/V/V \).
The loop is closed in this example by requiring that \( R_2 \) in
Fig. 20-12A be nine times the value of \( R_1 \). The second
set of curves in Fig. 20-13 describe the performance
under this closed loop condition. The curves reveal that
the gain at dc is now 20 dB or 10 V/V and that the band-
width has now become \( 10^6 \ Hz \). The gain bandwidth
product is still \( 10^7 \ Hz/V/V \). The bandwidth has been
increased by exactly the same factor that the gain was
reduced. This behavior is characteristic of dominant pole
amplifiers. The application of feedback has yielded
another important benefit. The open loop amplifier not
only had a nonflat amplitude response throughout most
of the audio spectrum, it suffered from phase or group
delay distortion above a few hertz as well. The amplifier
with feedback has a linear phase behavior from dc to
beyond \( 10^4 \ Hz \) and hence does not introduce any group
delay distortion in this frequency range.

### 20.2.4 Active Filters Employing Operational
Amplifiers

Filter technology has a long time-honored history that
actually predated electronics by several decades. In fact,
if Lord Kelvin (William Thomson) had not discovered
the physical and mathematical properties of so-called
wave filters in the middle of the 1800s, submarine tele-
cable communications and later long distance
telephone communications would have been delayed
until well into the 20th century.

In spite of the voluminous literature and interest in
this subject, what will be touched on here are just a few
of the filter types that have proven to be of paramount

---

**Figure 20-12.** Noninverting voltage amplifiers.

\[
A = \frac{V_o}{V_i} = \frac{R_1 + R_2}{R_1 + R_2} + R_1
\]

\[
V_o = 1 + \frac{R_2}{R_1}
\]

\[
R_{in} = \infty \quad R_{out} = 0
\]

B. Noninverting unity gain voltage amplifier.
importance in modern audio applications and more particularly those that are readily implemented by means of active circuitry. Even though the emphasis will be on active circuitry, a cursory examination of some simple passive structures is of value.

Fig. 20-14 displays a few passive filter structures along with their associated transfer functions. Note that in each instance the filter transfer functions involve a polynomial with $S$ appearing in the denominator. The characteristics of the various filters are associated with the structure of these polynomials. With the possible exception of antialiasing use, the filters employed in audio work are restricted to pole orders of three or less in order to maintain good transient response. A pole order of three corresponds to an asymptotic slope rate of $-18$ dB per octave in the filter stop band. The most popular polynomials for audio applications are the Butterworth, with maximally flat amplitude response, and the Bessel, with linear phase response (maximally flat group delay). The Butterworth polynomials through third order are:

1. $S + \omega_0$
2. $S^2 + \sqrt{2}S\omega_0 + \omega_0^2$
3. $S^3 + 2S^2\omega_0 + 2S\omega_0^2 + \omega_0^3$

Figure 20-13. Bode diagram for a dominant pole amplifier.

Figure 20-14. Passive filter structures.
These are often written in a normalized form such as

1. \[
\frac{S}{\omega_0} + 1
\]

2. \[
\frac{S^2}{3\omega_0^2} + \frac{S}{\omega_0} + 1
\]

3. \[
\frac{S^3}{15\omega_0^3} + \frac{2S^2}{5\omega_0^2} + \frac{2S}{\omega_0} + 1
\]

In the Butterworth polynomials, \( \omega_0 = 2\pi f_0 \), where \( f_0 \) is the frequency at which the response is 3 dB down. The Butterworth polynomials yield excellent amplitude response characteristics while their phase and group delay characteristics are far from being ideal. Their use in constant resistance crossover networks is almost universal.

The Bessel polynomials in normalized form are

1. \[
\frac{S}{\omega_0} + 1
\]

2. \[
\frac{S^2}{3\omega_0^2} + \frac{S}{\omega_0} + 1
\]

3. \[
\frac{S^3}{15\omega_0^3} + \frac{2S^2}{5\omega_0^2} + \frac{2S}{\omega_0} + 1
\]

Here, \( \omega_0 \) has the significance that the group delay at zero frequency is just the reciprocal of \( \omega_0 \). The group delay for any filter at any frequency is given by the negative of the first derivative of phase response with respect to \( \omega \):

\[ t_g = -\frac{d\phi}{d\omega} \quad (20-12) \]

For a system not to introduce any phase distortion, it is necessary that \( \phi \) be either independent of frequency or of the form

\[ \phi = -k\omega + \text{constant} \quad (20-13) \]

In the first instance \( t_g = 0 \) and for Eq. 20-13 \( t_g = k \), where \( k \) is a constant. Bessel filters are nearly ideal in this respect as their group delays are constant or nearly so throughout their passbands. Unfortunately, the amplitude response of Bessel filters for orders higher than one, though without ripples, is not as flat as the corresponding Butterworth filter. The first-order Bessel and Butterworth filters are identical.

Operational amplifiers make significant contributions in the area of active filter implementation. The following examples, though by no means exhaustive, will serve as an introduction to this important subject.

The circuit of Fig. 20-15 simulates a physical inductor. A physical inductor at low frequencies, where interturn capacitance is not of importance, can be thought of as a pure resistance in series with a pure self-inductance. As such, a physical inductor has an impedance \( Z \) that has both a real and an imaginary part.

A physical inductor also has a quality factor or \( Q \). These properties are summarized by the following equations:

\[ Z = R + j\omega L \quad (20-14) \]

\[ Q = \frac{\omega L}{R} \quad (20-15) \]

Third-order or higher filters are readily obtained by cascading two or more sections of the examples displayed in Fig. 20-16. The transfer functions of the various filters appear in Table 20-1.

This discussion of active filters employing operational amplifiers will now be concluded by exploring two design examples.

**Example 1.** Third-order Butterworth low pass with a corner frequency \( f_0 \) of 500 Hz and unity gain.

This filter can be implemented by cascading a first-order section followed by a second-order section. The required overall transfer function is

\[ \frac{V_0}{V_{in}} = \frac{\omega_0}{S + \omega_0} \times \frac{\omega_0^2}{S^2 + S\omega_0 + \omega_0^2} \quad (20-16) \]

Taking Fig. 20-16A for the first-order section along with its transfer function leads to the identification
By choosing for \( C \) a value of 0.02 \( \mu F \), Eq. 20-18 yields a value for \( R \) of 15.9 k\( \Omega \).
\[
\frac{1}{\sqrt{R_1R_2C_1C_2}} = \left(\frac{R_1C_2 + R_2C_2}{R_1R_2C_1C_2}\right) 
\text{(20-20)}
\]

Upon choosing \(R_1 = R_2\), Eq. 20-20 dictates that \(C_1 = 4C_2\). If \(C_1\) is chosen to be 0.02 \(\mu\)F, then \(C_2\) becomes 0.005 \(\mu\)F and Eq. 20-19 then requires that \(R_1\) be 10 k\(\Omega\). The reasonableness of these values allows the design to be concluded with the circuit of Fig. 20-17.

![Figure 20-17. Third-octave unity gain Butterworth low-pass filter with \(f_0 = 500\) Hz.](image)

**Example 2.** Second-order Bessel low pass with a zero frequency group delay of 500 \(\mu\)s.

The required transfer function is

\[
\frac{V_o}{V_i} = \frac{3\omega_0^2}{S^2 + 3\omega_0S + 3\omega_0^2} \quad \text{(20-21)}
\]

with \(\omega_0 = 1/500\) \(\mu\)s. Taking Fig. 20-16C along with its transfer function leads to the identification

\[
\frac{3\omega_0^2}{S^2 + 3\omega_0S + 3\omega_0^2} = \frac{1}{R_1R_2C_1C_2} \quad \text{(20-22)}
\]

\[
\frac{1}{S^2 + \left(\frac{R_1C_2 + R_2C_2}{R_1R_2C_1C_2}\right)S + \frac{1}{R_1R_2C_1C_2}}
\]

from which it is found that

\[
\omega_0 = \frac{1}{\sqrt{3R_1R_2C_1C_2}} \quad \text{(20-23)}
\]

and

\[
\frac{3}{\sqrt{3R_1R_2C_1C_2}} = \frac{R_1C_2 + R_2C_2}{R_1R_2C_1C_2} \quad \text{(20-24)}
\]

Upon choosing \(R_1 = R_2\), Eq. 20-24 requires that

\[
\frac{V_o}{V_i} = \frac{K}{S^2 + \left(\frac{\omega_0^2}{Q}\right)S + \omega_0^2}
\]

\[
20-16A = 1 \quad \frac{V_o}{V_i} = \frac{1}{RC} \quad \text{S} + \frac{1}{RC}
\]

\[
20-16B = 1 \quad \frac{V_o}{V_i} = \frac{S}{S + \frac{1}{RC}}
\]

\[
20-16C = 1 \quad \frac{V_o}{V_i} = \frac{R_1R_2C_1C_2}{S^2 + \left(\frac{R_1C_2 + R_2C_2}{R_1R_2C_1C_2}\right)S + \frac{1}{R_1R_2C_1C_2}}
\]

\[
20-16D = 1 \quad \frac{V_o}{V_i} = \frac{S^2 + \left(\frac{R_1C_2 + R_2C_2}{R_1R_2C_1C_2}\right)S^2 + \frac{1}{R_1R_2C_1C_2}}
\]

\[
20-16E = 1 \quad \frac{V_o}{V_i} = \frac{\left(1 + \frac{1}{R_1R_2C_1C_2}\right)}{S^2 + \left(\frac{R_1C_2 + R_2C_2}{R_1R_2C_1C_2}\right)S + \frac{1}{R_1R_2C_1C_2}}
\]

\[
20-16F = 1 \quad \frac{V_o}{V_i} = \frac{K(1/R_C)}{S^2 + \left(\frac{\omega_0^2}{Q}\right)S + \omega_0^2}
\]

</table>
Substitution into Eq. 20-23 while invoking the necessary value of $Z_0$ leads to

$$20-26$$

If $C_2$ is taken to be $0.05 \mu F$, then Eq. 20-26 requires $R_1$ and hence $R_2$ to be 5 k\ohm. Eq. 20-25 would then require

$$20-16G$$

which is quite close to a readily available value of 0.068 \mu F. These are all reasonable values; hence, the example concludes with the circuit of Fig. 20-18.

In fairness it is necessary to state that the solutions given to the two examples are not unique. In fact, even more elegant solutions than the ones given are possible though not as straightforward. These more elegant solutions will no doubt occur to the reader after further study.

### 20.3 Power Amplifiers

Power amplifiers for professional applications, unlike those intended for home entertainment use, must usually be capable of providing a multiplicity of voltage values at their output terminals. Furthermore, for reasons of safety and in order to avoid inadvertent mishaps in wiring or handling, it is often required that neither side of the output distribution lines be referenced to ground except in a balanced way through a high impedance in order to provide a static discharge path. These requirements are usually met by feeding the distribution lines from an isolated transformer secondary even though the transformer itself presents a source of distortion and bandwidth limitation.

Power amplifiers, when operated within their inherent limitations, are essentially constant-voltage sources. The sinusoidal rms voltage at the output terminals at rated power that is required in professional applications is commonly in voice coil values of 25 V, 70.7 V, or, in recent times, 200 V. The loudspeakers or other loads are, in the case of 25, 70.7, or 200 V lines, fed from the secondary of a stepdown transformer which has several primary taps for determining the actual average sinusoidal power supplied to an individual device. When feeding several devices from a common constant voltage distribution line it is only necessary to insure that the sum of the power taps to the individual devices does not exceed the output capability of the driving amplifier. High values, such as 70.7 V or 200 V, for the constant-voltage distribution system will minimize the $I^2R$ loss in the distribution lines themselves (see Chapter 14). It is an absolute necessity, however, that the transformer at the amplifier, when such is employed, and the step-down transformers
at the individual load devices be of high quality. Poor quality transformers with either high insertion losses and/or poor impedance characteristics will completely defeat the advantages offered by the constant-voltage distribution technique.

Many of the present-day power amplifiers intended for professional use are produced in two-channel versions even when the ultimate employment is to be with monaural program material. When preceded by active or passive crossover networks, such amplifiers can provide biamplification by devoting each amplifier channel to a separate part of the audio spectrum. This technique when properly employed may offer level adjustment, distortion, and loudspeaker damping advantages over the full-spectrum approach employing an individual amplifying channel. Additionally, such amplifiers may be employed with a balanced bridge output driven by both channels, which doubles the output voltage swing but requires a load impedance that is twice as large as a single channel alone. This technique can drive a 70.7 or even higher voltage balanced distribution line without a transformer at the amplifier but the ground isolation previously mentioned is lost in the process. This may furnish the user with a difficult choice.

Audio power amplifiers are designed in reverse, which means that the output stage is designed first followed by the design of the output driver stage that, in turn, is followed by the required intermediate stage or stages and then finally the input stage. Depending on the power, distortion, and efficiency requirements the class of operation of the output device or devices has traditionally been restricted to A, AB, B, or D. The most recent developments have widened the choice somewhat in that some current designs involve changing the supply voltage to the output stage under dynamic conditions. It appears that one may look forward to an entire alphabet of classes of operation. When a single device is employed in the output stage, class A operation, in which current exists in the active device throughout a complete cycle of signal swing, is the only acceptable class of operation. Class A is inherently the most linear class of operation. If pairs of output devices are employed in push-pull in the output stage, then classes A, B, AB, and AB plus B (at least two pair of devices) are distinct possibilities. Other than A, the other classes are in general more efficient but inherently are not as linear as class A. In class B operation each member of a push-pull pair is active over only one-half of a complete sinusoidal signal cycle. Class AB is intermediate in this regard between A and B. In AB plus B a pair of devices operates push-pull in class AB while a second pair of devices in push-pull operates nearly in class B. Class D is the designation given to the mode of operation wherein the output devices are operated in a switching mode. This means that the output devices are conducting as heavily as possible or not at all. This mode of operation offers efficiencies bordering on 90% but introduces a host of other problems with regard to radio-frequency interference as well as requiring specialized active devices, drive circuitry, and design techniques.

The advent of bipolar complementary symmetry transistors introduced the possibilities of many new circuit topologies in power amplifier design and the development of complementary symmetry power field effect transistors has opened up even more exciting avenues for truly superb amplifier developments.

Fig. 20-19 is a rather basic complementary symmetry bipolar transistor output stage for operation in classes A, AB, and B. The class of operation is dictated by the details of the biasing and drive arrangements.

The currents in $Q_1$ and $Q_2$ are equal at quiescence and there is no current in the load. If the bases of $Q_1$ and $Q_2$ are driven with a positive-going signal, $Q_1$ conducts more heavily while the current in $Q_2$ decreases, thus producing a net current in the load directed from left to right such that the left end of the load assumes a positive voltage relative to ground. On the other hand, if the bases of $Q_1$ and $Q_2$ are driven with a negative-going signal, $Q_1$ conducts less heavily while $Q_2$ conducts more, thus producing a net current in the load directed from right to left such that the left end of the load assumes a negative voltage relative to ground. The load in effect is connected in the emitter circuits of both transistors that consequently operate as common collector transistors. As is well known, the voltage gain of a common collector amplifier is slightly less than one and without polarity inversion. Hence, the driving circuitry must be able to produce a signal swing in excess of the swing to be expected across the load.
Fig. 20-20 represents a circuit configuration that is superficially similar to Fig. 20-19 but is drastically different in its operation. The currents in $Q_1$ and $Q_2$ are again equal at quiescence and there is no current in the load. When the bases of $Q_1$ and $Q_2$ are driven with a positive-going signal, $Q_1$ conducts more heavily while $Q_2$ conducts less, thus producing a net current in the load directed from left to right such that the right end of the load assumes a negative voltage relative to ground. On the other hand, if the bases of $Q_1$ and $Q_2$ are driven with a negative-going signal, $Q_1$ conducts less heavily while $Q_2$ conducts more, thus producing a net current in the load directed from right to left such that the left end of the load assumes a positive voltage relative to ground. The load now in contrast to Fig. 20-19 has been shifted from the transistor emitters to the transistor collectors.

Instead of dealing with a common collector stage as in Fig. 20-19 the circuit of Fig. 20-20 is that of a common emitter amplifier. That is, the load is really in the collector circuits of the transistors. Such a stage produces an output signal swing that is inverted in polarity and possibly of much larger amplitude than the input signal swing. The drive requirements of such a stage are greatly relaxed as compared with those of the circuit of Fig. 20-19. In fact, if power field-effect transistors (FET) are employed where it is desirable to use only a single type of power transistor. This configuration must be driven by a circuit that furnishes two drive signals of opposite polarity. Resistors $R_1$ and $R_2$ are typically a few hundred ohms while the resistors $R_3$ and $R_4$ are of the order of 1 Ω. At quiescence neither $Q_3$ or $Q_4$ is conducting and the emitter currents of $Q_1$ and $Q_2$ are equal in the range of 50–100 mA and there is no current in the load. If the base of $Q_1$ is driven with a positive-going signal while that of $Q_2$ is driven with a negative-going signal, the emitter current of $Q_1$ will increase while that of $Q_2$ will decrease and there will exist a net current in the load directed from left to right such that the left end of the load will assume a positive voltage relative to ground. In the first instance, the current supplied to the load by $Q_1$ was forced to pass through $R_3$ and in the second instance, the current supplied by $Q_2$ is forced to pass through $R_4$. Under small or moderate signal swings the voltage drops across $R_3$ or $R_4$ are not sufficiently large to forward bias either $Q_3$ or $Q_4$. When larger voltage swings are occurring, $Q_3$ and $Q_4$ will be brought into conduction on alternate halves of the cycle and thus will aid in supplying load current. The circuit does possess a basic asymmetry in that even though $Q_1$ (and $Q_3$ when it conducts) are operated as common collector amplifiers, transistors $Q_2$ (and $Q_4$ when it conducts) are operated as common emitter amplifiers.
Fig. 20-22 is a complete though modest amplifier. \(Q_1\) and \(Q_2\) are complementary symmetry monolithic darlington power transistors. \(Q_3\) is employed to adjust the forward bias on the output stage. \(Q_4\) is a constant current source that insures that \(Q_2\) receives adequate voltage drive under large signal conditions. Most of the open loop voltage gain is provided by \(Q_5\) while \(C_1\), determines the dominant pole, which was discussed in connection with operational amplifiers. \(R_{12}\) and \(Z_1\) determine the total current in the matched differential pair \(Q_6\). The ac voltage gain of the amplifier is set by \(R_9\) and \(R_{10}\) which determine the feedback fraction above a frequency of a few hertz. There is complete negative feedback at dc as brought about by the presence of \(C_2\) in series with \(R_{10}\). This in collaboration with \(Q_6\) insures that the output voltage of the amplifier is zero when no signal is applied at the input. By monitoring the current in \(R_1\) and \(R_2\), it is possible to provide protection against load short circuits by means of a relatively simple additional circuit. If \(C_2\), \(R_{10}\), and \(R_9\), were removed from the circuit of Fig. 20-22 altogether and further if the right-hand base of \(Q_6\) were connected through a resistor equal to \(R_{14}\), the resulting circuit would be a power operational amplifier built from discrete components. The present input would become the noninverting input while the right-hand base of \(Q_6\) would be the inverting input.

![Figure 20-22. Complete power amplifier.](image)

### 20.3.1 Protection Mechanisms

Power amplifier protection mechanisms fall roughly into two categories, the protection of the amplifier against faults in the load and protection of the load against faults in the amplifier. The amplifier designer must, unfortunately, shoulder the burdens of both categories. The load must be protected against turn-on and turn-off transients, against dc appearing at the amplifier output terminals unless that is the intended purpose of the amplifier, and against unwarranted oscillation in the amplifier caused by the load if the load itself presents a reasonable impedance to the amplifier. The amplifier must be protected against short-circuited or very low-impedance loads, excessive temperature within the amplifier, wide variations in ambient temperature, radio-frequency signals induced in the loudspeaker lines, radio-frequency signals induced in the input signal lines, dc on the input signal lines if such is not the intended use, and other types of reasonable abuse. All of the items above can be dealt with in practice but to do so involves an enormous additional expense in design, manufacture, and maintenance. Inferior as well as less costly products treat these features minimally if at all.

The most common of all load protection schemes is a fuse in series with the load. It may be a single fuse, fusing the overall system, or in a case of a multiway loudspeaker system, it may be one fuse on each loudspeaker.

Fuses help to prevent damage due to prolonged overload but provide essentially no protection against damage that may be done by large transients and such. To minimize this problem, high-speed instrument fuses such as the Littelfuse 361000 series should be used. Fig. 20-23 shows the fuse size versus loudspeaker power and impedance ratings.

![Figure 20-23. Fuse selector nomograph for loudspeaker protection. Courtesy Crown.](image)
of hard relay contacts energized by suitable circuitry. Upon turn-on these contacts are open and are subsequently closed by means of a delay circuit that allows the amplifier to stabilize before the load is connected. These same contacts open immediately upon amplifier turn-off. An additional signal is supplied to this muting circuitry by means of a low-pass filter connected to the amplifier’s final stage. If dc is sensed at this point in excess of a safe value, the circuit acts to disconnect the load from the amplifier.

The amplifier can be protected against dc at its input when such is not intended by either transformer or capacitor high-pass filters. It may further be protected against radio-frequency signals at the input or output lines by means of series-connected low-pass filters. These filters must be designed with care so as to not unnecessarily restrict the intended amplifier passband. Excessive heat sink temperature is sensed by an attached thermal sensor that controls internal cooling fans or may ultimately interrupt power to the output stage. Thermally sensitive bias tracking circuitry can be provided to insure appropriate bias conditions for the output over a reasonable range of ambient temperature. Short-circuit protection usually involves monitoring the currents in the output devices and restricting the drive applied to the output stage whenever excessive current is detected with long-term protection still being provided by the thermal mechanisms previously mentioned. Such a circuit suitable for the amplifier of Fig. 20-22 is given in Fig. 20-24. Resistors $R_{15}$ and $R_{16}$ form a voltage divider sensing the emitter currents of the output devices. In the event of excessive emitter current, $Q_7$ robs base drive from $Q_1$ while $Q_8$ robs base drive from $Q_2$. Diodes $D_3$ and $D_4$ prevent $Q_7$ and $Q_8$ from having their collector to base junctions forward biased under conditions of normal operation. This same circuit can readily be converted into a dissipation limiter rather than just a current limiter by referencing the junction of the $R_{16}$ resistors to ground rather than to the amplifier output terminal.

The amplifier depicted in Fig. 20-25 has an interesting protection mechanism that provides automatic turn-on muting along with protection of the output stage.

The output stage of this amplifier consists of complimentary MOSFETs connected in the common source configuration that yields voltage gain and signal polarity inversion in the output stage. When the amplifier is first energized any incoming signal is muted by the JFET $T_1$ which provides a low resistance to ground. As the capacitor connected to the gate of $T_1$ gradually charges toward $-15$ V this condition is relaxed and the amplifier becomes operative. During normal operation the currents in the output transistors $T_2$ and $T_3$ are monitored at points A and B. An excessive current in either device will trigger $Q_2$ which is a voltage discriminator or Schmitt trigger circuit. The amplifier will then be muted for a time determined by the $RC$ combination in the gate circuit of $T_1$.

### 20.3.2 High-Power Amplifiers

The demands of the sound reproduction and reinforcement industry for both higher power and higher performance amplifiers have brought about the necessity for a paradigm shift in power amplifier design. The older time-honored linear designs employing push-pull output
stages in classes A, AB, or AB + B have poor output power efficiencies and/or appreciable internal power dissipation at quiescence. Class A dissipates its rated power internally at quiescence and only approaches a power efficiency of 50% when delivering its full output power. A pure class B stage would have zero internal quiescent power dissipation and a power efficiency approaching 78.5% only at full output while being plagued with unacceptable crossover distortion. Class AB solves the crossover distortion problem while introducing some internal quiescent power dissipation along with a smaller output power efficiency than pure class B. Class AB + B retains the low quiescent power dissipation of class AB and approaches the power efficiency of pure class B when operated at full output. Such amplifiers most often employ conventional power supplies consisting of a power transformer whose primary is energized from the ac mains and whose secondary is applied to a full wave bridge rectifier connected to a capacitor input filter. This arrangement can also yield bipolar dc supplies when the secondary of the transformer is center tapped and two capacitor filters are employed. Large values of capacitance must be employed, as the fundamental ripple frequency is 120 Hz. Such supplies inherently suffer from poor voltage regulation and demand excessive root mean square (rms) current draw from the ac mains as their power factors fall in the range of about 0.6 to 0.7. These power amplifiers most often employ complementary symmetry bipolar junction transistors and ordinarily have power limitations that are dictated by the voltage breakdown properties of the active devices when conventionally employed. Some clever schemes for surmounting this limitation will be discussed subsequently. The linear power amplifier designs discussed above might well be referred to as being analog high-power amplifiers.

The paradigm shift necessary to achieve even higher output power and performance has affected the design philosophy of both the amplifier power supply as well as that of the power amplifier itself. Rather than employing continuous or analog techniques, the really high-power units now employ switching techniques in both the power supply and in the amplifier circuitry. The concept of having a pair of output devices, one positive and one negative, each alternately being either full on or full off, is not new. Audio power amplifiers employing solid-state active elements operated under what is termed class D have been around since about 1970. The less than spectacular performance of the early efforts was not a result of the failure in operating principle but rather the result of the shortcomings of the available active elements involved. These shortcomings have been diminished in modern power MOSFETs and IGBTs to the point that switching amplifiers are not only viable but also desirable in high-power applications. Additionally, switching topologies exceeding the properties of the classic class D have also been evolved. These will be discussed in a subsequent section.

Class D switching amplifiers have the desirable property that the output efficiency can approach 100% independent of the operating power level. This results because the active output devices ideally are either fully conducting or fully not conducting—i.e., they act as switches. This is best explained by reference to Fig. 20-26, which is a functional diagram of a class D amplifier, and Fig. 20-27, which displays pulse width modulation waveforms.

![Functional diagram of a class D amplifier.](image1)

In Fig. 20-26, the continuously running oscillator operates at a fixed amplitude and with a fixed frequency usually between 200 kHz and 500 kHz. The shaper converts this signal into a triangular waveform at the same fundamental frequency and supplies the resulting waveform as one input to the comparator. The other input to the comparator is the summing node of the
audio input signal and the feedback signal, which in the language of operational amplifiers means it is the error signal. For proper operation, the peak-to-peak value of the error signal must always be less than the peak-to-peak value of the triangular waveform at the other comparator input. This combination of the oscillator, shaper, and comparator forms a pulse-width modulator. Although the output of the comparator swings alternately positive and negative, the time spent in these excursions is in general different. The output pulse width of the modulator is proportional to the error signal. This results from the fact that the peak-to-peak value of the error signal is less than the peak-to-peak value of the triangular waveform and that the polarity from the comparator reverses depending on whether the instantaneous value of the error signal is greater or less than the instantaneous value of the triangular waveform. In the variable duty cycle, positive and negative pulses from the modulator toggle the active output devices depicted as switches either full-on or full-off. Thus, constant positive or negative voltage pulses are applied to the low-pass filter and load for variable intervals of time. The low-pass filter passes the time average value of these pulses in the audio band, producing a voltage across the load proportional to the instantaneous value of the original incoming audio signal. The high efficiency stems from the fact that there is no power dissipated in an output device when it is nonconducting and very little power dissipated when it is conducting in saturation, or fully on, as even though the current through the device is large, the voltage drop across the device is very small. Unfortunately, the output devices are highly specialized in that they must exhibit very fast switching times with the absence of charge storage effects. This alone pretty well rules out bipolar power transistors capable of handling the large currents and sustaining the high voltages involved. Vertically structured MOSFETs are usually employed as the switching elements in this basic simple design. Two other drawbacks to this simple class D structure are the possibility of radio-frequency generation and the difficulty of optimizing the low-pass filter for use with more than one value of load resistance. Loudspeakers are hardly constant impedance devices, much less constant resistance devices. The most recent designs in switching amplifiers have addressed these problems.

### 20.3.3 High-Power Analog Amplifiers

Crown International, principally through the work of Gerald Stanley, is responsible for a continuing series of technical innovations in high-power analog amplifiers involving class AB + B that was first introduced by Crown. Though not changing the basic efficiency of this configuration, the innovations have led to high-powered designs up to several thousands of watts in individual units. The innovations involve output stage topology, amplifier cooling, and power transistor safe operating area assessment as well as control. At the heart of these innovations is an output stage topology that is a full bridge configuration with one output terminal always at ground potential. A simplified view of this configuration is given in Fig. 20-28.

![Figure 20-28. Crown-grounded full bridge topology.](image)

In Fig. 20-28 the transistors at points 1, 2, 3, and 4 represent composites of several NPN and PNP bipolar power transistors constituting AB + B arms of the bridge. The NPN transistors at 1 are the positive voltage output stage while the PNP transistors at 4 are the complementary negative output voltage stage. The NPN transistors at 2 are the positive bridge balance output stage and the PNP transistors at 3 are the complementary negative bridge balance output stage. When a positive output is required, the transistors at 1 conduct connecting the left end of the load to the positive terminal of the supply and the transistors at 3 conduct connecting the negative terminal of the supply to ground. When a negative output is required, the transistors at 2 conduct connecting the positive terminal of the supply to ground and the transistors at 4 conduct connecting the left end of the load to the negative terminal of the supply. The control, bias, and driving circuitry must ensure that at quiescence there is no voltage drop across the load and, when delivering a signal, that the voltage division is correct across the diagonally opposite pairs of transistors that are driven toward non conduction. This arrangement offers two very distinct advantages as compared with a conventional complementary symmetry output stage: it requires only a single power supply voltage \( V_S \) to produce a peak-to-peak voltage swing across the load equal to \( 2V_S \) and it simultaneously halves the sustaining voltage requirements of the output devices.
The composite transistors at 1 and 2 are mounted directly without electrical insulators in order to ensure good thermal contact to one heat sink that itself is electrically insulated. The composite transistors 3 and 4 are mounted directly to a second electrically insulated heat sink. The heat sinks themselves, rather than the usual heavy metal extrusions, involve many thin metal fins such as those employed in refrigeration and air conditioning technology or automobile radiators. This greatly increases the surface area exposed to a forced air stream for cooling purposes and allows the power devices to operate with lower junction temperatures than would otherwise be the case.

The final contributor to high-power operation of this circuitry involves what amounts to a small, dedicated analog computer that emulates the operation of the output stage consistent with the operating conditions that exist in the amplifier in real time. This allows the output stage control circuitry to restrict the drive to the output such that the output devices remain always in what is the safe operating area of the moment.

Another approach to high-power operation, which also offers an efficiency advantage over class AB while basically employing AB circuitry, involves changing the supply voltage from a nominal value to a higher value when larger output swings are called for. This can be accomplished with a fixed output stage configuration powered by a variable switching power supply, by switching the supply voltage from a fixed nominal value and a fixed higher value, or by using two sets of output devices with one set powered by a nominal voltage supply and the other set powered by a higher voltage supply and switching between the sets of output devices. This last method of operation is termed class G. QSC Audio was the first manufacturer to introduce such an amplifier for employment in the sound reinforcement industry. This design can still fall in the analog category as the switching between the sets of output devices is purely accomplished by analog techniques as devised by Pat Quilter of QSC. Fig. 20-29 is a simplified schematic of the positive half of a complementary-symmetry class G output stage that illustrates the principal of operation.

For small-amplitude drive signals, the emitter follower in the lower part of Fig. 20-29 is powered by the supply with voltage $V$ and operates as a normal AB stage consistent with this value of the supply voltage. The upper transistor is not forward biased and is not conducting so the supply with 2$V$ plays no role. For large amplitudes of the drive signal, when the value of the drive signal approaches $V$, the lower transistor approaches saturation and sufficient forward bias is applied to the upper transistor to bring it into conduction, thus bringing into play the supply of voltage 2$V$. For even greater values of drive voltage, the supply of voltage $V$ is disconnected by the diode on the right because this diode is now reverse biased and the lower transistor is in full saturation. Under this condition, the upper transistor is operating as an emitter follower with a supply of voltage 2$V$. The operation of the negative half of the output stage is the same except all polarities are reversed.

A further step in this same direction also employed by QSC as well as other manufacturers is that of the class H topology for the power stage. Instead of two sets of devices permanently connected to two different voltage supplies on the positive half as well as the complementary negative half of the output stage, class H employs a single set of devices on the positive half and a complementary set on the negative half. The supply voltages to these devices are switched to different values according to the requirements of the audio signal at the moment. Such an arrangement is illustrated in Fig. 20-30.

In Fig. 20-30 the positive and negative class H output stages usually consist of paralleled bipolar power transistors and an associated driver with the negative half being complementary with the positive half. The class of operation of each half is basically that of class B except for the very lowest signal levels. Efficiency is improved by maintaining as low as possible voltage drop across the active devices when they are delivering current to the load. Consider for the moment that the output signal is swinging positive and its instantaneous value is approaching the fixed value of +$V$. Switch $S^+$ is a voltage comparator-operated switch. This switch is closed when the output signal exceeds a fixed positive reference voltage whose value is chosen so that the stage never goes into saturation. With $S^+$ closed, the output signal can now increase if required up to slightly less than the rail limit of +2$V$ whereas the voltage across the active transistors themselves is always less than +$V$. 

![Figure 20-29. Simplified positive half of a class G output stage.](image-url)
The operation of the negative half mirrors that of the positive half for negative swings of the output signal. One is not restricted to the employment of just four voltage supply values consisting of two positive and two negative. One might in fact employ three or more on each side by increasing the number of fixed voltage taps on the power supply, adding more comparator-operated switches, and reverse-biased diodes as appropriate for each switch. In this fashion, the voltage supply of the moment more accurately tracks the instantaneous requirements of the signal and the dissipation in the active output devices is kept near a minimum.

### 20.3.4 Switch Mode Power Supplies

Switching power supplies are now employed in practically all high-power audio amplifiers be they of the analog type of classes AB + B, G, and H or of the various manifestations of switching amplifier stemming from class D. A variety of considerations have compelled this change from former practice. When the power requirements are large, a switching power supply offers significant size and weight advantage over a conventional supply employing an ac-main-operated power transformer, full-wave bridge rectifier, and capacitor filter bank. More importantly, a switching power supply offers the advantage of active power factor correction. This latter feature is crucial for obtaining the maximum power from a single 120 Vac outlet having limited current capability. Additionally, most switching supplies feature a convenient selection feature that allows operation from either 120 V or 240 V mains. In fact, the more advanced designs of switching supplies can operate over an ac voltage range of 90 V to 270 V rms without any internal circuit changes.

These desirable features of switching power supplies come with a price in that the design of such units is highly specialized and much more engineering effort must be expended in yielding a viable unit. High-power units require auxiliary supplies for the control circuitry that must be fully active during main supply startup as well as normal operation. The fundamental switching frequencies fall in the range of 30 kHz to 100 kHz with the switching pulses being pulse width modulated. As a result, harmonics are generated in the radio-frequency range. This property necessitates the incorporation of a sophisticated electromagnetic interference (EMI) filter to prevent the appearance of the switching frequency and its harmonics as common-mode signals on the ac supply lines. Fig. 20-31 is a block diagram of a typical switch-mode power supply for use with high-power audio amplifiers.

The EMI filter must be designed to prevent common-mode signals that are generated in the power supply from being conducted to the external supply mains while at the same time offering minimum series impedance to the differential 60 Hz ac voltage of the supply mains. This is accomplished by having balanced inductors in each of the supply lines with positive mutual inductance between the inductors in upper and lower lines. This arrangement maximizes the inductance for common-mode currents that flow in the same direction in both conductors. For the oppositely directed differential currents of the 60 Hz main supply, the mutual inductance is negative, thus forcing the overall series inductance to a small value. A typical EMI filter circuit is shown in Fig. 20-32.

The line operated rectifier and capacitor filter immediately follows the EMI filter. Such an arrangement appears in Fig. 20-33.

The circuit of Fig. 20-33 features an inrush current limiter in the form of a thermistor that presents a large
resistance when cold and a decreasing resistance as the device heats up from the passage of current. This behavior limits the peak current drawn from the line when the circuit is first energized from a cold start. After the capacitor bank is fully charged the thermistor is shorted out by a relay-controlled switch as part of the start-up protocol of the dc-to-dc converter. With the link connected as shown, the storage capacitors act as voltage doublers. When the Hi side of the line is positive, diode A charges the upper capacitor with the indicated polarity. When the Hi side of the line goes negative one-half cycle later, diode B charges the lower capacitor with the indicated polarity. Voltage doubling occurs because the two capacitors are permanently connected in series. For a 240 V supply line, the link is moved to the 240 V position and the circuit is then that of a normal full-wave bridge rectifier having an effective capacitance of 0.5C. The nominal total dc output voltage is the same in either case.

The core of any switch-mode power supply is the dc-to-dc converter. Switch-mode supplies that are called on to deliver significant power usually employ either a half-bridge or full-bridge converter with the full-bridge converter being favored for employment in the supplies of the most powerful audio amplifiers that make use of full switching technology in their design. A greatly simplified diagram for such a full-bridge converter is exhibited as Fig. 20-34 from which the basic operation may readily be understood.

In Fig. 20-34 the switches S1 through S4 represent either insulated gate bipolar power transistors or N-channel power MOSFETs. On the first half of the switching cycle, switches S1 and S3 are closed in concert and connect the primary of the transformer across the bulk dc supply so that current flows in the primary from left to right for some variable period of time. On the second half of the switching cycle with S1 and S3 now open, switches S2 and S4 are closed in concert and connect the primary of the transformer across the dc bulk supply so that current flows in the primary from right to left again for some variable period of time. The switches are activated by the control circuitry and by varying the duty cycle of the switches it is possible to maintain the level of the rail voltages in spite of varying rail loads and variations in bulk dc supply values. The secondary of the transformer is center tapped and feeds a full-wave bridge rectifier and a capacitor filter for each rail. The capacitance values required here are modest as compared with those in the bulk supply as the ripple frequency is twice the switching frequency and can range from about 60 kHZ to 200 kHz. The RC network in parallel with the transformer primary is a snubber network that in conjunction with the diodes in parallel with the switches allows switching transients to be damped while returning energy to the bulk supply.

**20.3.5 Technological Innovation**

The most recent high-power analog amplifier design is based on a patented design that introduces a new class of operation. This design is based on an innovation that
truly represents the expression, “thinking outside of the box.”

The innovation put forth by the Swedish firm Lab.gruppen has resulted in the class TD, which is a tracking class D amplifier. The objective was to produce a very powerful audio power amplifier in which the entire signal path is that of an analog-type amplifier. This is accomplished by feeding the original audio signal to both an analog amplifier as well as a classic class D amplifier in parallel. The class D amplifier is structured in the form of a half-bridge as depicted in Fig. 20-26 except that instead of having a loudspeaker as the load on this amplifier, it is the output stage of the analog amplifier that serves as the load of the class D amplifier. The effect of this arrangement is to produce a class AB + B amplifier that has continuously varying positive and negative rail supplies that track the needs of the audio signal of the moment. The output stage of the analog amplifier operates with high efficiency as the voltage across the output devices at any instant exceeds the amplifier output voltage only by the amount necessary to insure active operation of the devices. This topology is illustrated in simplified form in Fig. 20-35. The overall system is powered by a switch-mode power supply. This design is said to retain the distortion and noise characteristics of an analog amplifier while closely approaching the output efficiency of a class D amplifier.

In Fig. 20-35 $T_1$ and $T_4$ represent several parallel N-channel power MOSFETs that represent the switching elements of a class D amplifier each with an associated low-pass filter typical of class D operation. Sandwiched in between these two parts of the half-bridge are the output devices of the analog amplifier that constitute the load for the class D amplifier. $T_2$ and $T_3$ represent several parallel complementary NPN and PNP bipolar power transistors connected as emitter followers that directly drive the loudspeaker load.

### 20.3.6 Class D in Full Bloom

Instead of trying to skirt the problems associated with class D, Gerald Stanley and his design group at Crown Audio, Inc. have faced them head-on and over a period of time have evolved wide-ranging innovative solutions from the ac power cord to the amplifier output terminals.

The innovations begin in the switch-mode power supply that can operate, without any necessity for internal changes, from line sources ranging from 85 Vac to 277 Vac 50–60 Hz. Full power is obtained for supply voltages ranging from 120 Vac to 240 Vac. The bulk dc supply is a full-wave bridge rectifier and capacitor filter combination. This is followed by a unique dc-to-dc converter consisting of two half-bridges that are operated in a novel way in that the high-frequency switching signals to the two halves of the converter are phase shift modulated. This mode of operation impresses across the primary of the high-frequency step-up transformer an alternating square wave voltage whose duty cycle can be varied from zero to 50%. The rail voltages are derived through full wave rectification and filtering of the secondary high-frequency voltage from the step-up transformer. The positive and negative rail voltages can range from zero to some maximum value as the duty cycle of the primary square wave ranges from zero to 50%. A control loop constantly compares the rail voltage and current with reference values and adjusts the duty cycle in such a fashion that voltage regulation of the rail supply output is maintained for both changes in load as well as raw supply and all the while maintaining an overall power factor close to 0.95. Protection mechanisms are included to handle internal amplifier or overload problems.

The output stage is a far cry from the classic class D design as it employs an innovative topology as well as an advanced form of pulse width modulation. The output stage topology is termed BCA, standing for balanced current amplifier. Fig. 20-36 is a bare bones illustration of the BCA output stage.
In Fig. 20-36 the batteries represent the positive and negative rail supplies, $S_p$ and $S_n$, represent two groups of several paralleled N channel power MOSFETs that serve to connect to the positive and negative rail supplies, respectively, and there are two matched inductors as well as two matched diodes. An understanding of the operation of this output stage and its associated modulation technique may be had by examining three conditions or modes of employment: quiescent mode when no audio output is called for, positive mode when a positive-going audio output is required, and negative mode when a negative-going audio output is required. Recall that one component signal of a pulse width or switching modulator is a triangular waveform. The fundamental frequency of the triangular waveform employed in the associated modulator for this output stage is 250 kHz so the full period is 4 microseconds (4 $\mu$s) and the half period is 2 microseconds (2 $\mu$s). In the quiescent mode when no audio output is required the switches $S_p$ and $S_n$ are closed and opened in concert. Both switches are closed for the first half-period or 2 $\mu$s and both are open for the second half-period also of 2 $\mu$s. The inductors in Fig. 20-36 have relatively large self-inductance and quite small resistance such that their time constants, being the ratio of $L/R$, are very much larger than 2 $\mu$s so that the current in each inductor starts from zero and grows linearly in the clockwise sense around the closed loop at the rate of $V_{CC}/L$ when the switches are simultaneously closed. There is no current in the diodes as they are reverse biased under this condition. All during the growth period, the voltage drop across the upper $L/R$ series combination and the lower $L/R$ series combination are each equal to $V_{CC}$ while the voltage between point A and ground remains at zero. All during this time energy is being stored in the magnetic fields associated with each inductor and this stored energy reaches a maximum value when the elapsed time reaches 2 $\mu$s. When the elapsed time reaches 2 $\mu$s both switches are opened simultaneously and the circuit effectively becomes the depiction presented in Fig. 20-37.

When the switches are simultaneously opened, the current begins to ramp down from the maximum value achieved in the previous 2 $\mu$s when the switches were closed and the diodes that played no role in the previous 2 $\mu$s maintain circuit closure but now to the opposite terminals of the batteries. In the next 2 $\mu$s the collapsing magnetic fields of the inductors continue to drive the current with a linearly decreasing magnitude and energy is being returned to the rail supplies. The energy recovery is not quite complete as there is a small heat loss in the imperfect inductors and diodes. During the ramp down process, the voltage from point A to ground again ideally remains at zero. Thus, in the quiescent state with no audio signal present, the voltage at point A remains at zero and there is no ripple arising from the modulation process.

When a positive-going audio signal is present the operation may be understood by reference to Fig. 20-38.
The three sketches in the top portion of the figure describe, respectively, the operation of the positive switch, the modulator behavior, and the operation of the negative switch while the final sketch at the bottom displays the effective voltage presented to the output filter of the BCA. Observe that the positive switch is turned on when the triangle waveform first crosses the negative error voltage value and stays on until the triangle waveform again crosses the negative error voltage value. Note also that the duration of the on-time of the positive switch is 2.4 \( \mu \text{s} \). Observe also that the negative switch is turned on when the triangle waveform first crosses the positive error voltage value and stays on until the triangle waveform again crosses the positive error voltage value. The duration of the on-time of the negative switch is 1.6 \( \mu \text{s} \). When both switches are off there is no output and when both switches are on simultaneously there is no output. There are two periods when the positive switch is on while the negative switch is off during which output is generated. Thus, the fundamental ripple frequency of the output is twice that of the fundamental frequency of the triangle waveform or 500 kHz. The switches themselves operate at only the fundamental frequency of the triangle waveform or 250 kHz. Another very important observation is that the on time of the two switches adds to 4 \( \mu \text{s} \), which is the period of the triangle waveform. This is always true for this type of modulation technique. If an even larger output had been required, the negative error voltage line would have been lower while the positive error voltage line would have been higher. In such an instance, the on period of the positive switch would be increased while that of the negative switch would be correspondingly reduced. The two positive output pulses would still have amplitudes of \( V_{CC} \) but each would endure for a longer period such that the average value following the output filter would be correspondingly larger.

When a negative-going audio signal is present, reference must be made to Fig. 20-39.

A study of Fig. 20-39 indicates that now the negative switch is turned on when the triangle waveform first crosses the negative error voltage value and remains on until the triangle waveform again crosses the negative error voltage line. In brief, the role of the two switches has now been reversed. The period of the negative switch is now 2.4 \( \mu \text{s} \) while the period of the positive switch is now 1.6 \( \mu \text{s} \). The output pulses as a consequence are now negative. The other general properties remain the same.

The output of the BCA under all three modes of operation—quiescence, positive audio output, and negative audio output—is further clarified by viewing the equivalent circuit displayed in Fig. 20-40.

When the three-position switch in Fig. 20-40 is in position two as shown in the drawing, the output of the
BCA is zero. This condition corresponds to the times when \( S_p \) and \( S_n \) are simultaneously both on or both off. Position one of the three-position switch corresponds to those intervals of time when \( S_p \) is on and \( S_n \) simultaneously off. This position generates a positive audio output to the load. Finally, position three of the three-position switch corresponds to those intervals of time when \( S_n \) is on and \( S_p \) simultaneously off. This final position occurs when a negative audio output is being generated.

The type of pulse width modulation employed with the BCA is called natural double-sided interleaved with \( n = 2 \). The \( n \) designator indicates the fundamental ripple frequency of the BCA output when generating audio signals relative to the fundamental frequency of the triangle waveform. The advantage of this type of modulation in addition to the fundamental ripple frequency being twice that of the triangle waveform is that there are no harmonically related distortion products to the audio frequency being processed and there are no odd integer multiple bands related to the fundamental frequency of the triangle waveform. As a consequence, only a relatively simple output filter is required for handling normal loudspeaker loads. Additionally, when operating a two-channel amplifier in the full-bridge mode, if the modulator in the second channel is in quadrature with that of the first, \( n \) becomes 4 rather than 2 so that the lowest ripple components appear at 1 MHz rather than at 500 kHz. Crown terms such amplifiers as being opposed current interleaved amplifiers (OCIA). This constitutes a new class of amplifier or class I. This type of operation is incorporated in Crown’s I-Tech series of switching power amplifiers.

The required modulator circuitry is actually quite simple as is illustrated in Fig. 20-41.

In reference to Fig. 20-41, \( A_1 \) is the error signal amplifier while \( A_2 \) is a simple inverter amplifier. \( C_1 \) and \( C_2 \) are high-speed comparators.

The innovations described in this section have led to the production of switching amplifiers having power ratings up to 8000 watts while producing only 0.35% of total harmonic distortion at rated power. The size and weight figures are equally as impressive being only 2 rack units and 29 pounds.

### 20.3.7 Signal Processing in Power Amplifiers

Most high-power audio amplifiers for professional applications currently feature a wide variety of signal processing functions. This was not always the case. Originally power amplifiers were just what the name implied with the possible exception of a selectable high-pass filter at the input for the protection of high-frequency compression drivers when such loudspeaker elements constituted the only load on the amplifier. During this period, full-range loudspeaker systems employed passive dividing networks and high-powered systems featured compressors contained in dedicated units preceding the power amplifier. The modest consoles of this period usually provided only high and low shelving filters. Modern changes began to occur first with the introduction of \( 1/3 \)-octave real-time analyzers and dedicated \( 1/3 \)-octave equalization units. These changes were further accelerated by the advent of TEF and similar computer-based analysis systems. Electronic crossover networks, signal alignment, and bi-or triamplification shortly came into vogue in order to correct system problems discovered by the new sophisticated analysis systems. Two-channel power amplifiers with the ability to operate the two channels independently or in the bridged mode became the de facto standard. The electronic crossovers and signal delays of this period were dedicated separate units and initially were determined manually.
based on analog techniques and slowly gave way to digital techniques as this newer technology developed. Digital techniques came into full flower with the development of powerful digital signal processing chips or DSPs. It now became economically feasible to concentrate the functions of filtering, equalization, signal delay, compression or limiting, and frequency division or crossover into a single system interposed between the input console and the power amplifier. This new digital signal processing unit was given different names by different manufacturers but was popularly referred to as a loudspeaker management system. The current trend in more powerful power amplifier design is to provide the entire required signal processing function within the confines of the amplifier chassis itself. In many instances there is no requirement for an external loudspeaker management system. These amplifiers usually accept audio in both analog and digital formats with the digital format conforming to the AES3 standard. If the amplifier is to be employed in live sound reinforcement, a premium is placed on having low latency in the amplifier’s digital signal processing functions. Latencies of 2 μs or less are highly desirable.

20.3.8 Computer-Controlled Power Amplifiers and Systems

Computers are permeating every field of human endeavor and audio systems are no exception. Crown International Electronics in the middle 1980s pioneered computer control to the depth of the level of individual amplifiers. Crown, building on the digital electronics and programming experience it had acquired in the development of the TEF analyzer, began designing a new line of power amplifiers that would be amenable to both digital control and digital monitoring with the incorporation of a plug-in digital module. Parallel to the development of these amplifiers, Crown also developed the computer interface and communication system necessary for interaction with these amplifiers. This work culminated in the Crown IQ system.

The original Crown IQ system was structured on three levels with microprocessors at each of the levels. At the uppermost level were the host computer and the IQ system software. The host computer could be any computer that had a serial (RS232, RS422, or RS4230) port. The computer with the installed IQ system software acted as a monitoring and control station. At the intermediate level was the Crown IQ interface that served as a communication device between the individual power amplifiers and the host computer. At the lowest level were the individual power amplifier plug-in microprocessor cards that were connected in a daisy chain by means of a single twisted pair to form a serial loop to the IQ interface as shown in Fig. 20-42.

Communication between the interface and the individual amplifiers was at a baud rate of 38,400 so that the system operation appeared to occur almost in real time. All of the normally manually controlled functions of each amplifier could be computer controlled by this system up to a total of 2000 two-channel power amplifiers. The outstanding feature of this approach, however, was that the actual operational status of each amplifier including on-off, input level, output level, distortion, and safe operating area were constantly monitored almost in real time. Subsequently, the Crown system was expanded to include plug-in modules incorporating digital signal processing capability in addition to the original features. This allowed, in addition to the original monitoring and control features, online filtering, signal delay, and equalization, all under computer control.

The modern era of control of sound systems began in 1993 with the step taken by Peavey Electronics Corporation in the introduction of the MediaMatrix® System that featured real-time network communication and control of digital audio signals by Ethernet supported by a CobraNet® hardware interface. This system allowed the interconnection, communication between, and
control of all of the elements associated with even the most sophisticated sound systems.

Crown’s original IQ system has evolved to the current form termed HiQnet™ that features communication via serial, Ethernet, USB, and CobraNet® audio. This current system not only links, controls, and monitors power amplifiers but also the other elements associated with the smallest or largest of sound systems as well, all under computer control.

Practically all power amplifier manufacturers currently feature some form of computer networking and control of their products.

21.1 Microphone Preamplifier Fundamentals

Microphones are transducers that typically have very low output signal levels. A voltage gain of 1000 (60 dB) or more may be required to bring the signals up to standard line levels, hence the name preamplifier. Amplifiers for such low-level signals are prone to problems unique to high-gain, low-noise electronic circuits. Microphone preamplifiers are available as stand-alone devices or as part of simple mixers or complex recording consoles. In this section, we will limit our discussion to preamplifiers and mixers intended for use with professional microphones that have balanced, low-impedance outputs.

21.1.1 The Microphone as a Signal Source

As discussed in Chapter 16, microphones may vary considerably in output impedance, output level or sensitivity, and self-noise. For professional microphones, impedance has a rated or nominal value of 150 Ω (U.S. standard) or 200 Ω (European standard). Dynamic microphones, like loudspeakers, have an actual impedance that varies with frequency. Note the similarity of the impedance plot of Fig. 21-2 to that of a loudspeaker. A single figure representing the impedance of such devices is usually taken as the first minimum that occurs after the first maximum as frequency is increased from a low-frequency limit. The first maximum is usually cone or diaphragm resonance. For microphones, this impedance would be measured between the signal output pins (2 and 3 for an XLR) and is variously referred to as output, source, internal, signal, or differential impedance. Such microphones are broadly classified as floating balanced sources. Floating refers to the fact that the common-mode impedances—i.e., those from output (pins 2 and 3) to case and shield (pin 1)—are very much higher than the signal or differential impedance. As emphasized in Chapter 32, Grounding and Interfacing, balanced refers to the matching of these common-mode impedances.

21.1.1.1 Electrical Model of the Microphone

Since the Shure SM57 dynamic microphone is so popular, it will be used as an example. Fig. 21-1 shows its internal schematic, the electrical equivalent circuit of the capsule and transformer, and the combined equivalent circuit. The equivalent circuits do not model the diaphragm resonance at approximately 150 Hz. Note the pair of 17 pF capacitances to the case. These determine the common-mode output impedances that play a role in noise rejection or CMRR when the microphone is connected to a preamplifier and cable. The actual measured output impedance of an SM57 is shown in Fig. 21-2. The Shure data sheet accurately specifies the actual impedance as 310 Ω. The equivalent circuit of Fig. 21-1 models the impedance behavior above 1 kHz as well as the equivalent noise resistance. Condenser microphones generally have both lower output impedances and less variation with frequency than dynamic types.

21.1.1.2 Interactions with Preamplifier and Cable

A microphone preamplifier is normally designed to recover as much of the available microphone output voltage as possible. Since the noise floor of the preamplifier is nearly constant, signal-to-noise performance is improved by making its input voltage as large as possible. It is very important to understand that the fraction of available microphone voltage actually delivered to the preamplifier depends on both the output impedance of the microphone and the input impedance of the preamplifier.

As shown in Fig. 21-3, these two impedances effectively form a voltage divider. The voltage lost in the output impedance $Z_S$ of the microphone depends on the input impedance $Z_L$ of the preamp. Loading loss, usually expressed in dB, compares the output voltage with some specified load to the output voltage under open circuit or unloaded conditions. For example, a 150 Ω impedance (actual) microphone will deliver 91% of its unloaded voltage when loaded by a preamplifier having a 1.5 kΩ input impedance. The loading loss is
then $20 \times \log 0.91$, which is 0.8 dB. Generally, loading loss is negligible (under 1 dB) if load impedance is ten or more times the source impedance. Therefore, as discussed in Chapter 16, it is neither desirable nor necessary to “match” the impedances of the preamplifier and microphone. If impedances are matched, half the available output voltage from the microphone is lost, degrading signal-to-noise ratio by 6 dB. Although impedance matching transfers maximum power, this is not what we want.

When a microphone is connected to a cable and a preamplifier, a passive two-pole (12 dB/octave) low-pass LC filter is formed as shown in Fig. 21-4. The behavior of LC filters as they approach their cutoff or resonant frequency is controlled by resistive elements in the filter. This resistive damping is largely provided by the input resistance $R_L$ of the preamplifier. Fig. 21-5 shows the deviation in frequency response of a Shure SM57 microphone loaded by the 2.5 nF capacitance of 150 ft of typical microphone cable and three different values of preamplifier input resistance. The upper curves, 10 kΩ and 3 kΩ are typical of preamps that don’t use an input transformer. Note the high-frequency response peaking caused by insufficient damping. The lower curve, 1.5 kΩ, is typical of a preamp using an input transformer.

Capacitance of shielded twisted pair cable is usually specified as that from one conductor to the other conductor and the shield. Belden 8451, for example, is listed at 34 pF/ft. However, the differential signal is affected by the capacitance between the conductors, which is about half that, or 17 pF/ft. With dynamic microphones, high cable capacitance causes high-frequency roll-off. For the SM57 microphone, about a thousand feet of this cable (about 17 nF) will limit high-frequency bandwidth to about 15 kHz. Because condenser microphones use internal amplifiers to drive the output cable, high cable capacitance can cause distortion. If the amplifier has limited output current, it will distort or clip high-level, high-frequency (i.e., high slew rate) signals such as vocal sibilance or a cymbal crash. “Star-quad” cable, although it offers amazing freedom from magnetic pickup problems, has about twice the capacitance per foot of standard cable. This fact must be seriously considered for long cables.

Keep in mind, however, that other types (or even models) of microphones may behave quite differently, depending on their exact equivalent circuit. For example, some condenser types have low (around 30 Ω) and almost purely resistive output impedances while some dynamic types can have actual midband impedances over 600 Ω.
To a greater or lesser degree, the frequency response of any microphone will be affected by the load capacitance of the connected cable and preamplifier as well as the input impedance characteristics of the preamplifier. Perhaps this is why the selection of microphones and preamplifiers is such a subjective issue.

### 21.1.2 Some Considerations in Practical Preamplifiers

Because many aspects of preamplifier circuit design and the tradeoffs involved are discussed in Chapter 25, Sections 25.6 and 25.9, we will discuss only a few topics here.

#### 21.1.2.1 Gain and Headroom

Microphone preamplifiers commonly have maximum voltage gains of about 60 dB to 80 dB and minimum gains from 0 dB to 12 dB. A typical microphone, such as the Shure SM57, will have an output of 1.9 mV or −52 dBu with a 94 dB SPL acoustic input. For a very high acoustic input of 134 dB SPL, its output would be 190 mV or −12 dBu. But a high-sensitivity microphone such as the Sennheiser MKH-40 will have an output of 25 mV or −30 dBu at 9 dB SPL and 2.5 V or +10 dBu at 134 dB SPL. Such high input levels can actually require the preamplifier to have a loss (i.e., negative gain) to produce usable line level output. Such high input levels can also overload the preamp. Both problems are most commonly avoided with an input attenuator or pad, typically of 20 dB. See Chapter 11 for a discussion of the distortion and level handling characteristics of audio transformers.

#### 21.1.2.2 Input Impedance

As shown in Fig. 21-5, some input transformers have input impedances that load the microphone and, as discussed in the preceding section, alter the response of the system at frequency extremes. However, well-designed transformers such as the Jensen JT-16B have substantially flat input impedance as shown in Fig. 21-6.

#### 21.1.2.3 Noise

The random motion of electrons in electrical conductors creates a voltage variously called thermal noise, white noise, or Johnson noise after its first observation by J. B. Johnson of Bell Labs in 1927. Thermal noise voltage is proportional to both temperature and the resistance of the conductor and is calculated as follows:

\[
E_t = \sqrt{4kTR\Delta f}
\]

where,
- \(E_t\) is the thermal noise in rms volts,
- \(k\) is Boltzmann’s constant or \(1.38 \times 10^{-23}\) Ws/°K,
- \(T\) is the temperature of the conductor in degrees Kelvin,
- \(R\) is the resistance of the conductor in ohms,
- \(\Delta f\) is the noise bandwidth in Hertz.

At a room temperature of 300°K (80°F or 27°C), \(4kT = 1.66 \times 10^{-20}\). For noise in the audio band of 20 Hz to 20 kHz, bandwidth is 19.98 kHz. It’s important to note that noise bandwidth here refers to a rectangular “brick wall” response, not the more conventional measure at the −3 dB points. For a 150 Ω resistance under these conditions, noise is

\[
\begin{align*}
223 \, \text{nVrms} &= -133.0 \, \text{dBV} \\
&= -130.8 \, \text{dBu}
\end{align*}
\]

For a 200 Ω resistance under the same conditions, noise is

\[
\begin{align*}
258 \, \text{nVrms} &= -131.8 \, \text{dBV} \\
&= -129.5 \, \text{dBu}
\end{align*}
\]

Here we use the nominal impedance of an idealized microphone simply to allow a simple but fair comparison of preamplifier noise performance.

Regardless of whether the conductor is copper wire, silver wire, an expensive metal-film resistor, or a cheap carbon resistor, the thermal noise is exactly the same! Excess noise refers to additional noise generated when dc flows in the resistor. Excess noise varies markedly...
with resistor material and construction. Note that only
the resistive portion of impedance generates noise—
pure inductors and capacitors do not generate thermal
noise. Therefore, in our Shure SM57 circuit model of
Fig. 21-1, thermal noise is generated by the 300 Ω resis-
tance but not by the 6 mH inductance.

In a practical microphone preamp, we are usually
concerned with the signal-to-noise ratio at the output.
Although there may be many sources of internal noise
in the preamplifier and its gain may be varied over a
wide range, for simplicity noise is usually stated in
terms of $E_{IN}$ or equivalent input noise. This simplifica-
tion works because, in a good design, the dominant
noise source is the first amplification stage and subse-
quent stages contribute no significant noise.

As shown in Fig. 21-7, the Equivalent Input Noise
(EIN) has three components:

1. $E_t$: the thermal noise of the source resistance.
2. $E_v$: the voltage noise of the amplifier.
3. $I_n$: the current noise of the amplifier.

When noise voltages are produced independently
and there is no relationship between their instantaneous
amplitudes or phases, they are said to be uncorrelated.
Total noise power is the sum of individual noise powers.
Therefore, the resultant voltage is the square root of the
sum of the squares of the individual voltages. For
example, adding two uncorrelated 1 V noises will result
in a 1.4 V noise because

$$E = \sqrt{1^2 + 1^2} = \sqrt{2} = 1.414.$$  (21-2)

When adding two noises, unless the second is a third
or more of the first (less than 10 dB difference), it will
have little effect on the total. For any amplifier,
minimum total noise is added when the source resis-
tance is such that $I_n$ flowing through the source creates
a noise voltage equal to $E_N$. This source resistance is
called the optimum source resistance for that particular
amplifier. Perhaps the most useful function of an input
transformer in a microphone preamplifier is to convert,
as explained in Chapter 11 Audio Transformers, the
impedance of the microphone to this optimum value in
order to maximize SNR.

Measurement of noise is fertile ground for technical
misrepresentation. Some rather unbelievable EIN
numbers have appeared over the years. Most were based
on measurements taken with the preamplifier input
shorted, which ignores the noise contributions of both

$R_s$ (source resistance) and $I_N$ (amplifier current noise),
leaving only $E_N$ (amplifier voltage noise). Bias current
noise generates additional voltage noise when it flows
in the source impedance (not just resistance). In this
case the inductance of our SM57 model will indirectly
contribute real-world noise. To have any meaning at all,
EIN must specify the source impedance. With a 150 Ω
source resistance,

$$E_{IN} = 223 \text{ nVrms} = -133.0 \text{ dBV} = -130.8 \text{ dBu}$$

for an ideal noiseless amplifier. If the preamplifier noise
is equal to that of the source, EIN will be 3 dB higher or
$-130.0 \text{ dBV} = -127.8 \text{ dBu}$. Noise figure, or NF, is a
measure of SNR degradation attributed to the ampli-
 fier—in this case 3 dB. From an engineering point of
view there is little point in attempting to achieve NF
below 3 dB.

Note that the thermal noise Eq. 21-1 also includes a
term for bandwidth. Noise specifications such as EIN
frequently appear in data sheets without a specified
noise bandwidth. All other things equal, noise increases
as the square root of bandwidth. Therefore, there is
1.25 dB less noise in a 15 kHz bandwidth, and 3 dB less
noise in a 10 kHz bandwidth, than in a 20 kHz band-
width. Likewise, while measurements such as
A-weighted noise are both legitimate and useful, they
cannot be directly compared to unweighted measure-
ments. When comparing noise specifications, be sure
it’s an “apples to apples” comparison.

### 21.1.2.4 Bandwidth and Phase Distortion

Performance in the time domain, or waveform fidelity,
is critically important to accurate music reproduction.
Accurate time domain performance, sometimes called
transient response, requires low phase distortion. Pure
time delays exhibit a linear phase versus frequency
characteristic. True phase distortions are expressed as
DLP or deviations from this linear phase relationship.
Phase shift is not necessarily phase distortion. In order
to achieve a DLP of 5° or less from 20 Hz to 20 kHz, frequency response must extend from 0.87 Hz to 35 kHz, assuming 6 dB per octave (first order) filter responses. If the low-pass filter is a second order Bessel, the cutoff frequency can be as low as 25 kHz. Notice that extreme high-frequency response is not required, but extended low-frequency response is!

Phase distortion not only alters musical timbre, but it has potentially serious system headroom implications as well. Even though frequency response may be flat, peak signal amplitudes can increase up to 15 dB after passing through a network with high phase distortion. This can be a serious problem in digital recording systems. Even ultrasonic phase distortions caused by undamped resonances can excite complex audible cross-modulation products in subsequent nonlinear (any real world) amplifier stages.

Low-frequency phase distortions are often described as muddy bass and high-frequency phase distortions as harshness or midrange smear. The complex cross-modulation products are usually described as dirty sounding and often are the cause of listener fatigue.

21.1.2.5 Common-Mode Rejection, Phantom Power, and RF Immunity

Common-mode rejection, as discussed in Chapter 11, Audio Transformers, is not just a function of the amplifier input circuitry. It depends on the impedance balance achieved by the combination of the microphone’s output circuitry, cable, and the preamp’s input circuitry. Common-mode rejection ratio (CMRR) is seldom an issue with dynamic microphones because, as shown in Fig. 21-1, the common-mode impedances are small parasitic capacitances. However, when phantom power is involved, very high CMRR can be difficult to achieve. The circuitry in the microphone that extracts phantom power from the two signal lines, as shown in the examples in Chapter 16, Microphones, can unbalance their line impedances to ground. The resistors that supply phantom power, shown in the preamplifier of Fig. 21-13, must also be tightly matched to achieve high CMRR. For example, CMRR may be limited to 93 dB if ±0.1% resistors are used and may be limited to 73 dB if ±1% resistors are used. For comparison, the JT-16B transformer used in Fig. 21-13 achieves a CMRR of 117 dB when phantom power resistors are absent. Sometimes, as in Fig. 21-9, phantom power is supplied through a center-tap on a microphone input transformer. This presents a transformer design problem that can be even more difficult—simultaneously matching both the number of turns and the dc winding resistance on each side of the center tap.

RF interference, usually in the form of common-mode voltage, is another potential problem for microphone preamplifiers because it is likely to be demodulated in amplifier circuitry. In transformer-less circuits, suppression measures usually consist of capacitors from each input to ground and sometimes series resistors, chokes, or ferrite beads. Unless the capacitors are carefully matched, they will unbalance the common-mode input impedances and degrade CMRR. Because they also lower common-mode input impedances, they can make the circuit more sensitive to normal impedance imbalances in the microphone. These tradeoffs can be largely avoided by using a Faraday-shielded input transformer that has inherent RF suppression characteristics.

A good microphone preamplifier should also be free of the so-called pin 1 problem. The microphone cable should be free of shield-current-induced noise (SCIN), which can be a serious problem with foil shield and drain wire construction. Both of these problems are discussed in Chapter 15.

21.2 Real-World Preamp and Mixer Designs

21.2.1 Transformers

Manufacturers of microphone preamplifiers have a natural desire to differentiate their product from all others. One of the major divisive issues is the use of audio transformers. According to the antitransformer camp, all audio transformers have inherent limitations such as limited bandwidth, high distortion, mediocre transient response, and excessive phase distortion. Unfortunately, many such transformers do exist and not all of them are cheap. The makers of such transformers are simply ignorant of sonic clarity issues, have a poor understanding of the engineering tradeoffs involved, or are willing to take manufacturing shortcuts that compromise performance to meet a price.

As stated earlier, bandwidth and phase distortion are intimately linked in any electronic device. A very high level of performance can be reached with proper transformer design. Consider the Jensen JT-16B microphone input transformer. Its frequency response is −3 dB at 0.45 Hz and 220 kHz and −0.06 dB from 20 Hz to 20 kHz, with a second order Bessel high-frequency roll-off characteristic. Low frequency roll-off is less than 6 dB per octave owing to properties of the core material, which further improves phase performance. Its deviation from linear phase is under 2° from
20 Hz–20 kHz, giving it truly excellent waveform fidelity and square-wave response.

As discussed in detail in Chapter 11, Audio Transformers, audio transformer distortion is quite different from electronic distortion in ways that make it unusually benign. First, transformer distortion is frequency and level dependent. Significant distortion occurs only at low frequencies and high signal levels, typically dropping to under 0.001% above a few hundred hertz. Second, the distortion is nearly pure third harmonic and is not accompanied by the high levels of much more irritating intermodulation distortion that occurs in electronics.

A high degree of RF attenuation, both normal mode and common mode, is also inherent in transformers that contain Faraday shields. For example, in Jensen designs, common mode attenuation is typically over 30 dB from 200 kHz–10 MHz. And, as discussed in Chapter 16, transformers enjoy a great CMRR advantage over most electronically balanced input stages because they are relatively insensitive to the impedance imbalances that normally exist in real-world signal sources. If well designed and properly applied, audio transformers qualify as true high-fidelity devices. They are passive, robust, and stable and have significant advantages, especially in electrically hostile environments.

21.2.2 Class A Circuitry

Another divisive issue among preamplifier manufacturers involves class A circuitry. Although it has certain advantages, it is not necessarily inherently superior to much more widely used class AB designs. Class A operation occurs when the active device (or devices in the case of a push-pull output stage) conducts current during the entire 360° signal cycle. Class AB occurs when each device conducts for more than 180° but less than 360°. In class B operation, each device conducts for exactly 180°. In class C, conduction is less than 180° and this is generally done only in RF circuits or where intentional distortion is desired.

Most op-amp output stages operate class AB to avoid crossover distortion of small signals. Practical active devices are generally unable to behave linearly near zero current (cutoff) as is required for low-distortion pure class B operation. A small idling or quiescent current flows in both devices at zero signal and operation remains class A (both devices conducting for full signal cycle) up to some signal level, at which point one device begins to be cut off for part of the cycle, producing class AB operation.

For example, in the Jensen-Hardy 990 amplifier module used in the circuit of Fig. 21-13, this output stage quiescent current is about 15 mA. Therefore, amplifier operation is class A until peak output current (plus or minus) reaches about 15 mA. Peak output current, of course, depends on peak signal level and load impedance. For example, the output voltage clips at about 24 Vpeak, so any load impedance higher than about 1.6 kΩ results in class A operation at all times. Likewise, with a 600 Ω load, operation is class A until output signal level reaches ±9 Vpeak. Above that peak level, operation becomes class AB. The “front end” circuitry of the 990, like most operational amplifiers, always operates class A unless the output is clipped. The line between class A and AB operation is very distinct: operation is no longer class A as soon as current in any active device (vacuum tube or transistor) becomes zero. The main advantage of class A circuit designs is that the curvature of the nonlinearity plot is likely to be smoother (i.e., free of a sharp discontinuity at crossover) so that there will be fewer problems related to negative feedback, slew rate, and gain-bandwidth limitations.

21.2.3 Shure SCM268 Four-Channel Mixer

The Shure SCM268 is an example of a compact, simple mixer with basic features. Notable features include transformers on balanced inputs and outputs, mic or line level output, phantom power, and optional pads allowing for balanced line level inputs, Fig. 21-8. A functional block diagram is shown in Fig. 21-9.

Figure 21-8. Shure SCM268 four-channel microphone mixer. Courtesy Shure Incorporated.

21.2.4 Cooper Sound CS 104 Four-Channel ENG Mixer

The Cooper Sound Systems CS 104 is an example of a portable, battery-powered mixer with a number of sophisticated features, Fig. 21-10. Notable features include stereo mixing, pan pots and channel linking,
transformers on main inputs and outputs, built-in stereo limiter, input overload indicators, selectable high-pass filters, prefade listen, tape monitor, and built-in tone and slate functions. Fig. 21-12 is its functional block diagram.

21.2.5 Jensen-Hardy Twin-Servo® 990 Microphone Preamplifier

The Jensen-Hardy Twin-Servo® 990 Microphone Preamplifier is an example of a high-performance design, Fig. 21-11. It features patented discrete component 990 amplifier modules that combine low-input noise, high-output voltage and current, low distortion, and high gain-bandwidth performance that is unavailable with integrated circuits. It uses two cascaded variable gain stages per channel to maintain high bandwidth and low distortion overall. Unlike most designs, this topology also keeps EIN very low at the lowest gain settings. Extended low-frequency response is preserved by using dc servo feedback circuitry to eliminate coupling capacitors and their attendant problems, Fig. 21-13.

21.3 Automatic Microphone Mixers

Automatic microphone mixers, also known as voice-activated mixers or sound-activated mixers, have become a necessary part of sound systems designed for speech. All automatic microphone mixers have a fundamental function: to attenuate (reduce in level) any microphone that is not being spoken into by a talker, and conversely, to rapidly activate any microphone that is being spoken into by a talker. An automatic microphone mixer should

---

Figure 21-9. Block diagram of a Shure SCM268.

Figure 21-10. Cooper Sound CS 104 battery-powered portable ENG/EFP four channel audio mixer.

Figure 21-11. Jensen Twin-Servo® 990 four channel microphone preamplifier. Courtesy Jensen Transformers, Inc.
be considered when the number of microphones required for the sound system is four or greater.

When used in a sound reinforcement system, an automatic microphone mixer provides a significant increase in gain before feedback when multiple microphones must be used without a sound engineer. It also improves the quality of the sound system output by reducing the amount of extraneous room sound being picked up, and by reducing comb filtering. In addition, it automatically adjusts system gain to compensate for the number of microphones in use at any instant. Thus, an automatic microphone mixer attempts to provide the same system control that might be produced by a human sound engineer.

As automatic microphone mixers are optimized for speech applications, their use in musical applications is not recommended. Mixing microphones for music is as much art as science, and therefore the artistic judgment of a human sound engineer is much preferred to the electronic decision process of an automatic microphone mixer.

In summary, when used in a speech sound system with multiple microphones, the ideal automatic microphone mixer assures that the number of active microphones at any moment equals the number of active talkers at the same moment. All unused microphones at that moment are attenuated.

### 21.3.1 The Audio Problems Caused by Multiple Open Microphones

High-quality audio becomes progressively more difficult to achieve as the number of open microphones...
increases. All audio systems face the same problems whenever multiple open microphones are needed. These problems are:

1. Build-up of background noise and reverberation.
2. Reduced gain before feedback.
3. Comb filtering.

These problems can plague boardrooms, city council chambers, conference centers, houses of worship, teleconferencing rooms, radio talk shows—anywhere multiple microphones are used. Since audio quality rapidly deteriorates as the number of open microphones increases, the solution is to keep the minimum number of microphones open that will handle the audio. An automatic microphone mixer keeps all unused microphone input channels attenuated, and activates any microphone spoken into within milliseconds.

21.3.1.1 Buildup of Background Noise and Reverberation

The first problem of multiple open microphones is the buildup of background noise and reverberation. This buildup can adversely affect the quality of recordings or broadcasts originating from the audio system. Consider the case of a city council with eight members and eight microphones. For this example, only one member is talking. If all eight microphones are open when only one microphone is needed, the audio output will contain the background noise and reverberation of all eight microphones. This means the audio signal will contain substantially more background noise and reverberation than if only the talker’s microphone were open. This buildup of background noise and reverberation greatly deteriorates the audio quality. Speech clarity and intelligibility always suffer as background noise and reverberation increase.

As the number of open microphones increases, the background noise and reverberation in the audio output also increase. In our city council example, the audio output from eight open microphones would contain 9 dB more background noise and reverberation than a single open microphone. To the human ear, the noise would sound almost twice as loud when all eight microphones were open.

To minimize background noise and reverberation buildup, an automatic microphone mixer activates only the microphone(s) being addressed and employs a NOMA circuit. NOMA is an acronym for number of open microphones attenuator. NOMA systematically decreases the master gain whenever the number of open microphones increases. Without NOMA, the audio system would produce objectionable noise modulation (pumping and breathing) as background noise and reverberation increase and decrease with the number of open microphones. With a properly designed automatic microphone mixer, background noise and reverberation remain constant no matter how many or few microphones are activated.

21.3.1.2 Reduced Gain Before Feedback

The second problem of multiple open microphones is reduced gain before feedback. Acoustic feedback (“howling”) can be a problem anytime a sound reinforcement (PA) system is used. To avoid feedback, PA systems are operated below the point where the system becomes unstable and starts to howl. However, this feedback safety margin is reduced each time another microphone is opened. Have one too many open microphones and the result is feedback.

The automatic microphone mixer solution is to keep unused microphones turned off and utilize NOMA. As more microphones are activated, the overall gain will remain constant thanks to the NOMA circuit. An automatic microphone mixer assures that if the audio system does not feedback when any one microphone is open, the system will remain feedback free even if all the microphones are open.

21.3.1.3 Comb Filtering

The third problem of multiple open microphones is comb filtering. Comb filtering occurs when open microphones at different distances from a talker are mixed together, Fig. 21-14. Since sound travels at a finite speed, the talker’s voice arrives at the microphones at different times. When combined in a mixer, these out-of-step microphone signals produce a combined frequency response very different from the frequency response of a single microphone. (A frequency response chart of the out-of-step signals looks like the teeth of a hair comb, thus the name.) The aural result of comb filtering is an audio signal that sounds hollow, diffuse, and thin.

The solution to comb filtering also is keeping the number of open microphones to an absolute minimum. By automatically turning off unused microphones, an automatic microphone mixer reduces comb filtering and the resultant poor audio.
21.3.1.4 Summary

1. Keeping the number of open microphones to a minimum always improves overall audio quality.
2. The primary function of an automatic microphone mixer is to keep unused microphone input channels attenuated (turned down or off) and to instantaneously activate microphones when needed.
3. Buildup of background and reverberant noise, reduced gain before feedback, and comb filtering can all be controlled by using an automatic microphone mixer.

21.3.2 Design Objectives for Automatic Microphone Mixers

As shown in Fig. 21-15, a conventional microphone mixer in a sound system amplifies the signal from each microphone and combines these amplified signals together to produce a single output. This output feeds a power amplifier and then one or more loudspeakers. Each doubling of the number of open microphones feeding into a sound system reduces the available gain before feedback by 3 dB. This fact surprises the layman who often believes that more microphones equate to the sound system being louder, not softer. A sound system with numerous microphones easily becomes ineffective if a sound engineer is not present to control levels and switch off unused microphones. Since gain before feedback can often be marginal because of the acoustical characteristics of a room, an automatic microphone mixer may be the only way to provide adequately loud program levels to the audience with an unattended sound system.

21.3.2.1 Examples of Design Objectives for an Automatic Microphone Mixer

1. Keeps the sound system gain below the threshold of feedback instability.
2. Requires no operator or sound technician at the controls.
3. Does not introduce spurious, undesirable noise or distortion of the program signals.
4. Can be installed as easily as a conventional mixer.
5. Responds only to the desired speech input signals and is relatively unaffected by extraneous background noise signals.
6. Activates input channels fast enough that no audible loss of speech signals occurs.
7. Allows more than one talker on the system when required by the discussion content while still maintaining control of the overall sound system gain.
8. Adjusts the system gain to compensate for a range of talker input levels.
9. Provides system status outputs for peripheral equipment control and can interface with external control systems for advanced system design if required.

The automatic microphone mixer operation should provide relatively easy and very rapid input activation. Desired speech from a talker should cause immediate activation of the appropriate input channel, which may not always happen if the design of an automatic microphone mixer is poor. Also, random false activation of microphones remote from the talker can occur with some automatic microphone mixer designs. However, this false activation is typically not troublesome as the false signals are normally much lower in level than the desired talker signal. The automatic microphone mixer is doing its job if all talkers are clearly heard by the audience when they speak, and the sound system remains below the point of feedback.
An automatic microphone mixer cannot improve the performance of microphones. Its primary benefit comes from limiting the number of microphone signals fed to the mixer output. A side benefit is often the apparent increase of critical distance in a multiple microphone system. (Critical distance is defined as a point in the room where the direct signal of the talker equals the reflected signal of the talker, i.e., 50% direct signal and 50% reverberant signal.) Because unused microphones remote from the talker are attenuated, room reverberation and ambience that would otherwise be amplified are reduced.

21.3.3 Controls and Features of Automatic Microphone Mixers

Automatic microphone mixers have many of the same controls and features of manual microphone mixers. Examples are:

- Level control for each input channel.
- Master level control for each output channel.
- Input signal attenuation (“trim”).
- Phantom power.
- Two or three band equalization for each input channel.
- Output level metering.
- Output signal level limiter.
- Nonautomatic auxiliary inputs.
- Headphone output with level control.

These controls and features may be configured in hardware—e.g., switches, potentiometers, LED strings—or they may be configured in software. In either case, the function of the control or feature remains the same.

21.3.3.1 Controls and Features Unique to Automatic Microphone Mixers

As automatic microphone mixers typically perform more functions than a manual microphone mixer, there are controls and features that are unique to automatic microphone mixers.

Input Channel Threshold. Determines at what signal level a gated automatic microphone mixer input passes the incoming microphone signal to the mixer’s output.

Input Channel On Indicator. Illuminates to indicate that an input channel is passing the microphone signal onto the mixer output.

Direct Output for Each Input Channel. Provides an isolated output for each input channel that is unaffected by the automatic microphone mixer action.

Last Microphone Lock On. Keeps on the most recently activated input channel on a gated automatic microphone mixer until another input channel is activated. This maintains room ambience when the automatic microphone mixer is used to provide a broadcast feed, a recording feed, or a feed to an assistive hearing system.

Hold Time. Keeps an activated input channel on a gated automatic microphone mixer on for a period of time after speech has ceased. This feature bridges the natural gaps that occur in speech patterns.

Input Attenuation. Determines how much gain reduction is applied to an input channel of a gated automatic microphone mixer when the channel is not activated. Typical range of adjustment is 3 dB to 70 dB of attenuation, with 15 dB being a common value.

Decay Time. Establishes the time required for an input of a gated automatic microphone mixer to be lowered from the activated state to the attenuated state. Decay time is always in addition to the hold time.

Manual/Auto Select. Allows the automatic microphone mixer to operate in a nonautomatic (manual) mode.

21.3.3.2 External Control Capability and Status Indication of Automatic Microphone Mixers

Most automatic microphone mixers include the ability to be controlled by external switches, potentiometers, touch screens, personal computers, and other types of control devices. These devices are connected to the automatic microphone mixer via screw terminals or multipin connectors on the mixer’s rear panel. The controllable functions and the communication protocol depends upon the manufacturer and model of the automatic microphone mixer. Examples of automatic microphone mixer functions that can be externally controlled follow.

Gain of an Input Channel or the Master Output. In a courtroom, the court clerk could control the volume level of the witness microphone or the entire sound system using a potentiometer located at a distance from the automatic microphone mixer.

Mute an Input Channel. In a city council chamber, a council member could have a privacy or “cough” switch located near the microphone.

Global Mute of All Input Channels. In a government hearing room, the presiding member could mute all inputs to regain control of a meeting.
Permanent Activation of an Input Channel. In a house of worship, a microphone over the congregation could be kept on at all times to provide constant room ambience for a hearing assistance system.

Routing of Input Channels to Different Outputs. In a hotel meeting facility with movable dividing walls, input channels could be sent to different banks of loudspeakers depending on the room configuration.

Status Terminal. As input channels are activated and attenuated by the automatic mixing process, it is valuable to have a status terminal that indicates if a particular input channel is activated or not. This status terminal, also known as a gate terminal, can be thought of as an electronic switch that changes from open to closed based on the activity of the input channel. Examples of use for a status terminal:

- **Control of an LED or lamp to indicate input channel activity.** In a city council chamber, a council member could have a tally light located near the microphone indicating when the microphone’s input channel is activated by the automatic microphone mixer.

- **Control of a relay used to attenuate the nearest loudspeaker.** As the typical feedback path in a sound system is between a microphone and the nearest loudspeaker, attenuating the closest loudspeaker when a microphone is active could improve gain before feedback.

- **Control of a video switcher connected to multiple cameras.** In a courtroom, the proceedings could be videotaped by using cameras that follow the activation of input channels by the automatic microphone mixer.

- **Mute other input channels.** In a hotel meeting facility, one input channel could override all others in case of an emergency announcement.

Combining the externally controlled functions with the status terminals provides hundreds of unique system configurations. Most manufacturers of automatic microphone mixers have documentation of such configurations, often printed in product installation manuals and available on the manufacturer’s web site. As previously noted, the communication protocol used to interpret the status terminals and control the mixer functions depends upon the manufacturer and model of the automatic microphone mixer.

21.3.3.3 Examples of Communication Protocols Used in Automatic Microphone Mixers

**Contact Closure Protocol.** The most basic of communication protocols, contact closure is provided by a simple single pole/single throw (SPST) switch or relay. The switch is connected to two terminals on the mixer that control a certain function —e.g., mute of an input channel. When the switch is closed, the input channel is muted. When the switch is open, the input channel is unmuted and can be activated.

**Resistance Change or Voltage Change Protocol.** Used primarily to control signal levels via a VCA (voltage-controlled amplifier), this protocol requires that defined changes in resistance or voltage be applied to the mixer’s control terminals. In response, the VCA in the automatic microphone mixer will change the level of the audio signal.

**TTL (Transistor-Transistor Logic).** An electronic protocol established in the 1960s, TTL is simple to use. A control terminal on the automatic microphone mixer has one of two states: logic high (+5 Vdc) or logic low (0 Vdc). A status terminal could be logic high when a mixer input channel is attenuated and logic low when the mixer input channel is activated. This change of voltage informs an external control device that there is a change in the input channel status and some predetermined action should take place —e.g., illuminate an LED or switch on a camera.

**RS-232.** Used for communication with a computer, RS-232 is another common electronic protocol. RS-232 is most often used when proprietary control software is supplied with the automatic microphone mixer or when the mixer is connected to a control system such as those manufactured by Crestron or AMX.

**RS-422.** Basically a balanced line version of RS-232, RS-422 is designed for situations where an extremely long cable run must be used to connect the automatic microphone mixer to the external control device.

21.3.3.4 Number of Open Microphones Attenuation (NOMA)

NOMA is a function shared by all well-designed automatic microphone mixers. It is a simple method of ensuring system stability by automatically reducing the mixer output gain in proportion to the number of activated input channels. NOMA offsets the increase of gain that occurs as more microphones are activated. The attenuation in decibels should vary as:
Attenuation in dB = 10\log N \quad (21-3)

where,
\( N \) is the number of activated microphones.

While NOMA helps maintain stable gain in a sound system as the number of activated microphones varies, it does not limit the number of microphones that can be activated.

21.3.3.5 Restricting the Number of Open Microphones (NOM)

Recent developments in automatic microphone mixer design have led to a feature best described as a NOM restrictor. This feature restricts the number of active input channels to a predetermined amount. For example, in a large legislative system with 100 microphones, it makes little sense to allow all 100 microphones to be active at any instant, even if all 100 legislators are talking.

Restricting the NOM to 5 microphones of the 100 allows spirited debate while not subjecting the audience to the cacophony of 100 open microphones.

21.3.3.6 Input Channel Attenuation

Gating automatic microphone mixers use some form of input channel attenuation to turn off unused microphones. The activation of an input channel becomes audibly apparent if the level change from the off state to the on state is too great. Practical experience has shown that a 15 dB change from off to on is a good compromise. However, as the number of microphones in the system increases, more input channel attenuation may be required for system gain stability. Adjustment of input channel attenuation is available on most automatic microphone mixers. This adjustment can be on an input-by-input basis or for all inputs at once. The relationship between gain before feedback, input channel attenuation, and the number of microphones is calculated by the following equation:

\[
\Delta G = 10\log \frac{N}{1 + (N - 1)10^{A/10}} \quad (21-4)
\]

where,
\( \Delta G \) is the gain improvement in dB with only one microphone activated,
\( N \) is the total number of microphones,
\( A \) is the attenuation for all input channels in dB.

Fig. 21-16 shows the relationship in graphical form. Note the asymptotic maximum value of gain improvement with infinite attenuation—i.e., all but one channel turned off. Also note that input channel attenuation greater than 30 dB offers little improvement for systems with up to 256 microphones.

![Graph showing gain improvement with different channel-off attenuations in a mixer that has a number of microphones and only one channel on.]

21.3.3.7 Automatic Gain Control

Automatic gain control (AGC) of an input or output is a feature of a few automatic microphone mixers. A sound engineer rides gain to bring up weak signals or reduce overly loud signals and attempts to do this without destroying the inherent dynamic range of speech. An AGC in an automatic microphone mixer is typically designed to reduce gain only should the input signal level increase. The AGC is adjusted so that the quietest talker has maximum gain (without feedback). All louder talkers will force the AGC to bring down the overall level.

The IRP Level-Matic circuit is an example. It automatically adjusts the master gain to maintain a uniform output level for input signal variations up to 10 dB. A loud talker causes the gain to steadily decrease. When the talker stops, the gain holds as established by his or her average talking level. If a quiet talker then speaks, the gain steadily increases to a new value set by his or her average speaking level.

Gain control is based on loudness versus frequency and loudness versus time response of the ear. Gain adjustments are made at a constant dB per second rate to minimize the pumping and breathing effects of
simple level compression circuits. If there is no signal, the AGC gain holds at its last value.

21.3.4 Types of Automatic Microphone Mixers

An automatic microphone mixer can have an analog circuit design, a digital circuit design, or a combination of the two. Though a digital design might offer more design flexibility due to software control, the digital automatic microphone mixer is not inherently better than an analog automatic microphone mixer. Be it analog or digital, an automatic microphone mixer will fall in one of the following functional groups:

1. Fixed threshold.
2. Variable threshold.
3. Gain sharing.
4. Direction sensitive.
5. Multivariable dependent.

21.3.4.1 Fixed Threshold Automatic Microphone Mixers

A detector circuit in the automatic microphone mixer activates an input channel when a microphone signal is present and attenuates the input when the microphone signal ceases. This basic function is often called a noise gate. To activate the input, the signal must be larger than a threshold preset for the channel during installation. This method has several shortcomings. First, there is the dilemma of where to set the activation threshold. If it is set too low, it will respond falsely to room noise, reverberation, and room-reflected sound. If the threshold is set too high in an effort to avoid false activation, desired speech signals may be chopped or clipped. The threshold should be set high enough to avoid activation by random noises, but low enough to turn on with desired speech signals. These are frequently contradictory requirements, and compromise is generally not satisfactory.

A more serious problem is that any number of input channels may activate with a very loud talker. One solution is a first-on inhibiting circuit that permits only one input channel to be on at a time. One-on-at-a-time operation is generally unacceptable for conversational dialog because the hold time needed to cover speech pauses will keep the second talker off.

Fixed threshold automatic microphone mixers have fallen out of favor and are now rarely employed. Early examples of fixed threshold activation products include the Shure M625 Voicegate (1973), the Rauland 3535 (1978), the Edcor AM400 (1982), and the Bogen AMM-4 (1985).

21.3.4.2 Variable Threshold Automatic Microphone Mixers

One attempt at overcoming the problems of a fixed threshold is to set the activation threshold based on a signal from a remote microphone. This microphone would be located in an area that is not expected to produce desired program input and is presumed to provide a reference signal that depends on variations in room noise or reverberation. Any desired talker input must then exceed this level by some preset amount. It is assumed that the desired talker signal will be louder than the reference. However, this may not be true, especially when the reference signal from a randomly selected microphone location does not represent the ambient sound in the vicinity of the talker’s microphone.

The discontinued JBL 7510 automatic microphone mixer employed a variable threshold design to override a fixed threshold. This design assumed that if a common acoustical disturbance was sensed at several microphone input channels, an input channel should not be activated. Instead, the overall system threshold should be raised. A talker must then be loud enough at the microphone to override the new raised threshold. Both the fixed threshold and the contribution of the background threshold reference would be set at installation. Release time, input attenuation, and gain were also necessary adjustments for each input channel. Variations on this concept of variable threshold design have been used in automatic microphone mixers from Audio Technica, Biamp, IED, Ivie, Lectrosonics, and TOA.

The Biamp autoTwo Automatic Mixer, Fig. 21-17, includes adaptive threshold sensing to minimize false gate triggering, a speech frequency filter to minimize false gating due to noise, logic outputs from channels for switching external circuits, and 6 dB of hysteresis to reduce gate fluttering when near threshold. The block diagram is shown in Fig. 21-18.

21.3.4.3 Gain-Sharing Automatic Microphone Mixers

A gain-sharing automatic microphone mixer works from the premise that the sum of the signal inputs from
all microphones in the system must be below some maximum value that avoids feedback oscillation. The safe system gain is set relative to the sum of all microphone signals in the system. If one microphone has more signal than the average of all signals, then that microphone channel is given more gain and all the other channels less gain roughly in proportion to the relative increase of signal level.

Dugan's U.S. Patent 3,992,584 describes such a system where a 3 dB level increase at one microphone causes that channel gain to go up by 3 dB, while the gain of the other channels decreases by 3 dB. Speech from two persons talking into separate microphones with levels differing by 3 dB (both appreciably above the background level) would appear at the output of the system with a 6 dB difference. In other words, the signal from a microphone with the highest output is given the most gain, and a signal from a microphone with the smallest output is given the least gain. With this operational concept, NOMA is not needed in the output stage. Theoretically, the system is configured so that the total gain is constant at a level that safely avoids feedback oscillation.

Automatic microphone mixers marketed by Dugan, Lectrosonics, Protech Audio, and Altec Lansing have used level proportional control based on average input signal amplitudes, Fig. 21-19.

![Figure 21-18. Block diagram of Biamp autoTwo Automatic Mixer. Courtesy Biamp Systems.](image)

![Figure 21-19. Protech Audio automatic mixer. Courtesy Dan Dugan.](image)
21.3.4.4 Direction-Dependent Automatic Microphone Mixers

A direction-dependent automatic microphone mixer responds to signals having acceptable levels within a predefined physical space in front of a microphone. By making the decision as to whether a channel should be on depends on the relative signal levels at two back-to-back cardioid microphone capsules in a single microphone housing. The Shure AMS (automatic microphone system) responds in part to the location of the sound source. This mixer works only with its own unique two-capsule microphones.

When an AMS input channel is activated, the front facing microphone signal is transmitted to the mixer output. This mixer functions like a variable-threshold system with its threshold being a fixed level above the background ambient noise but with the threshold also being a function of the sound source location and its angular relationship to the microphone.

Any input channel may turn on when the signal level from the front microphone capsule is $9.5\,\text{dB}$ above the level from the rear capsule. Effectively, a SNE of $5\,\text{dB}$ to $7\,\text{dB}$ is required for a channel to activate. Of course, a weaker sound source will not activate the channel. The level difference of $9.5\,\text{dB}$ is derived from the criterion that a cardioid microphone response at $60^\circ$ off-axis is typically one-third of its on-axis response. The activation angle of the mixer input channel is thus $120^\circ$. A sound source outside of the $120^\circ$ angle will not activate an input channel no matter what the sound pressure level.

To keep the AMS microphones compatible with conventional shielded twisted pair cable while keeping the two microphone signals separated, an unbalanced signal path is used. This approach can be more susceptible to induced hum and noise pickup than a conventional balanced signal path. The use of current source preamplifiers in the microphone and unusually low impedance inputs in the mixer minimizes this potential problem.

It is recommended that an AMS microphone be installed within three feet of each talker, and the talker must be located within the $120^\circ$ activation angle. Each AMS microphone should also be at least three feet from any wall behind it and at least one foot from objects behind it such as books, large ashtrays, or briefcases. This precaution is necessary to avoid unwanted reflection of the talker’s acoustic signal into the rear facing microphone capsule. Stray acoustic reflections can lead to unreliable input activation.

As the direction-dependent automatic microphone mixer process is covered under U.S. Patent 4,489,442, this type of automatic microphone mixer has been marketed only by Shure. In 2000, U.S. Patent 6,137,887 was issued to Shure for a new AMS design. Developed by Anderson, this patent adds a circuit that guarantees a single talker will activate only a single input channel, even if that talker is within the activation angles of multiple AMS microphones, Fig. 21-20.

![Shure AMS8100 mixer. Courtesy Shure Incorporated.](image)

21.3.4.5 Noise-Adaptive Threshold Automatic Microphone Mixers

This concept employs a dynamic threshold unique for each input channel. Using an inverse peak detector, each input channel sets its own minimal threshold that continually changes over several seconds based on variations in the microphone input signal.

Sound that is constant in frequency and amplitude, like a ventilation fan, will not activate an input but will add to the noise-adaptive threshold. Sound that is rapidly changing in frequency and amplitude, like speech, will activate an input. The mixer activates an input when two criteria are met:

1. The instantaneous input signal level from the talker is greater that the channel’s noise-adaptive threshold.
2. The input channel has the maximum signal level for that talker.

Without this second criterion, a very loud talker might activate more than one input channel.

Note that this system deems any sound that is relatively constant in frequency and amplitude as nonspeech. Sustained musical notes may activate an input on attack, but after several seconds the sustained note will raise the threshold and the input will be attenuated. As previously stated, automatic microphone mixers are designed primarily for speech applications, not music.

Developed by Julstrom and covered by the U.S. Patent 4,658,425, the noise-adaptive threshold configuration has been used in automatic microphone mixers.
21.3.4.6 Multivariable-Dependent Automatic Microphone Mixers

The automatic microphone mixer methods described so far essentially use input signal amplitude as the activation variable. The relative timing of signals at each input is another variable that can be employed. A multivariable-dependent system makes its activation decision from both input signal amplitude and the time sequence of the input signals.

Peter’s U.S. Patent 4,149,032 is such a design. The instantaneous positive signal amplitudes of all inputs are simultaneously compared to a threshold voltage (dc ramp) that falls 80 dB in 10 ms (or less) from a high value to a low value. Initially, all input channels are held in an attenuated state. The first input channel that has an instantaneous amplitude equal to the instantaneous value of the falling threshold is activated, while the other inputs remain attenuated. This activated channel remains so for 200 ms.

Once an input channel is activated, the threshold voltage is reset to its high value and immediately starts to fall again in search of another input to activate. If all talkers are silent and an amplitude match is not found, the threshold search progresses the full 80 dB in 10 ms and then resets. However, this scenario is not typical. Most of the time, a signal on one of the inputs will produce a threshold amplitude match early in the search. In practice, the average input activation time is 3 or 4 ms. Since the threshold resets every time an input is activated, the frequency of the threshold searches will be also every 3 or 4 ms on average.

As mentioned, the input activation is maintained for 200 ms. If on the second search the same input still has the largest signal amplitude, its activation status is renewed for another 200 ms. If during a future threshold search, a different input channel has the higher amplitude, it is activated for 200 ms. The first input activated times out and attenuates if not reactivated by a future search within the 200 ms. As long as a talker keeps speaking, his input is continually renewed for 200 ms intervals. This rapid response enables conversational dialog to be conducted and also permits easy activation of weaker sound sources during gaps in speech.

Since the activation gain of all input channels is the same, any signal source on an active channel has the same gain, and the relative levels of different talkers is preserved in the mixer output.

When multiple talkers vie for access to the system, the probability of all of them obtaining access decreases in proportion to the number. This effectively limits the maximum number of input channels that can be activated at any given time. For example, ten equally loud talkers will each be on 88% of the time. But as more than three or four persons talking at the same time is not intelligible, this limitation is normally of little consequence.

Also unique to the Peters design is the variable known as the access ratio. Simply put, the access ratio manufactured by Shure, including the now obsolete FP410 battery-operated portable mixer, Fig. 21-21.
is the time an input is kept activated (200 ms) compared to the decision time taken to activate an input (10 ms). Access ratio may be readjusted to control the number of input channels that can activate at one time. Selective adjustment of the access ratio can also reduce missed beginnings of words.

21.3.4.7 Automatic Microphone Mixers with Matrix Mixing to Multiple Outputs

Recent designs in automatic microphone mixers have introduced matrix mixing to multiple outputs. This feature allows any input channel to be sent to any number of output channels and to be sent at different levels depending on the signal mix desired at the individual output. The Lectrosonics AM16/12 is a marriage of analog with digital. All control is accomplished via proprietary software that operates on a Windows-based computer. Software control allows a 16 in/12 out automatic microphone mixer with matrix mixing to fit in a two-rack space chassis. The software control also deters unauthorized readjustment as there are no knobs to twiddle.

Matrix mixing may be used for creating unique audio feeds for recording, teleconferencing, hearing assistance, language translation, etc. A courtroom is an example of a facility where all of these different audio systems might be required. Matrix mixing also provides the capability for mix-minus configurations. Simply put, a mix-minus output signal contains all input channels except for one or more—i.e., complete mix of all inputs minus one (or more) undesired inputs. The mix-minus concept improves gain before feedback. If a microphone signal does not appear in the closest loudspeaker, gain before feedback is better than if the microphone signal does appear in that loudspeaker. In a typical meeting room, talkers do not need to hear their own voice in the closest loudspeaker. They need to hear their other talkers located far away from their location. Mix-minus provides this capability, Fig 21-22.

However, matrix mixing also creates a problem—how to adjust so many gain variables? Consider an automatic microphone mixer with twelve inputs and one output. This mixer requires thirteen gain controls—one for each input and one for the master output. Now consider an automatic microphone mixer with 12 inputs and 8 outputs. This mixer requires 104 gain controls. One hundred four potentiometers and knobs take up a lot of panel space and are quite expensive. The answer to this problem is control via software. One example of this design concept is the Lectrosonics AM16/12.

21.3.4.8 Automatic Mixing Controller

The Model E-1 Automatic Mixing Controller, Fig. 21-23, helps professional audio mixers handle multiple live mics without having to continually ride their individual faders. This eight-channel signal processor patches into the input insert points of an audio mixing console. It detects which mics are being used and makes fast, transparent cross-fades, freeing the mixer to focus on balance and sound quality instead of being chained to the faders. The Model E-1’s voice-controlled cross-fades track unscripted dialogue perfectly, eliminating cueing mistakes and late fade-ups while avoiding the choppy and distracting effects common to noise gates. Without the need for gating, a natural low-level room ambience is maintained.

Dugan automatic mixing controllers are used with multiple live mics and unscripted dialogue including talk shows, game shows, conference sound reinforcement, houses of worship, dramatic dialogue, wireless microphones in theaters, and teleconferencing. The Dugan controllers are typically connected in the insert points of the console’s mic inputs, Fig. 21-24. Fig. 21-25 is the block diagram of the E-1 automatic mixing controller. Each unit handles up to eight channels, and the units can be linked together to accommodate a maximum of 64 mic channels.

The Model E-1 is an eight-channel line-level or ADAT digital insert device in a half-rack, one unit high cabinet and has minimal controls. Additional controls are available via a virtual control panel provided by an embedded web server. I/O is connected by TRS insert cables or ADAT optical cables. The Model E can be linked for up to 64 channels, and it can link with the Dugan Models D-2 and D-3. Power is 9–24 Vdc or 9–18 Vac.

Three models are available. The Model D-2 has analog I/O for use in the insert points of analog mixing consoles. The Model D-3 has AES digital connections for insertion into digital mixers. Both models feature a separate control panel that can be placed on the meter bridge or in front of the console.

21.3.4.9 Automatic Microphone Mixers Implemented in Software

If software can control automatic microphone mixer hardware, then automatic microphone mixers can also be completely created in software. This completely digital approach to automatic microphone mixers can be found in software based products offered by Allen & Heath, ASPI, BSS, Crown, Dan Dugan, Gentner, Lectrosonics,
Figure 21-22. Block diagram of the Lectronics AM1612 mixer.
Peavey, and Rane. To date, the operational concepts used in digital automatic microphone mixers have not varied far from the previously described concepts underlying the analog automatic microphone mixers. This is likely to change, but as future digital automatic mixing concepts will be hidden deep within computer code, the manufacturers may be unwilling to reveal the details of operational breakthroughs; they will likely be kept as closely guarded company secrets. New concepts in automatic mixing might only become public knowledge if patents are granted or technical papers are presented.

The Polycom Vortex EF2280, Fig. 21-26, automatically mixes microphones and other audio sources while canceling acoustic echoes and annoying background noise. It is used in boardrooms, courtrooms, distance learning, sound reinforcement, and room combining. It connects easily to other equipment including codecs, VCRs, or other A/V products. The unit can be programmed from the front panel, or through Conference Composer™ software (included). Conference Composer’s Designer™ wizard ensures fast, accurate setup for a variety of applications.

A single Vortex EF2280 unit provides automatic mixing of up to eight microphones plus four auxiliary audio sources. Up to seven additional Vortex EF2280 or Vortex EF2241 units can be linked to the first unit. (NOM) information can be specified across all channels in the linked units. The microphone channels feature acoustic echo cancellation to prevent retransmission of signals to their original locations. A neural network AGC reacts only to valid speech patterns, bringing voices within desired levels. AGC controls are user adjustable, as are settings for the five-band parametric EQ offered on all input and output channels and output delay controls. Fig. 21-27 is the block diagram of the Vortex EF2280.

21.3.4.10 Which Type of Automatic Mixer Works Best?

There is no definitive answer to this question. It is impossible to tell which automatic microphone mixer design will operate best in a given situation by studying technical specifications, believing the marketing literature, poring over circuit schematics, deciphering lines of computer code, or rereading this chapter. Human speech is very complex and human hearing is very discerning. Like so many areas in professional audio, the critical ear is the final judge.

21.3.5 Teleconferencing and Automatic Microphone Mixers

Automatic microphone mixers are used in many teleconferencing systems. The design of such systems involves a number of complex issues that do not enter into the design of sound reinforcement systems. This section will discuss important design aspects of such installations.

As practiced in modern communication between separated groups of talkers, teleconferencing has two components—visual and aural. The visual is handled by television cameras, video monitors, and video projectors. The visual may be full motion in real time, slow scan, or single-frame presentation.

It is appropriate to identify the aural part of the teleconferencing system as the audio conferencing system. Considerable attention must be paid to a number of details for acceptable sound quality, intelligibility, and user comfort. Users of teleconferencing systems tend to
employ very subjective descriptions that have to be interpreted into quantitative engineering terms that can then be applied, measured, and included in system designs. Teleconference participants expect good speech intelligibility, easy identification of the talker, relatively high SNR, and other qualities. They also expect the overall aural experience to be better than a conversation conducted via telephone handsets.

An audio conferencing installation for voice and program has four primary facets:

1. Conference room and building acoustics.
2. Interface with telephone/transmission system.
3. Possible secondary use as a sound reinforcement system.
4. Proper equipment selection and setup.

### 21.3.6 Room and Building Acoustics

#### 21.3.6.1 Conference Room Noise

The first consideration for a teleconference installation is noise in the room. Obvious noise sources, like heating and air conditioning systems, should be evaluated and specified for acceptable levels. External noise must also be considered:

- Conversations in hallways or adjacent offices.
- Business machines in adjacent spaces.
- Elevators on opposite sides of the wall.
- Water flow in building services.
- Vibration of air conditioners on the roof.
- Loading docks

There will also be unwanted noise generated in the conferencing room itself:

- Fans in projectors and computers.
- Hum from light fixtures.
- Paper shuffling.
- Moving chairs.
- Coughing.
- Side conversations.

All of these undesired sound sources are much more obvious, annoying, and detrimental to intelligibility at the remote site of the teleconference than they are in the local site where they originate. Also, as the number of participants increases, the geographic area covered by the participants expands and unamplified speech becomes harder to hear due to greater distances between the talkers and the listeners. Consequently, for comfortable talking and listening, the ambient noise level in a room must be lower for larger groups.

Table 21-1 provides recommended noise level limits for conference rooms. These are levels at the conference.
table with the room in normal unoccupied operation and at least 2 feet from any surface. Methods for achieving low interfering noise levels are discussed in Chapter 6, Small Room Acoustics.

More accurate assessment will result if noise criteria (NC) are used because of the strong influence of frequency spectrum on speech interference and listener annoyance (see Chapter 5, Acoustical Treatments for Indoor Areas).

Fig. 21-28 shows the maximum microphone/talker distance for a marginally acceptable SNR of 20 dB in transmitted speech. The graph applies to omnidirectional microphones. The distance may be increased by 50% for directional microphones. If more than one microphone is active in the system, the number of open microphones must be taken into account by reducing the predicted SNR by 3 dB for each time the number of open microphones doubles. An automatic microphone mixer will alleviate this concern.

If an acoustical survey indicates the presence of interfering noise sources, construction techniques must be implemented to provide adequate sound transmission losses, or another room should be considered.

21.3.6.2 Conference Room Reverberation

Reverberation is often identified by conference participants as the “speaking into a barrel” effect. The sources of reverberation are variable. For example, there is the reverberation from hard surfaces in the room where
speech is originating at the moment. Requirements for comfortable listening in the room dictate reverberation times that are not too short, as a bit of acoustic liveliness in a meeting room is desirable. If an automatic microphone mixer is not employed to reduce the reverberation picked up by unused microphones, the reverberation heard at the remote site of the teleconference can be excessive and intolerable. In this situation, a very low (and uncomfortable) reverberation time at the local site is required. The potential for reduced intelligibility at the remote site is increased because the remote participants do not have the advantage of separating the speech signal from the reverberation via binaural hearing, plus not having the talker in the same room also tends to dull one’s attention.

There is also the reverberation added at the remote site. The incoming signal is reproduced by loudspeakers, the sound propagates around the room, and even more reverberation is added to the talker’s signal. So, unless there is only a telephone handset at the remote site, both sites need to have proper acoustical characteristics. This is often not the case as in many conferencing rooms the visual comfort of the room takes precedence over the aural comfort. Just ask the interior designer!

Room dimensions should be chosen to minimize standing waves and flutter echoes. If the room already exists, judicious use of acoustically absorbent material is advisable for control of the room’s acoustics.

Critical distance ($D_c$) is often used to predict appropriate talker to microphone distances. $D_c$ is where the direct signal of the talker is equal to reflected signal of the talker, i.e., 50% direct signal and 50% reverberant signal. The $D_c$ in conference rooms is typically in the range of 1–4 feet. $D_c$ may be estimated from reverberation time measurements:

$$D_c = 0.03\frac{V}{T} \tag{21-5}$$

where,

$D_c$ is the critical distance in feet,

$V$ is the room volume in ft$^3$,

$T$ is the reverberation time in seconds for 60 dB decay.

For good intelligibility, an omnidirectional microphone should be placed at $\frac{1}{2}$ of $D_c$ or less from the talker. When a directional microphone is used, the distance between talker and microphone may be increased up to 75% of the critical distance.

Because the sound decay in the first 60–100 ms usually is the most damaging to teleconference conversations, the usual reverberation time measurement, $RT_{60}$, may not be the most appropriate. One manufacturer of conference equipment insists that the room produce a decay of greater than 16 dB in the first 60 ms.

The one admonition to anyone faced with the design of a teleconferencing system is do not ignore the acoustical characteristics of the room. Insist upon a room that has the right acoustical environment or commit the resources to make it right before proceeding with the rest of the project. Acoustical deficiencies can rarely be corrected by electronic means. If it is new construction, work closely with the architect before the room design is complete.

### 21.3.6.3 Telephone/Transmission System Interface

Fig. 21-27 shows two teleconference rooms connected by a single two-wire telephone line. Each room has a

microphone and a loudspeaker with associated amplification. A hybrid interface between the send and receive lines and the telephone line serves to reduce loop gain within the room by reducing sidetone leakage.

Possible feedback loops are shown. Not only is there potential oscillation in the sending room, but also the coupling through the line to the receiving room and back is an equally probable feedback loop. Basic speakerphones use voice-activated gates to capture the line and permit transmission in only one direction at a time and thus interrupt the feedback path from the remote site. This can cause frequent dropouts in a conversation and forces the communication into a half-duplex mode of operation. Half duplex transmission refers to transmission in only one direction at a time.

The ideal is full duplex, which allows transmission in both directions all the time. A phone call from telephone handset to telephone handset provides full duplex communication. Full duplex is preferred for audio conferencing because there are no missing words or sentences, and conversations can be conducted in a normal manner. Control of reverberation and room noise is essential in any full duplex system.

An alternative connection system uses four wires as shown in Fig. 21-28. One pair of wires is used for each direction of transmission, thus eliminating the often troublesome hybrid sidetone leakage. As can be seen, there is still the possibility of feedback through the room at either end. However, there is usually cleaner signal transmission with the added expense of a second telephone line. Four-wire systems make full duplex communication possible.

Frequently audio conferences involve several sites giving rise to point-to-multipoint or multipoint-to-multipoint telephone interconnections. A conference bridge is used to connect a number of telephone lines so that all participants will be tied together. Bridging over 20 phone lines is now quite common. The actual bridging may be provided by an external bridging service company or bridging devices may be part of the on-site teleconferencing equipment.

A typical conference bridge limits the number of open ports to two because signal leakage in the bridge can cause retransmission of received audio on telephone lines. As a result, only one two-way conversation can occur and others can only listen. Also, the uncertain and variable quality of telephone connections can result in having a noisy line tying up the system and preventing access since the bridging control depends on signal-activated switching.

21.3.7 Teleconferencing Equipment

21.3.7.1 Telephone Interface

The telephone interface for a typical two-wire site is the hybrid. It converts the two-wire transmission of the connecting lines to internal four-wire paths to isolate the send and receive signals. A hybrid passes the microphone send signal (two of the four wires within the room) to the two-wire telephone line but attenuates it to the receive line. Conversely, a signal being received from the telephone line passes to the receive line (the other two of the four wires in the room) and is attenuated to the microphone send line. For many years, the hybrid in a standard telephone set was a transformer; now electronic equivalents are common.
The conference bridge operates in a similar manner. Good balance in both the bridge and the hybrid is necessary. This involves well-controlled and constant telephone impedance. Unless these devices can adapt to variable telephone line conditions, signal leakage may be retransmitted through them. If the boardroom has not been correctly treated acoustically, the combination of room echo and signal leakage creates an undesired feedback path. Many hybrids suppress leakage by less than 15 dB whereas 35 dB to 40 dB is regarded as the minimum acceptable for loudspeaker receive conference installations. The paths of signal leakage are shown in Fig. 21-31. Active hybrids are supplied by manufacturers such as Gentner Electronics, ASPI, and Telos. These products provide means for optimizing the impedance match to the telephone line, thereby giving additional suppression of signal leakage. Active hybrids can make the difference between a marginal and an acceptable teleconference.

Figure 21-31. The paths for signal leakage and undesired feedback in a typical teleconference system.

Typical telephone line impedances range from 600 Ω to 900 Ω. Telephone equipment expects send levels of 0 dBm. The receive level standard is −6 dBm, but these levels are reported to vary widely, −10 dBm is frequently experienced. The standard telephone line has 48 Vdc (some private exchanges use 24 Vdc) for system control that must be blocked with a transformer or capacitors. The dc current through the off-hook relay keeps the line open while the connection is active.

21.3.7.2 Microphone Considerations

For a small group in a conference room, it may be possible to use only one omnidirectional microphone on a table top, typically of the surface-mount type. However, even for a group of four to six people, the equivalent of several directional microphones with an automatic microphone mixer is preferred to reduce the number of open microphones to the minimum necessary for the discussion. Three cardioid microphones in a circle, spaced at 120° intervals, is a typical approach. There are a number of surface-mount microphones that can be used, provided that the distance to the talkers is acceptably short. The typical participant in a teleconference expects, at minimum, the sound quality heard from a handset where the microphone is within inches of the talker’s mouth. Thus, keeping the microphones close to the talkers is very important.

21.3.7.3 Microphone Mixing

Larger groups inevitably require a large number of microphones to keep the participant-to-microphone distance within the limits set by the room’s critical distance. Some form of automatic microphone selection and mixing is essential in this case. Systems can be designed using an automatic microphone mixer (as described earlier in this chapter) connected to a telephone line interface device. Or a system can be implemented using an integrated device where the automatic mixing and the telephone interface are contained in the same chassis. Depending on the complexity required, there are many suitable approaches to system design. Consult the equipment manufacturers for specific design suggestions, Fig. 21-32.

Figure 21-32. The configuration of a multimicrophone audio conference installation, without sound reinforcement.

21.3.7.4 Loudspeaker Considerations

Direct feedback from loudspeakers to microphones in any of the conference sites must be avoided; therefore, loudspeaker placement is critical. Loudspeakers should be placed in the null of the microphone pickup patterns. For cardioid microphones pointing in a horizontal direction, loudspeakers can be placed behind the microphones
and aimed upward. Never place loudspeakers in front of microphones as microphones cannot distinguish between talkers in the room (desired sound sources) and talkers heard via loudspeakers (undesired sound sources).

When there is talking in the room, automatic microphone mixers can reduce the level of the loudspeaker signal from the remote site. This is accomplished via attenuating relays, ducking circuits, etc. By contrast, Sound Control Technologies offers a system that places the loudspeaker symmetrically between a pair of microphones that are out of polarity with each other. The loudspeaker contribution to the send line is claimed to be reduced by 40 dB with this arrangement.

If sound reinforcement of conversations within the room (sometimes known as voice lift) must also be provided in addition to audio conferencing, even more attention must be given to reducing the audio coupling between the loudspeakers and the microphones. Such systems can be very difficult to design correctly and must be approached with great caution. The use of an experienced acoustical/audio consultant is highly recommended in these cases.

### 21.3.7.5 Send Level Control

Send level—i.e., the audio signal voltage supplied to the telephone line—should be within acceptable ranges. Compressors, AGCs and levelers are all devices to consider for this technical requirement.

### 21.3.7.6 Echo Canceler

Echo cancellers reduce residual echo return in audio conferencing installations. If the local site returns significant signal from its incoming port to its outgoing port, and there is significant propagation delay due to the transmission line, the remote site will hear an annoying echo when someone in the remote site speaks.

The imperfect balancing of hybrids is one path for echo. Signal reflection within the telephone line is another source of echo. Echo also occurs acoustically when loudspeaker sound reaches open (active) microphones that are transmitting speech. The use of satellite transmission links also makes echo problems worse because of the long propagation delays.

A line echo canceler attempts to reduce echoes that are electronic in nature, such as those caused by hybrid leakage. An acoustic echo canceler looks at the signal coming into a room and inserts a time-delayed mirror image of the incoming signal into the outgoing signal leaving the room. The idea is to cancel any of the incoming signal that leaks into the outgoing signal path as a result of the acoustical coupling between loudspeaker and microphone.

Echo canceler technology has rapidly advanced due to faster CPU speeds and new research into canceler algorithms. Early echo cancelers were very expensive and thus having a single canceler at each conferencing site was considered adequate. As the price of echo cancelers has declined, manufacturers such a Gentner and ASPI now offer devices that have an echo canceler for each microphone input channel.

### 21.3.7.7 Historical Examples of Teleconferencing Equipment

Two historical systems will be described in more detail in order to show the number of parameters that must be considered in addition to the usual sound reinforcement needs. The first is an automatic microphone mixer approach as exemplified by the Shure ST3000, first manufactured in the 1980s. The second is the Sound Control Technologies system that does not use automatic microphone mixing.

**Shure ST3000—An Analog Speakerphone.** A simplified block diagram of the ST3000 is shown in Fig. 21-33. A conference call connection is made by taking the telephone handset from its cradle and dialing the desired number. When it is determined there is a good connection with the dialed party, the controller conference switch can be depressed to turn on the conference system. Green talk LEDs turn on and the handset may be returned to its cradle. The controller loudspeaker volume may next be adjusted if necessary. Levels for any auxiliary equipment may also be adjusted. Use the mute switches to prevent the called party from hearing local conversation. Red LEDs indicate muted status. The conference is terminated by depressing the controller telephone switch for at least 1 second.

In Fig. 21-33, the upper left mixer amplifier feeds the various auxiliary outputs. Below this amplifier, the conference microphone inputs are shown. Only the mutable (i.e., for automatic mixing) microphone inputs feed the send signal path to the hybrid. The receive path leads to the power amplifier and loudspeaker. Relative send and receive signals in the room are controlled by the send/receive switching and suppression logic. The suppression logic causes either the send amplifier or the receive amplifier to attenuate its signal depending on the presence of a receive signal. Because standard voice quality telephone lines have restricted bandwidth requirements, bandpass filtering is included in the send
Preamplifiers and Mixers

Bandpass filtering in the receive channel reduces the possibility of extraneous noise from the telephone line.

In the early 1990s, digital technology replaced analog devices such as the Shure ST3000. Polycom is now one of the prime suppliers of digital, full duplex speakerphones.

Sound Control Technologies Ceiling Systems. Two configurations have been supplied by Sound Control Technologies. L oudspeakers and microphones are mounted in the ceiling over the conference participants. In one configuration, two loudspeakers are driven in antiphase (180° out of polarity) and a small microphone is mounted midway between them. Direct sound from the loudspeaker to the microphone is balanced for a null of 20 dB for receive signals. The basic element is shown in Fig. 21-34.

The second configuration uses a microphone and a loudspeaker mounted precisely 12 inches apart in reflecting baffle ceiling-mounted panels. Pairs of these loudspeaker/microphone units are placed above the conference table. All loudspeakers are driven in the same phase, while the microphones of symmetrically located units are mixed and balanced antiphase. A block diagram of such a system is shown in Fig. 21-35.

The microphone signals being mixed and balanced in antiphase feed the bus from which both the sound reinforcement (voice lift) and telephone send signals are derived. Notch filters are used for adjustment of spectrum balance. Delay may be included in the reinforced sound feeds if the room is large. The telephone return signal also feeds the sound reinforcement loudspeakers. An echo canceler is included to reduce the effects of telephone line echo or room acoustic echo.

As with the Shure system described previously, a telephone connection is made with a handset. Upon completion of the connection, the status of the line is determined by transmission of a group of tone bursts that allows the hybrid to electronically balance for the complex impedance of the telephone line. A push-button switch converts the connection to conference and the handset may be placed in its cradle.
21.3.7.8 The Present and Future of Teleconferencing

Most basic teleconference systems are sophisticated speakerphones with full duplex capability. Mid-level teleconferencing systems employ automatic microphones mixers and digital hybrids. The most sophisticated systems feature integrated teleconferencing devices that include multiple inputs with automatic mixing and echo cancellation, mix-minus signal routing capability, real-time feedback and level control, and operation via touchscreen.

Personal computers and digital signal processing (DSP) are becoming the dominant technologies that drive new developments in teleconferencing.

DSP advances are leading to teleconferencing systems that provide each participant with a customized electro-acoustical environment, unique to his or her own talking and hearing requirements. Advances in background noise reductions via electronic means are already impressive, as long as the noise has a repetitive nature. Microphone arrays that can be steered to best pick up a talker and steerable loudspeaker arrays are more prevalent.

But no matter how dominant digital technology becomes in teleconferencing, the speech input to the system from the human mouth will be analog, and the acoustical output to the human ear will also be analog. And that is the only technology forecast that will be 100% accurate.

22.1 General

Most of the circuits today do not require passive attenuators and/or impedance matching devices as their input impedance is high and their output impedance is low. However, if a low-impedance output feeds a long line to a high-impedance input, high-frequency losses will occur if the line is not terminated with a matched impedance. This may be thousands of feet or a few feet when using older equipment that was designed for matched operation. When connecting to external circuits, the signal must often be attenuated to meet standards, a good place for low-maintenance passive attenuators.

An attenuator or pad is an arrangement of noninductive resistors in an electrical circuit used to reduce the level of an audio- or radio-frequency signal without introducing appreciable distortion. Attenuators may be fixed or variable and can be designed to reduce the signal logarithmically or any other curve.

Attenuator networks have been in use since the inception of the telephone for controlling sound levels and the matching of impedances. Many of the present-day configurations are the work of Otto J. Zobel, W. H. Bode, R. L. Diezold, Sallie Pero Mead, and T. E. Shay, all of the Bell Telephone Laboratories. Also, tables of constants developed by P. K. McElroy (also of Bell Telephone Laboratories) for various values of expression and substitution in equations have long been time-savers for the design engineer.

Attenuators and pads may be unbalanced or balanced. In an unbalanced attenuator, the resistive elements are on one side of the line only, Fig 22-1. In the balanced configuration, the resistive elements are located on both sides of the line, Fig. 22-2.

An unbalanced pad should be grounded to prevent leakage at the higher frequencies. The line without the resistor elements, called the common, is the only line that should be grounded. If the side with the resistors is grounded, the attenuator will not work properly, in fact, the signal will probably be shorted out.

A balanced attenuator should be grounded at a center point created by a balancing shunt resistance.

Balanced and unbalanced configurations cannot be directly connected together; however, they may be connected by the use of an isolation transformer, Fig. 22-3. If the networks are not separated electrically, half of the balanced circuit will be shorted to the ground, as indicated by the broken line in Fig. 22-4. Here severe instability and leakage at the high frequencies can result. The transformer will permit the transfer of the audio signal inductively while separating the grounds of the two networks. Even if the balanced network is not grounded, it should be isolated by a transformer. Transformers are usually designed for a 1:1 impedance ratio; however, they have taps for other impedance ratios. Chapter 32, Grounding, discusses the proper way to connect equipment to eliminate ground problems.

22.1.1 Attenuator K Value
K = 10

To simplify the design of complex attenuators, a K
value is used in the equation. K is the ratio of current,
voltage, or power corresponding to a given value of
attenuation expressed in decibels. The equation for K is
K = 10

dB
------20

dB
------10

(22-2)

To simplify the calculation of attenuator networks,
the values of the most frequently used expressions as
tabulated by P. K. McElroy are given in Table 22-1. The
various values of the expressions are substituted in the
equations, saving much time.

22.1.2 Loss

The term loss is constantly used in attenuator and pad design. Loss is a decrease in the power, voltage, or current at the output of a device compared to the power, voltage, or current at the input of the device. The loss in decibels may be calculated by means of one of the following equations:

\[
\begin{align*}
\text{dB}_{\text{loss}} &= 10 \log \frac{P_1}{P_2} \\
\text{dB}_{\text{loss}} &= 20 \log \frac{V_1}{V_2} \\
\text{dB}_{\text{loss}} &= 20 \log \frac{I_1}{I_2}
\end{align*}
\]

where,

- \( P_1 \) is the power at the input,
- \( P_2 \) is the power at the output,
- \( V_1 \) is the voltage at the input,
- \( V_2 \) is the voltage at the output,
- \( I_1 \) is the current at the input,
- \( I_2 \) is the current at the output.

The insertion loss is created by the insertion of a device in an electrical circuit. The resulting loss is generally expressed in decibels.

A minimum-loss pad is a pad designed to match circuits of unequal impedance with a minimum loss in the matching network. This minimum loss is dependent on the ratio of the terminating impedances.

The minimum loss for attenuators of unequal impedance may be read from the graph in Fig. 22-5. The graph is entered at the bottom at the desired impedance ratio and then followed vertically until it intersects the diagonal line. The minimum loss in decibels is then read at the left margin. For instance, assume an impedance of 600\( \Omega \) is to be matched to an impedance of 150\( \Omega \); this is an impedance ratio of four. For this ratio, the graph indicates a minimum loss of 11.5 dB, which is the lowest value for which a passive attenuator can be designed. In actual practice the network would be designed for a loss of 12–15 dB.

22.1.3 Impedance Matching

An impedance-matching network is a noninductive, resistive network designed for insertion between two or more circuits of equal or unequal impedance. When properly designed, the network reflects the correct
impedance to each branch of the circuit. A noninductive resistor is a resistor having little or no self-inductance.

If two resistive networks are mismatched, generally the frequency characteristics are not affected; only a loss in level occurs. If the impedance mismatch ratio is known, the loss in level may be directly read from the graph in Fig. 22-5 or with the equation

$$\text{dBloss} = 20\log\left(\frac{Z_1}{Z_2} + \frac{Z_1}{Z_2} - 1\right) \quad (22-6)$$

where,

- $Z_1$ is the higher impedance in ohms,
- $Z_2$ is the lower impedance in ohms.

The equation used for designing a minimum-loss attenuator when only the larger impedance $Z_1$ is to be matched is

$$R_1 = Z_1 - Z_2 \quad (22-7)$$

Only a series resistor $R$ is used, Fig. 22-6.

If the smaller impedance is to be matched, use the following equation

$$R = \frac{Z_1Z_2}{Z_1 - Z_2} \quad (22-8)$$

The resistor is shunted across the line, Fig. 22-7.

**22.1.4 Installations, Practices, and Measurements**

It is not good practice to build pads of over 40 dB loss unless special precautions are taken to reduce the distributed capacity and leakage between the input and output sections. It is more practical to build two or more pads of lower loss and connect them in tandem. The total loss is the sum of the individual losses, assuming that all impedance matches are satisfied between sections.

$$R \mid Z_{\text{in}} = Z_1 \quad \text{ZLoad} = Z_2$$

**Figure 22-6.** Impedance matching a low-impedance load to a high-impedance source.

When installing attenuators, the input and output circuits must be separated from each other and well shielded and grounded to prevent leakage at the higher frequencies. As an example: an attenuator of 40 dB loss has a signal voltage reduction of 100:1 between the input and output terminals. Therefore, if coupling between the input and output circuits is permitted, serious leakage can occur at frequencies above 1000 Hz.

The resistance of an attenuator can be measured with an ohmmeter by terminating the output with a resistance equal to the terminating impedance and measuring the input resistance. The resistance as measured by the ohmmeter should equal the impedance of the pad. If the attenuator is variable, the dc resistance should be the same for all steps.

If the impedance of an attenuator is not known, its value can be determined by first measuring the resistance looking into one end with the far end open and then shorted. The impedance ($Z$) is the geometric mean of the two readings

$$Z = \sqrt{Z_1Z_2} \quad (22-9)$$

where,

- $Z_1$ is the resistance in ohms measured with the far end open
- $Z_2$ is the resistance in ohms measured with the far end shorted.

This measurement will hold true only for pads designed to be operated between equal terminations. If
the dc resistance of the two ends differs, the pad was designed to be operated between unequal impedances.

If an attenuator is to be converted to a different impedance, the new resistors can be calculated by

\[ R_x = \frac{Z_x R}{Z} \]  
\[ (22-10) \]

where,
- \( Z_x \) is the new impedance in ohms,
- \( Z \) is the known impedance in ohms,
- \( R \) is the known value of resistance in ohms,
- \( R_x \) is the new value of resistance in ohms.

Any balanced or unbalanced attenuator may be directly connected to another, provided the impedance match is satisfied and the configurations are of such nature they will not cause an unbalanced condition. Fig. 22-8A shows how an L, a bridged-T, and a plain-T pad may be connected in tandem. In Fig. 22-8B the method of connecting balanced attenuator configurations in tandem is shown.

### 22.2 Types of Attenuators

#### 22.2.1 L Pads

L pads are the simplest form of attenuator and consist of two resistive elements connected in the form of an L, Fig. 22-9. This pad does not reflect the same impedance in both directions. An impedance match is afforded only in the direction of the arrow shown in the figures. If an L-type network is employed in a circuit that is sensitive to impedance match, the circuit characteristics may be affected. An L-type network should not be used, except where a minimum loss is required and a network of the T configuration will not serve because its minimum loss is too high.

For unequal impedances, the impedance match may be in the direction of the larger or the smaller impedance but not both.

If the network is designed to match the impedance in the direction of the series arm, the mismatch is toward the shunt arm. The mismatch increases with the increase of loss, and, at high values of attenuation, the value of the shunt resistor may become a fraction of an ohm, which can have a serious effect on the circuit to which it is connected.

The configuration for an L-type network operating between impedances of unequal value, \( Z_1 \) and \( Z_2 \), is shown in Fig. 22-9A. The impedance match is toward the larger of the two impedances, \( Z_1 \), and the values of the resistors are

\[ R_1 = \frac{Z_1}{S} \left( \frac{K S - 1}{K} \right) \]  
\[ (22-11) \]

\[ R_2 = \frac{Z_1}{S} \left( \frac{1}{K - S} \right) \]  
\[ (22-12) \]

where,
- \( S = \frac{Z_1}{\sqrt{Z_2}} \).

The value of \( K \) is taken from Table 22-1.

For a condition where the impedances are equal and the impedance match is in the direction of the arrows, Fig. 22-9B, the values of the resistors may be calculated by the equation:

\[ R_1 = Z(i) \]  
\[ (22-13) \]

\[ R_2 = Z(l) \]  
\[ (22-14) \]

The values of \( i \) and \( l \) are taken from Table 22-1.

When the impedances are unequal and the impedance match is toward the smaller of the two impedances, Fig. 22-9C, the values of the resistors are determined by the equations

\[ R_1 = \frac{Z_1}{S} (K - S) \]  
\[ (22-15) \]

\[ R_2 = \frac{Z_1}{S} \left( \frac{K}{K S - 1} \right) \]  
\[ (22-16) \]

where,
- \( S = \frac{Z_1}{\sqrt{Z_2}} \).

For the conditions shown in Fig. 22-9D, resistors \( R_1 \) and \( R_2 \) are calculated by

\[ R_1 = Z(K - 1) \]  
\[ (22-17) \]

\[ R_2 = Z(l) \]  
\[ (22-18) \]

The values of \( K \) and \( l \) are taken from Table 22-1.

If a minimum-loss, L attenuator is used to match two impedances of unequal value, as in Fig. 22-9A, the resistor values will be

\[ R_1 = \sqrt{Z_1(Z_1 - Z_2)} \]  
\[ (22-19) \]
where, \( R_1 \) is the series resistor in ohms connected on the side of the larger impedance; \( R_2 \) is the shunt resistor in ohms.

The loss through the attenuator will be

\[
\text{dB}_{\text{loss}} = 20\log \left( \frac{Z_1}{Z_2} \right)
\]

**22.2.2 Dividing Networks**

*Dividing or combining networks* are resistive networks designed to combine several devices or circuits, each having the same impedance, Fig. 22-10A. The resistors may be calculated with the equation

\[
R_B = \frac{N - 1}{N + 1} Z
\]

where,

- \( R_B \) is the build-out resistor in ohms,
- \( N \) is the number of circuits fed by the source impedance,
- \( Z \) is the circuit impedance in ohms.

The loss of the network is

\[
\text{dB}_{\text{loss}} = 20\log(N - 1)
\]

where,

- \( N \) is the number of input or output circuits.

Unused circuits of a dividing or combining network must be terminated in a resistive load equal to the normal load impedance.

This same circuit can be reversed and used as a combining network. This circuit was often used in the design of sound mixers.

Combining or branching networks may also be designed as a series configuration, Fig. 22-10B. For equal impedances the equation is
where,

\( R_1 \) is the terminating resistor in ohms,

\( N \) is the number of branch circuits,

\( Z \) is the circuit impedance in ohms.

**The insertion loss may be calculated:**

\[
20 \log(N - 1) = dB_{loss} \tag{22-25}
\]

where,

\( N \) is the number of branch circuits.

A series configuration can only be used in an ungrounded circuit. The insertion loss of a combining network may be avoided by the use of an active combining network (see Sections 22.2.15 and 22.2.16).

### 22.2.3 T Attenuators

A T-type attenuator is an attenuator network consisting of three resistors connected in the form of a T, Fig. 22-1. The network may be designed to supply an impedance match between circuits of equal or unequal impedance. When designed for use between circuits of unequal impedance, it is often referred to as a taper pad.

If a T pad is to work between equal impedances, the resistor values will be

\[
R_1 = R_2 = Z(d) \tag{22-26}
\]

\[
R_3 = 2Z(f) \tag{22-27}
\]

where,

\( Z \) is the input and output impedance in ohms,

\( d \) and \( f \) are taken from Table 22-1.

A T type attenuator may be designed for any value of loss if designed to operate between equal impedances. The resistors for a T pad of unequal impedances are calculated with the following equations:

\[
R_1 = Z_1 h - 2\sqrt{Z_1 Z_2}(f) \tag{22-28}
\]

\[
R_2 = Z_2 h - 2\sqrt{Z_1 Z_2}(f) \tag{22-29}
\]

\[
R_3 = 2\sqrt{Z_1 Z_2}(f) \tag{22-30}
\]

where,

\( Z_1 \) is the larger of the two impedances.

The values of \( f \) and \( h \) are taken from Table 22-1.

A balanced T pad is called an H pad. The pad is first calculated as an unbalanced T configuration. The series resistance elements are then divided and one-half connected in each side of the line, Fig. 22-2. The shunt resistor remains the same value as for the unbalanced configuration. A tap is placed at the exact electrical center of the shunt resistor for connection to ground.

The average noise level for a T pad is 100 dB and constant. Therefore, the signal-to-noise level varies with the amount of attenuation.

### 22.2.4 Bridged T Attenuators

A bridged T pad is an attenuator network containing four resistive elements, Fig. 22-11. The resistors are equal in value to the line impedance; therefore, they
require no calculation. This network is designed to work between impedances of equal value only. The contact arms for resistors \( R_5 \) and \( R_6 \) are connected mechanically by a common shaft and vary inversely in value with respect to each other.

\[ R_5 = (K - 1)Z \]  
\[ R_6 = Z(l) \]  

where,

- \( Z \) is the line impedance in ohms,
- \( R_5 \) is the bridging resistor in ohms,
- \( R_6 \) is the shunt resistor in ohms.

The values of \( K \) and \( l \) are taken from Table 22-1.

The impedance variations for a typical high quality attenuator used in a mixer network are shown in Fig. 22-13. The greatest impedance variation occurs as the attenuator arm approaches zero attenuation and amounts to about 80 ohms. This impedance variation is not too serious, as the mixer-combining network with its building-out resistors isolates this variation to a great extent from associated attenuators.

### 22.2.5 \( \pi \) or \( \Delta \) Attenuators

A \( \pi \) or \( \Delta \) attenuator is a resistive network resembling the Greek letter pi (\( \pi \)), or delta (\( \Delta \)), Fig. 22-14. Such networks may be used between impedances of equal or unequal values.

For networks operating between impedances of equal value

\[ R_1 = Z(e) \]  
\[ R_2 = \frac{Z}{2}(g) \]  

where,

- \( R_1 \) is the input and output resistor in ohms,
- \( R_2 \) is the series resistor in ohms,
- \( Z \) is the input and output impedance in ohms.

Find \( e \) and \( g \) in Table 22-1.
When the impedances are unequal values, the resistors are calculated with the following equations:

\[ R_1 = Z_1 \left( \frac{K^2 - 1}{K^2 - 2KS + 1} \right) \]  \hspace{1cm} (22-36)

\[ R_2 = \sqrt{\frac{Z_1Z_2}{2}} (g) \]  \hspace{1cm} (22-37)

\[ R_3 = Z_2 \left( \frac{K^2 - 1}{K^2 - \frac{2K}{S} + 1} \right) \]  \hspace{1cm} (22-38)

where,
- \( R_1 \) and \( R_3 \) are shunt resistors in ohms,
- \( R_2 \) is the series resistor in ohms,
- \( Z_1 \) is the input impedance in ohms,
- \( Z_2 \) is the output impedance in ohms,
- \( S = \sqrt{\frac{Z_1}{Z_2}} \).

The values of \( K \), \( K^2 \), and \( g \) are taken from Table 22-1.

An O-type attenuator is a balanced \( \pi \) attenuator. The circuit element values may be obtained by first calculating for a \( \pi \) configuration and then dividing the series resistor and placing half in each side of the line, Fig. 22-15. The shunt resistors remain the same value.

**22.2.6 U Attenuators**

*U* attenuators, Fig. 22-16, may be of a symmetrical or balanced-type configuration and are useful for matching a high impedance to a low impedance. The impedance match is of first importance, the loss being secondary.

For a symmetrical configuration to work between unequal impedances when the impedance match of \( Z_1 \) is important, the resistors may be calculated as follows:

\[ R_1 = Z_1 \left( \frac{KS - 1}{2S} \right) \]  \hspace{1cm} (22-39)

\[ R_2 = \frac{Z_1}{S} \left( \frac{1}{K - S} \right) \]  \hspace{1cm} (22-40)

where,
- \( R_1 \) is the series resistor in ohms,
- \( R_2 \) is the shunt resistor in ohms,
- \( Z_1 \) is the larger impedance in ohms,
- \( Z_2 \) is the smaller impedance in ohms,
- \( S = \sqrt{\frac{Z_1}{Z_2}} \).

The value of \( K \) is taken from Table 22-1.

When the low impedance, \( Z_2 \) is to be matched the equations are:

\[ R_1 = \frac{Z_1}{2S} (K - S) \]  \hspace{1cm} (22-41)
where,
\[ S = \sqrt{\frac{Z_1}{Z_2}} \]
The value of \( K \) is taken from Table 22-1.

Any U pad may be balanced to ground by connecting a ground to the electrical center of the shunt resistor.

### 22.2.7 Ladder Attenuators

Ladder-type pads, Fig. 22-17, are so named because they look like a ladder laying on its side. The ladder pad is actually a group of \( pi \) attenuators in tandem, \( R_2 \) being common to each section. Because of resistor \( R_4 \), this type of attenuator has a fixed 6 dB loss, exclusive of the attenuator setting, which must be taken into account when designing a ladder attenuator. The ladder attenuator does not have a constant input and output impedance throughout its range of attenuation. However it does reflect a stable impedance into its source.

![Unbalanced ladder attenuator with five fixed steps of loss](image)

Ladder potentiometers for mixer control use may be obtained in two types of construction—slide-wire and contact types.

For mixers, the slide-wire type control is generally employed because it permits a smooth, even attenuation over a wide range. The contact type, although not quite as smooth in operation as the slide-wire, has only one row of contacts, which reduces the noise and maintenance.

Ladder networks may also be designed for balanced operation. This is accomplished by connecting two unbalanced networks side by side, Fig. 22-18. The circuit elements are not divided in the same manner as for other types balanced networks. If an unbalanced ladder network is compared with a balanced ladder network, resistors \( R_1 \) are divided by two, resistors \( R_4 \) are also divided by two, and at the output \( R_2 \) is now twice the value for the unbalanced configuration. Resistor \( R_3 \) remains at its original value on each side of ground.

The equations used to calculate the resistor values are:
\[
R_1 = \frac{K^2 - 1}{2K} (Z) \tag{22-43}
\]
\[
R_2 = Z(e) \tag{22-44}
\]
\[
R_3 = \frac{R_2Z}{R_2 + Z} \tag{22-45}
\]
\[
R_4 = \frac{Z}{2} \tag{22-46}
\]

where,
\( R_1 \) is the series resistance in ohms,
\( R_2 \) is the shunt resistance in ohms,
\( R_3 \) is the input shunt resistor in ohms,
\( R_4 \) is the series resistance in the contact arm circuit in ohms,
The values of \( K \) and \( K^2 \) are taken from Table 22-1.

The value of \( K \) is dependent on the loss per step, not the total loss.

The noise level for a ladder attenuator is on the order of –120 dB, and as the attenuation increases, the SNR increases. This type of attenuator will show impedance variations at both the input and output and between steps. However, when used in a combining network with the proper building-out resistors, these variations are of little consequence. A typical impedance curve is shown in Fig. 22-19.

### 22.2.8 Simple Volume and Loudness Controls

A simple volume control consists of a potentiometer with the two ends connected to the source and the wiper
and one end connected to the load, Fig. 22-20. The volume control should be a high impedance with respect to the source so it will not load it, and the load impedance should be a high enough so as not to affect the control. The output voltage is calculated with the following equation:

\[ V_{out} = V_{in} \frac{R_2Z_2}{R_1 + \left( \frac{R_2Z_2}{R_2 + Z_2} \right)} \]  

(22-47)

where,

- \( R_1 \) is the upper section of control,
- \( R_2 \) is the lower section of control,
- \( Z_2 \) is the load impedance.

If the load impedance is high compared to \( R_2 \), the equation is simplified to

\[ V_{out} = V_{in} \left( \frac{R_2}{R_1 + R_2} \right) \]  

(22-48)

The attenuation is
Normally, volume controls have a logarithmic taper, so the first 50% of the pot only represents a change of 7–8%, following the ear’s sensitivity. If a special taper is required, a linear pot can be altered to change its characteristics by shunting a fixed resistor from one end of the potentiometer to the wiper. Three methods of shunting a straight-line potentiometer are shown in Fig. 22-21. In the first method, the shunt resistor is connected from the wiper to ground. With the correct value shunt resistance, the potentiometer will have a taper relative to the angular rotation, as shown below the schematic. The second method makes use of a second potentiometer ganged with the straight-line potentiometer. In the third method, two shunt resistors connected at each side of the wiper result in a taper resembling a sine wave. A fourth method, not shown, uses a shunt resistor connected from the wiper to the top of the potentiometer.

A loudness control incorporates a circuit to alter the frequency response to follow the Fletcher-Munson curves of equal loudness—i.e., the softer the level, the more the low frequencies must be boosted with respect to 1 kHz and above. To approximate this a capacitor is tapped off the volume control at about 50% rotation. As the wiper is rotated below the tap, the signal has the high frequencies rolled off, giving the effect of low-frequency boost.

22.2.9 Light-Dependent Attenuators

A light-dependent attenuator (LDA) is one where the attenuation is controlled by varying the intensity of a light source on a light-dependent resistor (LDR) (cadmium sulfide cell). LDAs were popular before op-amps and are still useful for remote control as they are not affected by noise or hum on the control line. LDAs eliminate problems of noisy potentiometers as the potentiometers operate the lamp circuit that has an inherent lag time. This type of circuit is also very useful for remote control as the remote control line carries lamp control voltage so it is not susceptible to hum and extraneous pickup.

A simple volume control is shown in Fig. 22-22. \( R \) and LDR form an attenuator. When the light source is bright, the resistance of the LDR is low; therefore, most of the signal is dropped across \( R \). When the light intensity is decreased, the resistance of LDR increases and more signal appears across the LDR. This circuit has constantly varying impedances.

\[
\text{dB} = 10 \log \left( \frac{R_1 + \left( \frac{R_2 Z_2}{R_2 + Z_2} \right)^2}{Z_1 Z_2} \right)
\]  

(22-49)

![Figure 14-22. Volume control using a light-dependent resistor.](image)

A constant impedance attenuator would require more LDRs and light sources to approximate a constant impedance type of attenuator.

The advantages of a LDA are:

1. No wiper noise.
2. One control can operate many attenuators.
3. Controls can be remoted from the attenuator.

The disadvantages are:

1. Lamp burnout or aging.
2. Slow response time.

22.2.10 Feedback-Type Volume Control

In a feedback-type volume control attenuation is controlled by the amount of feedback in the circuit. Feedback-type volume controls have the advantage of reduced hum and noise as they reduce the gain of the active network rather than reducing just the signal level.

![Figure 22-23. Noninverting linear-feedback, gain-controlled amplifier.](image)

A noninverting op-amp feedback gain controlled amplifier is shown in Fig. 22-23. Feedback resistor \( R_2 \) is used to adjust the gain of the op-amp and therefore the output. When \( R_2 \) is zero, gain will be one as the system
has 100% feedback. Increasing the value of \( R_2 \) decreases feedback, consequently increasing gain by the ratio of \( R_2/R_1 \). Gain can be determined with the equation

\[
E_0 = E_{in} \left( \frac{R_1 + R_2}{R_1} \right) 
\]  
(22-50)

### 22.2.11 Voltage-Controlled Amplifiers

A voltage-controlled amplifier (VCA) is used as an attenuator by varying a dc control voltage. VCAs are often used for automatic mixing since the control voltage can be stored in analog or digital form and on command can be programmed back into the console and VCA.

![Figure 22-24. VCA volume control.](image)

VCAs are also useful for remote control operation and in compressors or expanders. VCAs have attenuation ranges from 0–130 dB and response time better than 100 \( \mu \)s. A typical circuit is shown in Fig. 22-24. Since the input is a virtual-ground summing point, \( R_1 \) is used so as not to load the preceding circuit. The output circuit must feed a virtual ground so an operational amplifier current-to-voltage converter (any operational amplifier with a resistor from output to inverting input and with the noninverting input grounded) must be used. The circuit can be used with a linear taper potentiometer to give a linear control characteristic.

### 22.2.12 Field Effect Transistor Attenuators

A field effect transistor attenuator is one where an FET is used to control gain. Field effect transistors have characteristics much like a tube—that is, high-input impedance and moderate-output impedance. In its simplest form, the FET is used as the lower leg of a voltage divider, Fig. 22-25A.

The voltage output is

\[
V_{out} = V_{in} r_{DS(on)} + V_{out(max)} 
= \frac{V_{in}}{R + r_{DS(on)}} 
\]  
(22-51)

where,

\( r_{DS} \) is the resistance of the drain to source.

To improve distortion and linearity, feedback is required around the FET as in Fig. 22-25B. If a low-output impedance is required, an op-amp can be used in conjunction with the FET, Fig. 22-25C. In this circuit, the op-amp is used to match impedances. The FET can also be used to control feedback, Fig. 22-25D.

The gain in this circuit is

\[
AV = 1 + \frac{R_f}{r_{DS}} 
\]  
(22-52)

where,

\( R_f \) is the feedback resistor.

When \( r_{DS} \) is minimum, gain is maximum as most of the feedback is shorted to ground. The FET can also be used as a T attenuator, Fig. 22-25C. This provides optimum dynamic linear range attenuation and tends to hold the impedances more even.

### 22.2.13 Automated Faders

In an automated fader, the fade control can be programmed into a data storage device and used to adjust the fader settings during mixdown, Fig. 22-26. The fader is adjusted manually, and when the desired setting is made, a write voltage is injected into the programmer (encoder) that supplies data to the data track of the tape recorder. During playback, the data track is decoded and, through the read control, adjusts the attenuator to the recorded level. If the mixdown is not proper, any control can be adjusted or updated and the tape played over again.

### 22.2.14 Automatic Attenuators

In an automatic attenuator, the attenuation varies automatically between two points, usually off and a prescribed setting. Automatic attenuators are often voice operated but can be manually operated. They are used to automatically turn off unused inputs, as a Ducker and gating.
22.2.15 Mixers

A mixer is a device used to mix two or more signals into one composite signal. Mixers may be adjustable or nonadjustable and either active or passive.

A passive mixer uses only passive devices (i.e., resistors and potentiometers), Fig. 22-27.

The main disadvantage of passive mixing is that an amplifier is required after mixing to boost the gain back to the level at the input of the mixer. As the attenuator controls are lowered, the signal on the mixing buzz is reduced; however, the mixing buzz noise remains the same, so the SNR is reduced, causing more apparent noise at low levels where high signal-to-noise is most important. This can be seen in the analysis of Fig. 22-28.

In Fig. 22-28A, the input signal of –110 dBm is not attenuated; therefore, the signal going into the booster...
amplifier is –91 dB and out of the booster amplifier is –58 dB \[-110 + (+33) + (-14) + (+33)\]. The mixer noise going into the booster amplifier is –125 dB; therefore, the output noise is –92 dB \[-125 + (+33)\] or 34 dB below the signal.

In Fig. 22-28B, the input signal of –110 dBm is attenuated 20 dB in the mixer so the signal to the booster is –111 dB and the signal output is –78 dB. The mixer input noise is still –125 dB into the booster and –92 dB out of the booster, a difference between the signal and the noise of only 14 dB, hardly enough to be useful.

An active mixer is one that uses operational amplifiers (op-amps) or some other active device along with resistors and/or potentiometers to control gain or attenuation.

A unity-gain current-summing amplifier is used for a standard active mixer. The mixer is usually designed for an input impedance of about 5–10 k\(\Omega\), an output impedance of less than 200 \(\Omega\), and a gain of 0 to 50. A typical active mixer is shown in Fig. 22-29.

In unity-gain current-summing amplifiers feedback to the minus or inverting input presents an extremely low apparent input impedance or virtual ground on the inverting input.

The positive input is also essentially ground since the current through \(R_n\) will only produce about 0.5 mV. While the positive input can be grounded, it is better to make the \(R_n\) a value about the same as the parallel combination of \(R_1 + R_2 + R_f\) to reduce offset voltage.

Any small, positive-going input applied to the input of \(R_1\) is amplified by the high-gain op-amp driving the output negative since the input signal is on the inverting input. The output signal is fed back through \(R_f\) the feedback resistor, and it continuously attempts to drive the voltage on the input to ground.

Since the input is a virtual ground, the input impedances are determined by \(R_1\) and \(R_2\). The gain of the circuit is

\[
\text{input 1}_{\text{gain}} = \frac{R_f}{R_1} \quad (22-53)
\]

\[
\text{input 2}_{\text{gain}} = \frac{R_f}{R_2} \quad (22-54)
\]

If the gain of both inputs were to be the same, \(R_1\) and \(R_2\) would remain constant and \(R_f\) would be varied. Mixers, however, usually require separate gain control for each input so \(R_1\) and \(R_2\) are varied to change the gain of the system. Increasing \(R_1\) or \(R_2\) decreases the gain. The main disadvantage of this system is that the input impedance varies with gain.

The advantage of an active mixer is that gain is included in the mixing circuit; therefore, it does not need a gain makeup amplifier that amplifies both the signal and the mixing noise after the mixer. With active mixing, the mixing noise is also reduced along with the signal, improving the SNR, particularly at low level.

### 22.2.16 Summing Amplifiers

A standard audio circuit function is the linear combination of a number of individual signals into a common output without crosstalk or loss. This function is well suited for the summing amplifier, which is often referred to as active combining network. Summing amplifiers operate much like the mixer in Section 22.2.15. Fig. 22-30 shows a 10-input summing amplifier using one op-amp. Channel isolation is important in summing amplifiers to eliminate crosstalk.

The primary determinant of interchannel isolation is the nonzero summing-bus impedance presented by the virtual ground of the inverter and, to a lesser extent, by
the source impedances at the inputs. To illustrate the method of calculating interchannel isolation, refer to Fig. 22-31. There are two attenuations that a signal must undergo in order to leak from one channel to an adjacent channel. The first attenuation consists of $R_i$ and $R_{in}$; the second consists of $R_i$ and $R_s$.

The equation for calculating isolation is

$$\text{Isolation from } E_{ina} \text{ to } E_{inb} = \left( \frac{R_i + R_{in}}{R_{in}} \right) \frac{R_{sb} + R_i}{R_{in}}$$

where,

$R_{sb}$ is the $E_{sb}$ source resistance in ohms,

$R_{in}$ is the $A_1$ closed-loop input impedance in ohms or

$$R_{in} \approx \frac{R_f}{A_{vo} \beta}$$

23.1 Filter and Equalizer Definitions

A filter is a device or network for separating signals on the basis of their frequency. Filters can either be defined in terms of their pass band only where, the frequencies of interest are allowed through, or in term of their stop band, where certain frequencies are removed. The default design mode for most filters is as a low pass where all frequencies below a cutoff frequency, and extending down to dc, are allowed to pass. A simple re-arrangement usually allows for a high pass to be made, where all frequencies above a cutoff frequency, and extending upward, are transmitted. Other mode complex responses such as bandpass are constructed from these basic elements.

Passive filters have no amplification components in the circuit. They cannot add energy to the signal so can only act to attenuate signals.

Active filters use transistor or operational amplifier-based gain stages allowing the option of boosting some of the, or the whole, spectrum.

An equalizer is a device that uses filters to compensate for undesirable magnitude or phase characteristics of a systems response.

23.1.1 Pass Band

The pass band is a band of frequencies that pass through a filter with a loss of less than 3 dB relative to the nominal gain of the filter.

23.1.2 Stop Band

The stop band is a band of frequencies that pass through a filter with a loss of greater than 3 dB relative to the nominal gain of the filter.

23.1.3 Cutoff Frequency

A cutoff frequency is the frequency at which the gain first falls to 3 dB below the nominal gain of the filter, as you move out of the pass band.

23.1.4 Corner Frequency

A corner frequency is the frequency at which the rate of change of a response makes a noticeable change. In the case of a low-pass or high-pass filter, this is the same as the cutoff frequency, but other filters such as shelving filters may have additional corner frequencies.

23.1.5 Bandwidth

The bandwidth is the difference between the upper and lower cutoff frequencies on either side of the pass band.

23.1.6 Transition Band

The transition band is the range of frequencies over which the gain the filter falls from its level at the cutoff frequency to the nominal attenuation level in the stop band.

23.1.7 Center Frequency

The center frequency of a band of frequencies is defined as the geometric mean of the lowest and highest frequencies of the band.

\[ f_m = \sqrt{f_1 \times f_2} \quad (23-1) \]

where,

\[ f_1 \] is the cutoff frequency of the high-pass filter,

\[ f_2 \] is the cutoff frequency of the low-pass filter.

23.1.7.1 Geometric Symmetry

A response showing mirror image symmetry about the center frequency when plotted on a log scale is said to have geometric symmetry. This is the natural response of many electrical circuits as the response function tends to contain multiplicative terms.

23.1.7.2 Arithmetic Symmetry

A response showing mirror image symmetry about the center frequency when plotted on a linear scale is said to have arithmetic symmetry. A bandpass filter with a constant envelope delay will have arithmetic symmetry in both phase and amplitude. The center frequency in this case will be given by the arithmetic mean

\[ f_c = \frac{f_1 + f_2}{2} \quad (23-2) \]
23.1.8 Order

The order of a filter is determined by the number of reactive elements in the circuit. These can either be inductive or capacitive and generally only include those added for purposes of the frequency response within the audio band and not for stability or RF suppression. If all of the elements act as either low pass or high pass, the roll off in the stop band will approach 6 dB per octave per order. A fourth-order low pass will have a roll-off of 24 dB per octave above the cutoff frequency, but a fourth-order band pass will have 12 dB per octave on either side of the center frequency.

23.1.9 Phase Angle

The phase angle at a particular frequency is a measure of the relative time for a particular frequency to pass through a system from input to output. Phase angle is a relative measure and is usually expressed in degrees where 360° represents one wavelength. In most formulas, phase is used in terms of radians where \( 2\pi \) represents one wavelength. The instantaneous phase of a sinusoidal signal is given by

\[
\alpha = \omega t = 2\pi \times ft
\]  

(23-3)

23.1.10 Phase Delay

The phase delay of a system at a given frequency is the equivalent time offset that would induce the same phase offset as measured on a sinusoid of the same frequency.

\[
\tau_p = \frac{\alpha}{\omega} = \frac{\alpha}{2\pi f}
\]  

(23-4)

23.1.11 Group Delay

A filter can exhibit a group delay over a group of frequencies covering a section of the audio spectrum if those frequencies are all subject to the same time delay. The group delay is given as the first derivative of the phase with respect to frequency

\[
\tau_g = \frac{d}{d\omega} \phi(\omega).
\]  

(23-5)

The threshold of perceptibility for group delay has been shown to be between 1 to 3 ms over the 500 Hz to 4 kHz range of the audio spectrum.\(^1\)

23.1.12 Transient Response

The transient response of a filter is the time response to an input stimulus. Impulse and step inputs are common stimuli for this measurement. Narrow bandwidth filters, when subjected to rapidly changing input, ring because it takes a certain amount of time for the energy in the network to change upon application or removal of the signal. Ringing can most clearly be seen as a damped tail on a signal after it has been removed, Fig. 23-2.

![Figure 23-2. Ringing of a filter after the removal of a signal.](image)

23.1.13 Minimum Phase

A minimum phase system is one for which the phase shift at each frequency can be uniquely determined from the magnitude response using the Hilbert transform. A filter with more than one path from input to output, in which the different branches have a different group delay, will be a linear time invariant (LTI) system but may be nonminimum phase.

23.2 Passive Filters

Passive filters do not have any amplification components in the circuit and as such cannot put out more energy than is put in. A passive filter can never have a boost in the energy response, although with some resonant circuits, instantaneous voltages may be higher than the input voltage. In this case the output impedance will rise, preventing any significant current from being driven. To build a passive filter with boost, we must construct a filter that cuts all other frequencies and then use a separate amplifier to increase the overall gain.

23.2.1 First-Order L and C Networks

Inductor- and capacitor-based filter networks may be analyzed in terms of their impedances by reducing the circuit to its resistance and reactance components.
The impedance may be represented as a single complex number where the real part is the resistance and the imaginary part is the reactance. The imaginary part of a complex number is given by the magnitude multiplied by the square root of negative one. The mathematical notation for this number is $i$ but in engineering, $j$ is commonly used to avoid confusion in expressions involving current.

$$Z = R + jX \quad (23-6)$$

Analyzing a network in terms of complex impedance allows the calculation of both magnitude and phase at any frequency according to

$$\theta = \tan^{-1}\left(\frac{\text{imaginary}}{\text{real}}\right) = \tan^{-1}\left(\frac{X}{R}\right) \quad (23-7)$$

$$A = \sqrt{\text{imaginary}^2 + \text{real}^2} \quad (23-8)$$

where, 
\(\theta\) is the phase angle of the complex number, 
\(A\) is the magnitude of the complex number.

### 23.2.1.1 Capacitive Networks

The capacitor has impedance that approaches a short circuit at high frequency and an open circuit at low frequency. The reactance of a capacitor is given by:

$$X_c = \frac{1}{2\pi fC} \quad (23-9)$$

where, 
\(X_c\) is the capacitive reactance, 
\(f\) is the frequency in hertz, 
\(C\) is the capacitance in farads.

![Figure 23-3](image)

**Figure 23-3.** Simple filter networks using only a capacitor and a resistor.

If a capacitor is connected in series with the signal path as in Fig. 23-3A, the capacitor and the resistor form a potential divider. Low frequencies will be attenuated as the impedance of the capacitor increases at lower frequencies.

$$V_{out} = V_{in} \frac{R}{R + jR} \quad (23-10)$$

The cutoff frequency of this filter is at the frequency where \(R = |Z_c|\), so substituting into Eq. 23-8, we find

$$f = \frac{1}{2\pi RC} \quad (23-11)$$

Using the complex analysis in Eq. 23-8, we can determine the phase at this frequency.

$$V_{out} = V_{in} \frac{Z_c}{R + jZ_c} \quad (23-12)$$

The cutoff frequency of this filter is at the frequency where \(R = |Z_c|\), so substituting into Eq. 23-10, we find that again

$$f = \frac{1}{2\pi RC} \quad (23-13)$$

Using the complex analysis in Eq. 23-10, we can determine the phase at this frequency.

$$V_{out} = V_{in} \frac{jR}{R + jR} \quad \frac{j}{1+j} = \frac{1+j}{2}$$

So according to Eqs. 23-7 and 23-8, the magnitude is 0.707 or −3 dB and the phase angle is −45°.

If a capacitor is connected in parallel with the signal path as in Fig. 23-3B, the capacitor and the resistor form a potential divider. High frequencies will be attenuated as the impedance of the capacitor reduces at higher frequencies.

$$V_{out} = V_{in} \frac{Z_c}{(R + Z_c)} \quad (23-12)$$

The cutoff frequency of this filter is at the frequency where \(R = |Z_c|\), so substituting into Eq. 23-10, we find that again

$$f = \frac{1}{2\pi RC} \quad (23-13)$$

Using the complex analysis in Eq. 23-10, we can determine the phase at this frequency.

$$V_{out} = V_{in} \frac{jR}{R + jR} \quad \frac{j}{1+j} = \frac{1+j}{2}$$

So according to Eqs. 23-7 and 23-8, the magnitude is 0.707 or −3 dB and the phase angle is +45°.
23.2.1.2 Inductive Networks

The inductor has impedance that approaches an open circuit at high frequency and a short circuit at low frequency. The reactance of an inductor is given by

\[ X_L = 2\pi fL \]  
(23-14)

where,

- \( X_L \) is the inductive reactance in ohms,
- \( f \) is the frequency in hertz,
- \( L \) is the inductance in henrys.

Inductors are prone to parasitic resistances especially for large inductances where a long coil is wound. In a large value inductor, the parasitic resistance is reduced by using heavier gauge wire, which causes the size to grow rapidly as the inductance becomes larger. The full expression for the impedance of an inductor is

\[ Z_L = R_L + j2\pi fL \]  
(23-15)

where,

- \( Z_L \) is the impedance of the inductor,
- \( R_L \) is the dc resistance of the inductor.

If an inductor is connected in series with the signal path as in Fig. 23-4B, the inductor and the resistor form a potential divider. High frequencies will be attenuated as the impedance of the inductor increases at higher frequencies.

\[ V_{out} = V_{in} \frac{Z_c}{R + Z_L} \]  
(23-16)

The cutoff frequency of this filter is at the frequency where \( R = |Z_L| \), so substituting into Eq. 23-14, we find that

\[ f = \frac{L}{2\pi R} \]  
(23-17)

Using the complex analysis in Eq. 23-10 and ignoring the parasitic resistance, we can determine the phase at this frequency.

\[ V_{out} = \frac{V_{in} \times R}{R + jR} = \frac{j}{1 + j} = \frac{1}{2} - \frac{1}{2}j \]

So according to Eqs. 23-7 and 23-8 magnitude is 0.707 or \(-3\) dB and the phase angle is \(-45^\circ\). Note that this is the opposite phase angle to the capacitor-based low-pass filter.

23.2.2 Second-Order L-Type Networks

An L-type filter consists of an inductor in series with a capacitor, with the outputs across one or more of the components. Since there are two reactive elements in the circuit, it forms a second-order filter with a roll-off of 12 dB per octave. There are two configurations of this network.

\[ IL_{dB} = 10\log \left[ 1 + \left( \frac{f}{f_c} \right)^2 \right] \]  
(23-18)

The insertion loss for the low-pass configuration as shown in Fig. 23-5A is given by

\[ IL_{dB} = 10\log \left[ 1 + \left( \frac{f}{f_c} \right)^2 \right] \]  
(23-19)

where,

- \( f_c \) is the frequency of a 3 dB insertion loss,
- \( f \) is any frequency,
- \( IL_{dB} \) is the insertion loss in decibels.

These configurations are commonly used in basic loudspeaker crossover networks as in Fig. 23-6. Both a high-pass and a low-pass response may be derived from the same circuit. The L-type filter in this application presents constant impedance to the input port. The
impedance of the inductor Eq. 23-12 and the capacitor Eq. 23-7 vary with frequency and are chosen such that, at the crossover frequency, their impedances equal the characteristic impedance, $Z_0$. Each port is in parallel with a load, which for simplicity of analysis we will consider to be constant and of value $Z_0$.

When the frequency is very much lower than the crossover frequency, the value of $Z_L$ becomes $2\pi f_c L$, which is very small. At the same time, the value of $Z_C$ becomes $Z_0$ as $2\pi f_c C$ becomes smaller. The total impedance becomes $Z_0$.

At the crossover frequency, the inductor and capacitor impedances equal $Z_0$, so the total circuit impedance also equals $Z_0$.

When the frequency is very much higher than the crossover frequency, the value of $Z_L$ becomes $Z_0$ as $2\pi f_c L$ becomes larger. At the same time, the value of $Z_C$ becomes $1/(2\pi f_c C)$, which is small. The total impedance becomes $Z_0$.

### 23.2.3 T and π Networks

T and π networks are classes of constant-$k$ filters. They are formed by combing L-type filters with one leg being in common. The line impedance $Z_0$ is a critical parameter in the design of these filters. The impedance presented by a T network to the input and output transmission lines is symmetrical and is designated $Z_T$. This impedance is equal to the line impedance in the passband and progressively decreases in the stop band. The impedance presented by a π network to the transmission lines is also symmetrical and is designated $Z_P$. This impedance is equal to the line impedance in the passband and progressively increases in the stop band.

The full T and π networks have twice the attenuation of the L-type half sections.

#### 23.2.3.1 Low Pass

A T-type low-pass filter has two inductances: $L_1$ in series with the line and a capacitance $C_2$ in parallel. As frequency increases, the inductive reactance increases, presenting an increasing opposition to transmission. As frequency increases, capacitive reactance reduces, so the parallel capacitor becomes more effective at shunting the signal to ground. The design equations for the component values are

$$Z_L = \frac{1}{\left(\frac{1}{2\pi f_c L} + \frac{1}{Z_0}\right)} \quad (23-20)$$

$$Z_C = \frac{1}{\left(\frac{2\pi f_c C}{Z_0}\right)} \quad (23-21)$$

where,

$Z_0$ is the circuit impedance,

$f_c$ is the crossover frequency.

The total impedance at the input is

$$Z_{in} = Z_C + Z_L \quad (23-22)$$

These equations are the same as for the L-type network. In the T network, the actual value of the capacitor is $2C_2$, where the capacitors from two low-pass L-type networks are combined in parallel. In the π network, the actual value of the inductor is $2L_1$, where the inductors from the L-type network are combined in series.

#### 23.2.3.2 High Pass

The basic designs of constant-$k$ high-pass filters are shown in Fig. 23-8. The positions of the inductors and capacitors are opposite to those in the low-pass case. The design equations are
Chapter 23

23.2.3.3 Parallel Resonant Elements

A parallel resonant circuit element has impedance that is at a maximum at the resonant frequency (Fig. 23-9). The impedance of the element is given by

\[ Z = \frac{Z_L \times X_C}{X_L + X_C} \]  

(23-27)

where,
- \( Z \) is the impedance,
- \( X_L \) is the reactance of the inductor,
- \( X_C \) is the reactance of the capacitor.

At very low frequencies, the reactance of the inductor approaches a short circuit, reducing the overall impedance. At high frequencies, the reactance of the capacitor approaches a short circuit, reducing the overall impedance.

23.2.3.4 Series Resonant Elements

A series resonant circuit element has impedance that is at a minimum at the resonant frequency. The impedance of the element is given by

\[ Z = X_L + X_C \]  

(23-28)

where,
- \( Z \) is the impedance,
- \( X_L \) is the reactance of the inductor,
- \( X_C \) is the reactance of the capacitor.

At very low frequencies, the reactance of the capacitor approaches an open circuit, increasing the overall impedance. At high frequencies, the reactance of the inductor approaches an open circuit, increasing the overall impedance.
23.2.3.5 Bandpass

The impedance characteristics of the series and parallel resonant elements can be used to form a bandpass filter as in Fig. 23-11. The frequencies $f_1$ and $f_2$ are the cutoff frequencies of the pass band. The design equations for the component values are

$$L_1 = \frac{Z_0}{2\pi(f_2-f_1)}$$  \hspace{1cm} (23-29)

$$L_2 = \frac{(f_2-f_1)Z_0}{2\pi f_1 f_2}$$  \hspace{1cm} (23-30)

$$C_1 = \frac{f_2-f_1}{2\pi f_1 f_2 Z_0}$$  \hspace{1cm} (23-31)

$$C_2 = \frac{1}{2\pi(f_2-f_1)Z_0}$$  \hspace{1cm} (23-32)

where,

- $f_1$ is the lower cutoff frequency,
- $f_2$ is the upper cutoff frequency,
- $Z_0$ is the line impedance.

![Figure 23-11. T network bandpass filter.](image)

23.2.3.6 Band Reject

The configuration for a band reject filter using series and parallel resonant elements is shown in Fig. 23-12. The configuration is the reverse of the bandpass T-network filter. In this case the frequencies $f_1$ and $f_2$ are at the edge of the reject band. The design equation for the component values are

$$L_1 = \frac{(f_2-f_1)Z_0}{2\pi f_1 f_2}$$  \hspace{1cm} (23-33)

$$L_2 = \frac{Z_0}{2\pi(f_2-f_1)}$$  \hspace{1cm} (23-35)

$$C_2 = \frac{f_2-f_1}{2\pi f_1 f_2 Z_0}$$  \hspace{1cm} (23-36)

![Figure 23-12. T network band-reject filter.](image)

23.2.3.7 Ladder Networks

Passive filters of arbitrary length may be constructed by adding RC, RL, or LC L-type sections into a network of arbitrary length called a Cauer network. The interaction between the various stages in this topography starts to become important as the impedance of one section loads the next.

23.2.4 Filter Design

As the number of components in a filter increases, the number of possible transfer functions also increases. Increasing the order of a filter by adding more of the same sections will not necessarily produce the optimum results. Consider chaining two low-pass filters with a cutoff frequency of $f_c$. The attenuation at the cutoff is 3 dB, so with two sections in series, the attenuation at $f_c$
is 6 dB. This means that the 3 dB cutoff point has moved somewhat lower.

We can analyze a filter in the Laplace domain in terms of input signals of the form $e^{st}$ with $s$ defined as

$$s = \sigma + j\omega$$  \hspace{1cm} (23-37)

where,

$\sigma$ is a value for exponential decay,

$\omega$ is $2\pi f$, $f$ being the frequency.

This gives us a transfer function that can be expressed as polynomial functions in $s$. A first order low-pass filter is of the form

$$h_1(s) = \frac{1}{(s + p_0)}$$  \hspace{1cm} (23-38)

The value of $p_0$ defines the cutoff frequency. Adding more sections in series progressively multiplies more terms,

$$h_n(s) = \frac{1}{(s + p_0)(s + p_1)}$$  \hspace{1cm} (23-39)

For a normalized version of Eq. 23-37, $p_0$ is set to be one, and all other values in the sequence of $p_n$ can be defined according to a formula. The exact formula used depends on the most important characteristic of the filter you are designing.

### 23.2.4.1 Butterworth

The Butterworth filter is maximally flat and has the most linear phase response in the pass band but has the slowest transition from pass band to stop band for a given order. The polynomial transfer function in the form of Eq. 23-37 can be constructed using a formula.

$$B_n(s) = \prod_{k=1}^{n} \left[ s^2 + 2\cos\left(\frac{2k + n - 1}{2n}\pi\right)s + 1 \right]$$  \hspace{1cm} (23-40)

Eq. 23-40 gives the polynomials for an even order of filter. To calculate the polynomial for an odd order, add a term $(s + 1)$, and then apply the formula with $n = n-1$. Table 23-1 gives the calculated values for the Butterworth polynomials up to fifth order.

### 23.2.4.2 Linkwitz-Riley

The Linkwitz-Riley filter is used in audio crossovers. It is formed by cascading two Butterworth filters so that the cutoff at the crossover frequency is $-6$ dB. This means that summing the low-pass and high-pass responses will have a gain of 0 dB at crossover and all other points.

### 23.2.4.3 Chebyshev I and II

Chebyshev filters have a steeper roll-off than the Butterworth filters but at the expense of a ripple in the response. There are two forms of the Chebyshev filter. Type I has a ripple in the pass band and maximum attenuation in the stop band. Type II is the reverse, with a flat pass band and a ripple in the stop band that limits the average attenuation.

The filter’s transfer function is defined in terms of a ripple factor $\varepsilon$

$$H(\omega) = \frac{1}{\sqrt{1 + \varepsilon^2 C_n^2 \frac{\omega}{\omega_0}}}$$  \hspace{1cm} (23-41)

where,

$C_n$ is the polynomial for the order $n$, as given in Table 23-2.

The magnitude of the ripple in decibels is

$$\text{ripple}_{dB} = 20\log\left(\frac{1}{\sqrt{1 + \varepsilon^2}}\right) \text{ dB} .$$  \hspace{1cm} (23-42)

23.2.4.4 Elliptical

The elliptical filter has a ripple in both the pass band and the stop band, with the shortest possible transition band for the order of the filter with a given ripple. The ripple in the pass band and the stop band are independently controllable. This is a generalized form of the Butterworth and Chebyshev filters. If the pass band and stop band ripple is set to zero, we have a Butterworth filter. If the pass band has a ripple and the stop band does not, we have a Chebyshev Type I. If the stop band has a ripple and the pass band does not, we have a Chebyshev Type II.

The transfer function is the same form as Eq. 23-39 with a different polynomial

\[ H_n(\omega) = \frac{1}{1 + \varepsilon^2 E_{n,\xi}(\frac{\omega}{\omega_0})} \]  

(23-43)

where,

\( E_{n,\xi} \) is the elliptical polynomial for the order \( n \) and selectivity factor \( \xi \).

23.2.4.5 Normalizing

Normalizing is the process of adjusting the values of filter components to a convenient frequency and impedance. For analysis, the frequency is usually normalized to 1 rad s\(^{-1}\) and the impedance to 1 \( \Omega \). For designing practical audio circuits the filter is normalized to 1 kHz and 10 k\( \Omega \).

23.2.4.6 Scaling

Scaling is the design process of changing the normalized frequency or impedance values for a filter by varying resistor and capacitor values. Frequency can be changed relative to the normalized frequency by either changing all of the resistor values or all of the capacitor values by the ratio \( \rho \) of the desired frequency to the normalized frequency. From Eq. 23-11, frequency varies inversely with the product of the capacitor and resistor value.

\[ \rho = \frac{f_{\text{norm}}}{f_1} \]  

(23-44)

where,

\( \rho \) is the scaling factor,

\( f_1 \) is the new frequency.

By multiplying all of the resistor values by a factor, and dividing all of the capacitor values by that same factor, we can change the normalized impedance of the network without changing the RC product, thus keeping the frequency unchanged.

\[ \rho = \frac{Z_1}{Z_{\text{norm}}} \]  

(23-45)

where,

\( \rho \) is the scaling factor,

\( Z_1 \) is the impedance.

23.2.5 Q and Damping Factor

A damping factor, \( d \), or its reciprocal, \( Q \), appears in the design equation of some filters. The circuit behaves differently depending on the value of \( d \).

When \( d \) is 2, the damping is equivalent to the isolated resistance-capacitance filters.

When \( d \) is 1.41 (square root of 2), the filter is critically damped and gives maximum flatness without overshoot.

As \( d \) decreases between 1.414 and 0, the overshoot peak increases in level with its being 1 dB at \( d = 1.059 \), 3 dB at \( d = 0.776 \).

When \( d \) is 0, the peak becomes so large that the filter becomes unstable, and if gain is applied it can become an oscillator.

23.2.6 Impedance Matching

Source and load impedance have an effect on a passive filter’s response. They can change the cutoff frequency, attenuation rate, or \( Q \) of the filter. Fig. 23-13 shows the effects of improper source and load impedance on three different passive filters. The peaks in the response before the cutoff frequency lead to a ringing in the filter, making it potentially unstable at these frequencies. The bridged T filter is not affected by the impedance mismatch because of the resistors in the filter; however, these resistors create an insertion loss.

23.3 Active Filters

Any passive filter may be turned into an active filter by using amplification at the input and output to provide the option of gain, Fig. 23-14. This also provides important buffering, giving the circuit a high-input impedance and low-output impedance, guarding the circuit against external impedance mismatches. This allows active
filter sections to be connected together without concerns for mutual interference.

More advanced active filters use filter components in the feedback loop of a gain stage to add functionality with fewer components. Active filters have advantages over passive filters in that they can be made much smaller, especially for low-frequency filters that would otherwise use bulky inductors. The removal of inductors also makes active filters less prone to low-frequency hum interference. The disadvantages of active filters are that they are more complex, having more components to fail; require a power supply; and have a dynamic range limited at the top by the power supply and at the bottom by high-frequency self-noise in the amplifiers.

### 23.3.1 Filter Topologies

#### 23.3.1.1 Sallen-Key

Sallen-Key filters are second-order high-pass or low-pass sections exhibiting a 12 dB per octave cutoff slope in the stop band. Equal component value filters are the easiest to design, with the frequency-determining resistors being of equal value and the frequency-determining capacitors being of equal value. They have the advantage of being able to high pass or low pass simply by interchanging their positions.

In the second-order low pass of Fig. 23-15, frequency is changed by scaling the values of $R$ and $C$ in the input network in accordance with Eq. 23-42. To keep the offset at a minimum, it is best to have $R_0$ equal to the input impedance of $2R$. Damping factor, $d$, is controlled by the ratio of $R_f$ and $R_0$ such that

$$R_f = (2 - d)R_0$$  \hspace{1cm} (23-46)

The gain of the circuit is fixed at
Filters and Equalizers

\[
gain = 1 + \frac{R_f}{R_0} = \frac{1 + (2 - d)R_0}{R_0} = (3 - d)
\]  
(23-47)

where

- \(d\) is the damping factor,
- \(R_f\) is the op-amp feedback resistance,
- \(R_0\) is the resistance between ground and the inverting input.

The second-order high-pass filter of Fig. 23-16 is constructed by reversing the locations of \(R\) and \(C\) in Fig. 23-15. The gain and damping factor follow the same equations as for the low pass.

A unity gain Sallen-Key filter can also be made. To independently control frequency and damping, the ratio of the capacitors must be changed such that in the low pass

\[
C_f = \left(\frac{4}{d^5}\right)C_1.
\]  
(23-48)

The cutoff frequency is still determined by the product of \(R\) and \(C\), so it can be adjusted with the value of \(R\) or by scaling \(C_f\) and \(C_1\) together.

Fig. 23-17 is a Sallen-Key filter implemented as a bipolar junction transistor circuit.

### 23.3.1.2 State Variable

The state variable filter consists of two low-pass filters and a summing stage. High-pass, bandpass, and low-pass outputs are all available from the circuit. The operation relies on both the magnitude and phase characteristics of the low-pass sections to generate the outputs.

At high frequency, the low-pass sections attenuate the signal so that the feedback signal is small, leaving the unaffected signal at the high-pass output. As the input frequency approaches the center frequency, the levels at both the bandpass and low-pass outputs begin to increase. This leads first to an increase in positive feedback from the bandpass section giving a damping dependent overshoot. When the input frequency is below the center frequency, the net phase shift of both low-pass sections is 180 degrees, leading to negative feedback and an attenuation of the high-pass output.

The cutoff frequency of the filter in Fig. 23-18 can be changed as in the preceding circuits by varying \(R_1\) and \(R_2\) or \(C_1\) and \(C_2\) while keeping other values identical. The damping factor is varied by changing the band-pass feedback gain, controlled by the ratio of \(R_3\) and \(R_4\).

\[
d = \frac{R_4}{R_3}.
\]  
(23-49)

The overall gain is controlled by \(R_{12}\). If \(R_1\), \(R_2\), and \(R_{12}\) are equal, the gain is one.

\[
gain = \frac{R_1}{R_{12}}
\]  
(23-50)
The values of $R_8$, $R_9$, $R_{10}$, and $R_{11}$ are not critical and should be chosen for minimum dc offset at each op-amp stage.

### 23.3.1.3 All-Pass Filter

The circuit shown in Fig. 23-19 is an all-pass amplifier with unity gain at all frequencies and having a phase shift proportional to frequency according to

$$\theta = 2\tan^{-1}\left(\frac{f_0}{f}\right)$$  \hspace{1cm} (23-51)

where,

- $\theta$ is the phase shift from input to output,
- $f_0$ is $1/(2\pi RC)$.

The phase shift is approximately proportional to the frequency over a range of frequencies below and above $f_0$. These circuits can be cascaded to induce more phase-shift over the same frequency range or each designed with a different $f_0$ to extend the range over which phase is proportional to frequency.

$$\theta = \omega t = 2\pi ft$$  \hspace{1cm} (23-52)

Since phase is proportional to frequency, and from Eq. 23-50 phase is an expression of time, these circuits may be used to introduce a small amount of delay.

### 23.3.2 Pole-Zero Analysis

A pole-zero plot, Fig. 23-20 is graphical way of representing the complex transfer function of a filter. The pole-zero plot describes a surface that has peaks of infinite magnitude that stretch the surface upward and zeros that do the same downward. The height of the surface along the $\omega$ axis, where $\sigma = 0$, is the normal magnitude response.

If the expression for the function is reduced to a factored form in the $s$-plane where $s$ is the Laplace domain variable Eq. 23-35, then the transfer function of a system can be represented as
23.3.2.1 Zeros

The zeros of the function are the values of \( s \) at which \( P(s) \) is zero and consequently \( H(s) \) is zero. These occur at values \( p_1, p_2, \) and so on, and represent frequencies at which the transfer function exhibits maximum attenuation.

23.3.2.2 Poles

The poles of the function are the values of \( s \) at which \( Q(s) \) is zero and consequently \( H(s) \) is infinite. These occur at values \( q_1, q_2, \) and so on, and represent frequencies at which the transfer function exhibits maximum gain.

23.3.2.3 Stability

A pole or a zero in the right-hand side of the \( s \)-plane means that for that value of \( s, \sigma \) is greater than zero. In the time domain representation, the signal is given as

\[
f(t) = \int_0^\infty e^{st} F(s) ds \tag{23-54}
\]

The term \( e^{st} \) may be expanded to \( e^{\sigma t} \times e^{j\omega t} \). If the value of \( \sigma \) is greater than zero, the expression represents an exponentially increasing factor, meaning that the filter is unstable. This situation cannot arise in a passive filter so they are inherently stable.

23.4 Switched Capacitor Filters

Any active filter based on resistive and capacitive components may be reconfigured as a switched capacitor filter. The resistive elements are replaced by an equivalent switched capacitive element. The advantages of using switched capacitors in place of resistors is that they are easier to implement in silicon, since capacitors take up less space than resistors, and tolerances of capacitor-to-capacitor ratios can be more easily controlled the resistor-capacitor products.

The circuit shown in Fig. 23-21 transfers charge, and therefore current, between the two voltage sources under control of the switch. The charge \( \Delta Q \) transferred every switch period of length \( t_s \) may be expressed in terms of current Eq. 23-53 or voltage Eq. 23-54.

\[
\Delta Q = I t_s
\]

\[
\Delta Q = C(v_1 - v_2) \tag{23-56}
\]

Combining these two equations we can find the equivalent resistance.

\[
\frac{I}{f_s} = C(v_1 - v_2)
\]

\[
R = \frac{(v_1 - v_2)}{I} \tag{23-57}
\]

The equivalent resistor value in Eq. 23-55 has a fixed capacitive term and a frequency term. Its value may be controlled by varying the switching frequency. This makes switched capacitor filters ideal for filters that need to be tuned.

23.5 Digital Filters

Filters may be implemented using entirely mathematical means from their transfer function representations in the time domain. The time and frequency domains are
related by the Fourier transform. Digital filters make use of extensively recursive algorithms involving multiplications and additions, for which digital signal processors (DSPs) are optimized. The precision of the sampled data in magnitude and time is an important factor, not only at the input and output but all through the calculations.

23.5.1 FIR Filters

A finite impulse response (FIR) filter performs the convolution in the time domain of the input signal and the impulse response of the filter. While FIR filters are simple in concept and easy to design, they can end up using large amounts of processing power relative to other designs. Hundreds of multiplications per sample are often needed. They are, however, inherently stable as there are no feedback loops that can get out of control when finite precision arithmetic is used. They can also be designed to have linear phase, preserving wave shape and having a constant time delay for all frequency components.

The FIR filter structure is shown in Fig. 23-22. Each Z\(^{-1}\) is a delay that represents one unit of time equivalent to the sample period of the system. The notation derives from the Z domain transform, which is a way of expressing transfer functions in a discrete time form. The recursive nature of the algorithm is apparent, with the multiply and add sections being repeated for every sample in the stored impulse response.

The FIR filter treats each incoming sample as an input impulse stimulus and generates an output that is a truncated copy of the impulse response scaled by the magnitude of that sample. The summing of the results from each successive sample by superposition generates the full output signal. The result for each output sample in a filter with \(M\) coefficients is

\[
y(n) = \sum_{m=0}^{M} x(n-m) \times h(m)
\]

where,

- \(n\) is the sample number,
- \(x(n)\) is the \(n\)th input sample value,
- \(h(m)\) is the \(m\)th filter coefficient value,
- \(y(n)\) is the \(n\)th output sample value.

This requires the storage of \(M-1\) previous input samples and is executed in \(M\) multiply and add operations per sample.

23.5.1.1 FIR Coefficients

The coefficient values for an FIR filter are generally computed in advance and stored in a look-up-table for reference while the filter is operating.

Consider the ideal, or brick wall, digital low-pass filter with a cutoff frequency of \(\omega_0\) rad s\(^{-1}\). This filter has magnitude 1 at all frequencies less than \(\omega_0\) and magnitude 0 at frequencies between \(\omega_0\) and the Nyquist frequency. The impulse response sequence \(h(n)\) for a filter normalized for frequencies between 0 and \(\pi\) is

\[
h(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} H(\omega) e^{j\omega n} d\omega
\]

\[
= \frac{1}{2\pi} \int_{-\omega_0}^{\omega_0} e^{j\omega n} d\omega
\]

\[
= \frac{\omega_0}{\pi} \sin \left( \frac{\omega_0}{\pi} n \right)
\]

This filter cannot be implemented as an FIR since its impulse response is infinite. To create a finite-duration impulse response, we truncate it by applying a window. By retaining the central section of impulse response in this truncation, you obtain a linear phase FIR filter. The length of the filter primarily controls the steepness of the cutoff, while the choice of window function allows you to trade off between pass band and stop band ripple, Fig. 23-23.
23.5.1.2 FIR Length

The required number of taps (N) in an FIR filter at a sample rate (f_s) for a given transition band specified by a width (f_t) and attenuation in dB(A) can be estimated as

\[ N = \frac{f_s A}{f_t 22} \] (23-60)

As an example, we can calculate how many taps a 100 Hz, fourth order high-pass filter in a 48 kHz system would use. Fourth order gives a roll-off of 24 dB per octave, so the response will be 24 dB down by 50 Hz. The transition band is for a 20 dB minimum attenuation in the stop band and therefore is 50 x 20/24 or 42 Hz wide and the desired attenuation is 24 dB so the equation gives us 48,000 x 20 / (42 x 22) = 1049 taps. This is a very long filter and introduces 520 samples or 10.8 ms of delay at the 48 kHz sample rate.

If we consider the same example, but for a 1000 Hz cutoff frequency, everything scales by a factor of 10, giving a much more acceptable filter length of 105 samples with a delay of 1.1 ms. This illustrates the limitation of using FIR filters for low frequencies, Fig. 23-24.

23.5.2 IIR Filters

There are many possible configurations of infinite impulse response (IIR) filters, two of which are shown in Figs. 23-25 and Fig. 23-26. They show the direct form of a biquad filter in which the input and output samples are passed into the delay line. The transpose form has a sum between every delay and scaled copies of the input and output samples are inserted into the delay line. Direct form I is better suited to fixed point implementation where it is important that the delayed terms maintain as much precision as possible.

The biquad IIR filter is a second-order filter, and forms the most common basis for higher-order IIR filters. This form fits well with the transfer function equations such as the Butterworth polynomials in Table 23-1. The feedback coefficients correspond to the poles of the filter and the direct coefficients correspond to the zeros. Each section can be represented as a short FIR filter, but unlike the direct implementation of an FIR, these sections can have complex coefficients, even if the input and output are to be real only.

23.5.2.1 Calculation of Coefficients from Poles and Zeros

IIR filters are designed in terms of the Z transform. In this transform, the time domain representation of the filter is used and the notation z^{-1} is used in place of the common exponential terms in the discrete Fourier transform:
This gives us the expression for the Z transform:

\[
H(z) = \sum_{n = -\infty}^{\infty} h[n]z^{-n} \tag{23-62}
\]

The biquad has two poles in the denominator and two zeros in the numerator. It may be expressed in the factored form as:

\[
H(z) = \frac{G(z - r_{01}e^{-jq_{01}})(z - r_{02}e^{-jq_{02}})}{(z - r_{p0}e^{-jq_{p0}})(z - r_{p1}e^{-jq_{p1}})} \tag{23-63}
\]

where,

- \( G \) is the gain,
- \( r_0 \) denotes the real part of the zero location,
- \( q_0 \) denotes the imaginary part of the zero location,
- \( r_p \) denotes the real part of the pole location,
- \( q_p \) denotes the imaginary part of the pole location.

Table 23-3 lists the equations for the individual coefficients for a purely real implementation of a biquad filter, given the locations of the poles and zeros.

### 23.6 Equalizers

Equalizers are devices or components that are designed to compensate for undesirable characteristics in the magnitude or phase response of another part of the system and thus make the response equal again. Equalizers consist of filters implemented in such away as to provide control over the frequency response in terms of how the operator thinks of the response curve that they are trying to recreate. Equalizers give control over one or more of the parameters that affect the response over the audio range, usually 20 Hz to 20 kHz, and ideally do so such that the parameters do not interact. Controls are arranged in terms of center frequencies, bandwidths, and gains rather than actual circuit values that control these things. This means that often the controls are dual-ganged so that the ratio of two resistor values may be kept constant while their absolute values are changed.

#### 23.6.1 Tone Control

The simplest form of equalizer is the tone control as used on portable radios. The control only acts to attenuate the high frequency. Another version of this type of equalizer that is becoming more prevalent than the tone control is the bass boost, which as its name suggests acts as the exact opposite to add a controlled gain to the low frequencies.

The tone control circuit shown in Fig. 23-27 includes transistor-based buffer amplifiers around the passive filter section in the middle. This allows the operation of the equalizer to be independent of source and load impedances.

![Figure 23-27. Simple low-pass tone control](image)

#### 23.6.2 Graphic Equalizers

A graphic equalizer is used to shape the overall spectrum of program material. The term graphic refers to the way that the controls are set out on the front panel such that the positions of the slider controls draw the desired frequency response. Graphic equalizers typically use \(1/3\) -octave band filters but may be constructed with any spacing. The \(1/3\) -octave refers to the spacing between adjacent filters and not necessarily the width of the filter.

A graphic equalizer is constructed using a series of filters with fixed frequency and width. The centers of the filters are typically on the ISO preferred frequencies rather than the mathematically correct \(1/3\) -octave spacing. This means that in order to cover the spectrum completely, some of the filters must have different widths. The output of each filter is added to the original signal to a degree controlled by a slider control. The levels add together and are prone to producing a ripple in the response between the centers. In Fig. 23-28, the
four sliders for 800 Hz, 1000 Hz, 1250 Hz, and 1600 Hz were set to +5 dB. The overall peak is greater than desired and a ripple of 2 dB is induced across the band.

23.6.2.1 Transversal Equalizers

Fig. 23-28 shows an example of how graphic equalizers based on tuned filters exhibit ripple in the response when groups of adjacent controls are used. The actual response that we were trying to create would have been better achieved using a single filter as in Fig. 23-29. The Transversal equalizer configures as a graphic equalizer produces ripple-free response for any equal or flat setting of the controls. It produces minimum phase response curves and avoids phase mismatch anomalies at the band edges that can be a problem in other equalizers. The response curve is mathematically a best match for the desired response.

The FIR filter discussed previously is a digital implementation of a transversal filter. Whereas a conventional tuned filter operates in the frequency domain, a transversal filter operates in the phase or time domain. If a unity gain all-pass circuit stage, Fig. 23-19, is substituted for each $Z^{-1}$ delay element in Fig. 23-22, an analog transversal filter is created. The coefficients are implemented by summing the outputs of the successive delays via different weighting resistors to a summing amplifier.

23.6.3 Parametric Equalizers

Parametric equalizers allow adjustment of the filters in terms of the three main parameters that define a filter.

- The boost or cut in dB.
- The center frequency.
- The bandwidth or $Q$.

It is difficult to make a parametric filter that provides completely independent control over all three parameters over a wide frequency range. Several filter components have to be varied with one control. For this reason, parametric equalizers sometimes have one of the controls as a multiposition switch instead of continuously variable. This allows a band of calibrated components to be switched into place rather than having to worry about how variable component values track.

Parametric equalizers are always active and typically there are several second-order sections in a unit. Each band’s center frequency is adjustable over a limited frequency range so that the parameters’ independence can be maintained. This means that each section in a unit typically covers a slightly different frequency range, each section having a ratio of between 10:1 and 25:1 between the highest and lowest center frequency. The lowest band will adjust down to 20 Hz and the highest band up to 20 kHz. Each section will typically provide more scope for cutting levels than for boosting. Typical boost level is up to 15 dB while the available cut may be down to −40 dB. The bandwidth or $Q$ is not consistent in its labeling between manufacturers. Some specify bandwidth in Hz, some specify $Q$, and others specify octave fraction. In terms of $Q$, the range of this control will typically be between 0.3 and 3, with the critically damped value of 0.707 being in the center position of the control.

An overall gain is usually provided to help maintain the average level and to maximize headroom by avoiding clipping.

23.6.3.1 Semi-Parametric Equalizers

A reduced version of the parametric equalizer is commonly found on mixing consoles. This is the semi-parametric or swept frequency equalizer. This type has only the center frequency and cut or boost controls. The $Q$ is usually set to be a midrange critically damped
value but can also be configured so that the $Q$ varies with gain.

23.6.3.2 Symmetric or Asymmetric $Q$

Straightforward designs produce constant $Q$ filters that have the same $Q$ for any amount of boost or cut. If the frequency response curves for the same amount of boost as cut are mirror images of each other across the unity gain axis, the response characteristic is called reciprocal or symmetrical. This means that the bandwidth of frequencies affected when boost is applied is greater than that affected when cut is applied. Fig. 23-30 shows that in the symmetrical response, the cutoff frequency in attenuation mode $F_c$ is less than that in boost mode $F_b$.

![Figure 23-30. Symmetrical response with different bandwidth in cut and boost.](image)

This is not always the most musically useful response. It is more common in spectrum shaping to want to gently apply boost to a broader region. Boosting a narrow region tends to lead to instability. At the same time, it is more useful to be able to notch out a fairly precise frequency, without removing a large portion of the surrounding spectrum. For this reason, equalizers tend be designed so that the bandwidth increases with gain.

23.6.4 Programmable Equalizers

All types of equalizers can be programmable. In digital equalizers, the filter coefficients are stored in memory and may be recalled or modified at will. Unless a digital equalizer implements only a fixed set of coefficients it is inherently programmable.

In programmable analog equalizers, a digital control system is used to physically manipulate the analog filters. This can be either by controlling switches that swap components in or out of the circuit, or by using voltage-controlled gain to alter the filter’s response. In the case of switched capacitor filters, the digital control system can adjust the filters by manipulating the switching frequencies to adjust the equivalent resistor values and thus the filter characteristics.

23.6.5 Adaptive Equalizers

The adaptive equalizers have long been used in communications systems for multipath echo cancellation. They are the ultimate equalizers for sound systems that must adapt to acoustic conditions that may change at any time. A common example of an adaptive equalizer in sound reinforcement is a feedback suppressor. In this application, the equalizer monitors the signal passing through it for the characteristic exponential increase in level of a frequency that is associated with feedback buildup. When this increase is detected, a very narrow and deep notch filter is placed at that frequency to suppress the feedback. This can typically operate in a fraction of a second such that you were unaware that the event occurred.

24.1 Delay

Delay is relative. For a delay to have an effect on a sound it must be heard in conjunction with the original, nondelayed sound. There are two ways that this can occur. A single sound can arrive at the listener via two different length paths, such as a direct sound and a reflected sound, or two signals with different delays can be added electrically and then heard from a single location, Fig. 24-1.

![Figure 24-1. Different sound paths through air.](image1)

24.1.1 Comb Filter

Two copies of the same signal at different delay times combine to add or subtract depending on the relative phase of each frequency as shown in Fig. 24-2. If the waves are a whole period apart, they combine to give a peak in level, if they are half a period apart, they cancel out to an extent controlled by their relative levels. This effect sets up a comb filter, so named for its appearance on a frequency plot as shown in Figs. 24-3 and 24-4. The series of peaks in the response fall first at dc, then at every frequency whose period is equal to an integer multiple of the delay time. The cancellation notches occur at the exact midpoints between these frequencies.

![Figure 24-2. Effects of adding signals of different frequencies with the same delay.](image2)

24.1.2 Directional Perception

In the case of sounds traveling through the air, the path lengths with their corresponding travel times are different for every point in space, resulting in a different comb filter for every location.

The brain uses the results of the different comb filters that are in effect at the location of each ear and combines this information in conjunction with the arrival times, relative levels, and directional filtering due to the shape of the pinnae to determine the originating direction of a sound. Other cues such as the ratio of direct to reverberant energy are used to help determine distance.

A completely dry sound heard in a set of headphones will appear to originate inside your own head. Gradu-
ally adding reverberation to it will make the sound appear to move away out in front of you. The sound can be made to appear to move from side to side by alerting the relative levels in each ear, as is commonly done in a pan control, but the same effect can be achieved by altering the relative delay of the dry sound to each ear. The reasons that this delay technique is not commonly used are that the level control is much simpler to implement and the result is compatible with monaural reproduction when the left and right channels are summed.

A sound is perceived as originating in the location at which it was first heard. This is generally the correct location as the direct sound will always arrive before any reflected sounds. The same sound coming from a second location will be perceived in different ways depending on its timing and level relative to the first:

- If the second sound is more than 30 ms after the first it will be heard as a distinct echo.
- If the second sound is more than 10 dB louder than the first, it will be heard as a distinct echo.
- If the second sound is within 10 dB and less than 30 ms after the first, it will cause an image shift in where the source location is perceived.
- If the second sound is more than 10 dB below the first, it will contribute to the spatial feel of the sound but will not be heard as a distinct sound or alter the apparent location of the first.

These rules of thumb are approximations of the psychoacoustic effects in operation. The perception curves are more complex than the rules of thumb suggest. The actual values are plotted in Fig. 24-5 and tabulated in Table 24-1.

24.2 Uses of Delay

Delay is sometimes useful. It should also be noted that there can be undesirable delays in a system. This is particularly true with digital recessing equipment where there is always a conversion delay in and out of the processor plus any processing delay. It is not uncommon for processors to have a minimum delay of a few milliseconds, and these delays should be considered when calculating the amount of delay that you actually want to use.

24.2.1 Delay in Loudspeaker Systems

A sound amplified through a loudspeaker system will be subject to image shifts and audible echoes only if there is a reference point against which to judge it. This is usually the case in sound reinforcement with the original sound being the reference or in multiple loudspeaker
setups where another loudspeaker can act as the reference.

</table>

It is not generally desirable for loudspeakers in a system to appear to be generating echoes as this will have a detrimental effect on the intelligibility of the system. Whether the image shift effects are important depends on the application. In a stage system, it is desirable to have the apparent sound source at the stage, regardless of the placement of the loudspeakers. In a distributed announcement system, the creation of a coherent source image is not as important as the intelligibility.

Sound travels at 334 m/s or 1130 ft/s. A sound traveling 33 ft will be delayed by 30 ms, so with sound sources greater than 33 ft apart, delay should be used to avoid the creation of echoes.

### 24.2.2 Setting Delay Times

In Fig. 24-6 the sound from the source, a person talking, is to be augmented by a loudspeaker and the apparent source of the sound is to be kept on the stage. To achieve this, the sound from the source must arrive at the listener before the sound from the loudspeaker. The time taken for the signal to arrive at the listener from the loudspeaker is a combination of the distance traveled in air from the loudspeaker to the listener and the negligible time taken for the signal to arrive electrically at the speaker. We must delay the signal to the loudspeaker by an amount that allows the direct sound traveling more slowly though the air to catch up and overtake the sound from the loudspeaker. The delay should slightly exceed the time taken for the sound to travel the difference in distance between the source and the loudspeaker so that the direct sound will be heard first and localized to the source. The loudspeaker can then add up to 10 dB of level 5 to 10 ms later to increase the level of the sound without changing its apparent position.

A graphical method for setting delays is shown in Fig. 24-7. The positions of the source and loudspeakers are plotted and a series of concentric circles drawn around them at 30 ms (33 ft) intervals. The SPL level from the polar response pattern of the loudspeaker can also be plotted, but for simplicity in this example, omnidirectional sources are used where the level decreases by 6 dB per doubling of distance.

If we look at point A, where source and loudspeaker are in a direct line, the time difference is 30 ms. If we add a small amount to this to allow the direct sound to be heard first, we come up with a delay setting of
35 ms. We can now analyze the sound at each of the three points:

1. The loudspeaker is 6 dB louder than the source and 5 ms later. The overall sound is heard as originating at the source but 6 dB louder.
2. The loudspeaker is 2 dB louder than the source and 20 ms later. The overall sound is heard as originating at the source but 2 dB louder.
3. The loudspeaker is the same level as the source but 35 ms later. At this point the delay is too long and a distinct echo is heard.

In reality, the coverage pattern of the loudspeaker should be chosen to ensure that the level of the sound is sufficiently attenuated outside the area where the delay works effectively.

### 24.2.3 Reverberation Synthesis

Reverberation is the result of many reflections of the original sound. The general pattern of events, as shown in Fig. 24-8 is that there is first a direct sound, followed by a short gap, referred to as the initial time gap (ITG). Next come the first distinct early reflection echoes caused by sound bouncing off surfaces near either the source or the listener. Thereafter the reflected sounds start to generate their own second, third and higher-order reflections and the energy level settles down to a constant decay rate. This decay rate is related to the distances traveled and the amount of absorption in the room.

Delay is used as the basis for reverberation synthesis because it provides a convenient method for storing the signal and releasing it at a later time, much as reflections from the surfaces of a room arrive at the listener at a later time than the direct sound. Typical applications for synthetic reverberation include the enhancement of program material in the production of recordings, the introduction of special effects in live entertainment productions, and compensation for poor or lacking natural reverberation in entertainment spaces.

Requirements for good reverberation synthesis are essentially the same as for an acoustically well-designed hall. There are many parameters that need to be considered to help achieve realism in reverberation simulation.

- **Distance from Source.** The perception of distance is controlled primarily by the relative energy levels of the direct components and the decay components.

- **Room size.** The perceived room size is controlled by the delay time from the first grouping of direct sound and early reflections to the start of the decay tail and by the length of the decay tail. The requirements for the decay tail are the same as for an acoustically well-designed room. A relatively smooth decay rate is desirable, with longer decay times at lower frequencies than at higher frequencies to simulate the high-frequency losses as sound travels through the air.

- **Brightness.** The spectral balance of the decay tail determines the character of the reverberation. A lot of high-frequency roll-off simulates a room with a lot of absorption from carpets, curtains, or designed absorption devices and gives a dark sound. Less height frequency roll-off simulates a hard-surfaced room such as the inside of a stone church, giving a bright sound.

- **Character.** The smoothness of the decay determines the character of the sound. A room with large opposing flat surfaces will exhibit a flutter echo where the sound bounces back and forth between the walls with little diffusion. A room with more architectural features or multiple surfaces will tend to scatter the sound more, creating a denser and more evenly distributed decay.

- **Envelopment.** The sense of the reverberation coming from all around you rather than a specific location is controlled, making different patterns for the different playback channels. This can be effectively achieved using two-channel stereo as well as in systems with multiple dedicated speakers. The most important differences are in the pattern of the early reflections. The decay tail portions should keep the same with the direct to reverberant energy ratio and decay time but can be randomized to produce a denser sound field. Portions of the randomized signal can be altered in their frequency response to mimic the ear's nonuniform response to sounds from behind, further increasing the sense of envelopment.

---

**Figure 24-8.** Energy Time Curve showing the delay of sound in a room
A tapped delay a shown in Fig. 24-9 is suitable for creating early reflections. Delays $T_1 \ldots T_N$ are unequal in length and in the range of 10 ms to 30 ms with amplitudes set by $g_1 \ldots g_N$ as appropriate for the character of the room. In Fig. 24-10, a reticulating path is provided via $g_f$ that produces the exponentially decaying portion. This could simply be fed into the start of the reflection generator, but a more satisfactory result is obtained by using a separate decay section, where the delay taps are set more densely and may be over a wider range, typically between 5 ms and 100 ms. The delay tap times should be chosen to not be harmonic products of each other to minimize the buildup of standing waves and comb filters. Any gain product in the reticulating path must be less than one, otherwise, the sound will exponentially increase until distortion occurs.

**24.2.4 Delay-Based Effects**

Flange is an audio effect caused by mixing an original (dry) copy of a sound with a delayed (wet) copy. The amount of delay is varied over time, creating a varying pattern of comb filters that sweep up and down through the audio spectrum. Chorus is used to make one voice or instrument sound like many and has the same topography as a flanger, but with longer delays.

**24.3 Implementations**

The implementation of a delay requires some means of storing the signal and then releasing it after a controlled period of time. This can be done either by storing a continuous record of the sound or by breaking it up into samples that are stored separately. Some preparation of the signal is usually required to make it compatible with the chosen storage medium and method and may involve some postprocessing to restore the stored signal to a usable form.

### 24.3.1 Small Delays

Small delays may be realized using the phase shift characteristics of an all-pass filter. Such a circuit, illustrated in Fig. 24-11, is limited to delays of the order of less than a wavelength of the highest frequency. These sections may be chained together to produce longer delays but become impractical for delays longer than a few milliseconds. This method is sometimes used in active crossover systems for a loudspeaker. The delays needed to time-align drivers within a cabinet are small and fixed, and the circuit may be easily combined with the frequency filtering requirements.

**24.3.2 Acoustic Delay Methods**

One way to implement a long delay is to use the speed of sound and send the signal to be delayed through a fixed air path, such as a tube with a loudspeaker at one end and a microphone at the other. For such a device to work effectively, the tube must be damped to prevent internal reflections and have an absorber at one end to prevent the establishment of standing waves. This type of system has many disadvantages as the system becomes very large for any useful delay time. The frequency response changes with tube length due to the damping material and the signal attenuates as it travels, meaning that large amounts of gain are required. The large gain in turn leads to the requirement that the tube must be mechanically isolated from vibration and out-
side sounds to prevent these from being added to the delayed sound.

24.3.3 Tape Delay

A more practical early implementation method for continuous delay was to use a magnetic tape loop. An example of such a device is shown in Fig. 24-12. The sound is recorded onto the tape at the record head and then is read back by one or more playback heads. The tape then passes an erase head and loops back to the start. The delay time is given as

\[ Time = \frac{\text{distance between heads}}{\text{tape speed}} \]  

(24-1)

Only the length of the tape limits the maximum delay time. The performance of this system depends on the quality of the recording system. Dynamic range, frequency response, and SNR are affected by the tape speed and track width. These parameters may be improved by using the usual tape recording tricks such as compression and various forms of preemphasis/deemphasis noise reduction. Such systems need regular maintenance including head cleaning and replacement of the tape to maintain optimum performance.

24.3.4 Analog Shift Register Delays

Analog shift registers as illustrated in Fig. 24-13 appear in two forms, the bucket brigade and the analog charge coupled device (CCD). They both operate in a very similar manner and differ at the silicon level in the type of switches: a metal oxide-semiconductor capacitor (MOSC) structure for a CCD and a metaloxide–semiconductor junction FET capacitor (MOSJC) structure for the bucket brigade. They are classed as shift registers because they move single samples of a signal in the form of an electrical charge from one stage to the next in response to timing signals. The delay \( T \) of a shift register is proportional to the number of register elements \( N \) and inversely proportional to the frequency \( f_s \) of the timing signal.

\[ T = \frac{N}{f_s} \]  

(24-2)

The term charge transfer device (CTD) has been applied to both the bucket brigade and CCD-based structures of an analog delay. The term CCD has become colloquially associated with a type of light-sensitive array used in cameras but actually refers to the method used to read the information off these devices. The idea of a CTD is that it stores a sample of analog information as a packet of charge on a capacitor and, under control of a timing signal, transfers it to the next storage site. All the requirements of sampling theory for audio-frequency band limiting should be met. The performance parameters for a CTD include transfer efficiency \( \epsilon \), the fraction of charge left behind in each transfer; the leakage of charge from a cell during the holding period; and the leakage of charge into a cell due to semiconductor thermal effects. Taken together, these effects degrade the SNR of the signal as it passes through the CTD and also lead to distortion due to the nonlinear nature of the leakages. The practical use of CTD is limited to applications requiring less than 100 ms of delay or longer where SNR and distortion may be tolerated. CTDs have largely fallen out of use as delay lines because digital systems have become cheaper.

24.3.5 Digital Delays

Digital delay operating principles have undergone a number of important changes since they were first used in sound systems. Probably the most significant is in the type of storage or memory. Shift registers were almost universally used in the first commercially produced
units. Digital shift registers are conceptually similar to analog CTD devices with the important advantage that only the presence or absence of a charge carries the significant signal information. Now random access memory (RAM) provides flexibility and economic tradeoffs for design. Until recently, the cost of memory was the dominant factor in delay design considerations. Currently, with the trend for DSPs to include large amounts of on-board memory, the systems have vastly reduced in cost and now the dominant cost factor is in the A/D and D/A converters.

24.4 Sampling in time

Both analog CTD delays and digital delays rely on breaking the delayed signal up into discrete samples. These samples are created by looking at a signal’s amplitude at regular intervals and disregarding its amplitude at all other times. The procedure is shown in Fig. 24-14. The sequence of pulses (B) controls a switch that turns on the signal (A) for a brief instant, then disconnects it for the remainder of the sampling period. The result is an amplitude-modulated pulse train (C) where each pulse has amplitude equal to the instantaneous signal value. According to the sampling theorem, a continuous bandwidth-limited signal that contains no frequency components higher than a frequency \( f_c \) can be recreated if it is sampled at a rate greater than 2\( f_c \) samples per second. This rate is called the Nyquist frequency. Since the real world never completely satisfies theoretical conditions, sampling frequencies are usually chosen to be higher than 2\( f_c \). Thus, 20 kHz bandwidth delays will typically be found with a sampling frequency of 48 kHz rather than the bare minimum of 40 kHz.

![Figure 24-14. The process of sampling a signal.](image)

24.4.1 Aliasing

Sampling of the audio signal is a form of modulation. Modulation of a bandwidth-limited signal with an upper frequency of \( f_c \), by the sampling frequency \( f_s \) produces additional copies of the original spectrum centered on frequencies \( f_c, 2f_c, 3f_c, \) etc. If the sampling frequency is not high enough or the bandwidth is not adequately limited, part of the spectrum centered on \( f_c \) will fold over into the original signal spectrum as in Fig. 24-15. The fold-over components become part of the signal in the recovery process, producing unwanted frequencies that cannot be filtered out.

![Figure 24-15. Frequency spectrum folding over around the sampling frequency.](image)

An example of the effect of aliasing can be seen on moving wagon wheels in a movie that appear to reverse direction. The sampling rate of the film is lower than the rate at which individual spokes pass the top of the wheel. When the image is reconstructed, the spoke frequency has folded over and the wheel appears to move at a different rate. This phenomenon is known as aliasing. Fig. 24-16 shows that aliasing where the sample points lie have the same amplitude on two waveforms of different frequencies.

![Figure 24-16. Aliasing.](image)

Aliasing must be eliminated or at least largely reduced by selection of a high sampling rate and an adequately sharp antialiasing filter. At the output side, a similar low-pass antiimaging filter must be used to reduce the number of high-frequency glitches due to the switching at the sample rate.
The economics of delay design dictate that a relatively low sampling rate be used as this reduces the amount of storage that is required for a given length of signal. The number of storage locations required is the product of the sample rate and the length of the delay.

The required cutoff rate of the antialias filter is governed by the separation of the upper frequency $f_c$ and the Nyquist frequency $f_s/2$. As these two frequencies become closer, the number of poles required in the filter increases, adding cost to the filter.

Antialias filters may be implemented as either analog or digital circuits. A digital antialiasing filter still requires some form of an analog antialias filter but relies on a high rate of oversampling to ease the design requirements. The digital filter does not have the demanding memory requirements of the delay line, so it can operate at a much higher sample rate than the storage section.

### 24.4.2 Capturing a Sample

A sample and hold circuit takes a very fast snapshot sample of the instantaneous voltage of an analog signal and then changes into a hold mode to preserve that voltage. A hold circuit forces the amplitude of the sample to have constant value throughout a sample period. In Fig. 24-14D, the sample amplitude is shown being set at the beginning of the sample period.

A basic sample and hold circuit is shown in Fig. 24-17. The signal amplitude is frozen for a brief period of time on a capacitor until the next sample period is initiated, at which time the new signal amplitude is transferred to the capacitor. The switch is momentarily closed, under the control of the sample pulse, and then reopened. The amplifier $A_1$ must have low-output impedance to make it capable of driving enough current to charge the capacitor to the appropriate voltage during the brief ontime of the sampling pulse. The output amplifier $A_2$ must have high-input impedance so as not to draw excessive charge from the capacitor as any leakage of current will cause a change in the voltage. The capacitor should also be low-leakage to help hold the voltage stable. An analog delay may be constructed entirely out of sample and hold circuits that transfer charge from one to another.

### 24.4.3 Errors in Sampling Magnitude

Any sampling system, digital or analog, will take a finite time to convert the input voltage into a form suitable for storage. This time is called the aperture time and relates to the amplitude resolution of the conversion. The sampling error $\Delta V$ is equal to the amount that the input voltage, $V$, changes during the aperture time $t_a$:

$$\Delta V = t_a \frac{dV}{dt}$$

(24-3)

For a sinusoidal input with peak amplitude $A$

$$\Delta V = t_a \frac{d}{dt} A \sin \omega t$$

(24-4)

$$\Delta V = t_a A \omega \cos \omega t$$

where, $\omega$ is $2\pi f$.

The rate of change of voltage is greatest at the zero crossing when $t = 0$

$$\Delta V = t_a A \omega$$

(24-5)

Expressing this error, $e$, a fraction of full scale,

$$e = \frac{\Delta V}{2A}$$

(24-6)

$$= \pi f t_a$$

where,

$V$ is voltage,

$A$ is peak amplitude,

$f$ is frequency,

$t_a$ is aperture time.

As an example, a 20 kHz signal samples to a resolution of 16 bits (1 part in 65,536 or 0.0000152) requires an aperture time of $0.0000152/20,000\pi$, or 0.24 ns. This is a very short time interval for an analog-to-digital converter to operate in. A sample and hold circuit is used to preserve the voltage long enough for the conversion to take place. The aperture time of the system becomes the open switch time of the sample and hold rather than the conversion time of the analog-to-digital converter (ADC).
24.5 Analog-to-Digital Conversion

Details for the large number of analog-to-digital conversion methods are outside the scope of this chapter, but the efficiency with which it is accomplished is so important to the success and acceptability of a digital delay or reverberation system that an overview of the common conversion principles is useful.

24.5.1 Pulsed Code Modulation

Pulsed code modulation (PCM) uses a number to represent the value of each sample. The continuously varying analog signal is divided up in time by sampling and divided up in amplitude by quantization.

The quantization resolution is defined by the number of bits used in the binary number and defines the amplitude resolution of the signal. The number of possible states for a number with \( n \) bits is \( 2^n \). For a 16-bit number, there are \( 2^{16} \) or 65,536 different voltages that may be represented. For a 1 V peak-to-peak signal, this is equivalent to a 30 \( \mu \)V resolution. An error in the representation of the analog value results because there is a range of voltages that yield the same output code. This error is called the quantization noise and is given by

\[
Q = \frac{A}{2^n}
\]  

(24-7)

where,

- \( Q \) is the smallest analog difference that can be resolved by the converter,
- \( A \) is the maximum amplitude,
- \( n \) is the number of bits.

Another way of expressing this error is as the dynamic range of the converter.

\[
DR = 20 \log 2^n = 20n \log 2
\]  

(24-8)

A 16-bit coding system will therefore have a dynamic range of \( 6.02^{16} = 96 \) dB.

The multibit binary word represents the amplitude of samples at regular intervals, usually in two's complement form. In this scheme the codes vary between \( 2^{n-1} \) and \( 2^{n-1} - 1 \). The most significant bit (MSB) indicated the sign, with all negative values having MSB = 1. The code is often used in it fractional form, where the numbers represent values between \(-1\) and 0.999.

24.5.2 Delta Modulation

Delta modulation is based on whether the newest sample in a sequence is less than or greater than the last. A delta modulator produces a stream of single bits representing the error between the actual input signal and that reconstructed by the demodulator.

A simple delta modulator, as shown in Fig. 24-18, consists of three parts: a comparator whose output is high or low depending on the relative levels of the input signal \( (SST) \) and the reconstructed signal \( y(t) \), a D-type flip-flop that stores the comparator output under control of a sampling clock, and a reference decoder that integrates the binary output to reconstruct the signal \( y(t) \). The demodulator is a simple integrator circuit with the same characteristics as those used in the reference path of the modulator. It will reconstruct the reference signal \( y'(t) \), which is a close approximation of the original input.

The simplicity of the coding and decoding schemes has resulted in use of the delta modulator for communication and motor control applications. The simplest integrating network consists of a resistor and a capacitor, but the quantization noise from this is quite high so more practical systems use double integration in the reference path.

Distortion in delta modulation occurs if the rate of change in the input signal is greater than the maximum rate of change of the output of the integrator. The maximum rate at which a sinusoidal signal, \( \sin(wt) \), varies is
The maximum required charge in voltage per sample is therefore

\[ \Delta V = A \omega \Delta t \quad (24-9) \]

The value of \( \Delta V \) relative to the maximum amplitude \( A \) defines the amplitude resolution of the system. The SNR is proportional to the sampling frequency and inversely proportional to the signal bandwidth. When presented with a fixed input, the delta modulator will hunt for the value by changing the output between 1 and 0 every sample. The resulting output is a tone of magnitude \( \Delta V \) at the sampling frequency and is called the *idling noise*.

Delta modulation is more immune to errors in storage or transmission than PCM. A single-bit error in the output has a resulting error in the analog signal of \( \Delta V \). In a PCM system a single-bit error could cause an error of up to half the full-scale value. When compared to a PCM system in terms of bits per second, delta modulation will have comparable dynamic range but a smaller frequency range. At lower bit rates, delta modulation can have a better SNR and dynamic range than a PCM system and this has implications for delay lines, where the total number of bits that must be stored can be reduced for the same quality of signal.

### 24.5.3 Sigma-Delta Modulation

By reorganizing the sequence of operations, the delta Modulator becomes a *sigma-delta modulator*. A first-order SDM as shown in Fig. 24-19, has one low-pass filer integrator in the signal path and a direct feedback path to a summing point that produces an analog error signal. The comparator of the delta modulator is replaced with a quantizer, which is a comparator against a fixed zero reference. Demodulation is accomplished using a low-pass filter as in delta modulation.

Both delta modulators and sigma-delta modulators use sampling frequencies much larger than the Nyquist frequency, typically of the order of 100 times. This places the quantization noise energy at very high frequencies where it can easily be removed by filtering.

### 24.5.4 Decimation

The process of sampling well above the required Nyquist frequency is called *oversampling*. The objective is to cause the modulation noise inherent in the sampling process to appear at frequencies further removed from the audio signal so that it can be more easily removed by filtering. The high SNR of an oversampled system can be preserved while reducing the overall bit rate by the process of *decimation*.

The quantization noise from PCM encoding decreases by 6 dB for every bit added but decreases by only 3 dB for every doubling of the sample rate. Decimation of the oversampled PCM data can result in a large reduction in the overall bit rate. Decimation filters are used to achieve this and can be thought of as performing an interpolation on the existing data to fill in the additional bits in the output.

A sigma-delta modulator can have as much as a 15 dB SNR improvement for a doubling of the sample rate. Decimation of the SDM signal can be used to convert the single bit data stream to a multibit PCM format suitable for storage in RAM and processing by DSP.

25.1 Introduction

Mixing consoles are an immense subject; their understanding though is a key to professional audio. In this section consoles are discussed from the basics of their architectures, features, design elements, and all the way through to DSP and its implementation in digital mixer design. Consoles abound in forms quite unlike the traditional big sea of knobs. Productions huge and modest are regularly done with a screen and a mouse—indeed, nearly everywhere in operations that don’t require immediate access to controls, mostly live. But consoles they are; they’re just hiding in unfamiliar shells; their schema are, despite outward appearances, directly traceable to traditional audio architectures.

Commercial mixing consoles live or die not just on how closely they fit their particular application; a several-hundred-thousand-dollar buy decision is often made on things as fiercely disparate as more or less favorable finance schemes and the way consoles sound (or more often are reputed to sound). This section does not include console cost other than drawing distinctions between straightforward and extravagant approaches, but it does explore many aspects of what makes consoles sound better or worse.

Along the way, explanations are given of what each common control does and how it is normally used and why. Examples of how they have developed and been implemented in electronics are also given. A range of console arrangements (architectures) gives enough clues to analyze how any encountered system actually operates. Description of circuitry and techniques is less theoretically driven than practically derived, with no apologies given for blow-by-blow analyses of real commercial multitrack mixing console designs. It is hoped that this will augment and lend perspective to earlier descriptions of typical circuit blocks.

Seemingly the only thing preventing most mixers from being digital nowadays is that the cost benefit for many applications has not yet tilted far enough in that direction; although hardly mature, the technology and the available quality are not impediments. Given that, one might question why this chapter retains a lot of “analog stuff.” The answers are manifold: A lot, arguably still most, of mixers in use today are still analog and far from a prediction made in the mid-eighties that the Last Great Analog Console had probably already been built, manufacturers both established and new seem to think it worthwhile to wheel out new analog behemoths once in a while. And, almost in mirror fashion, at the low end of the market economies of scale and slim margins still preclude digital on cost alone, where any meaningful control surface is needed. But those aren’t the main reasons consoles exploded, evolved, and matured operationally in the same era as similarly burgeoning analog technology; the technology inevitably influenced the application with its own rationalized costs and limitations. The applications—consoles and their constituent signal-processing elements—are nowadays being emulated digitally. Yes, a huge amount of the engineering of digital mixing consoles is in accurately recreating foibles inherited from their analog ancestors, good or ill. It behooves one to understand why things ended up the way they did, so that one can optimally progress into the new domain. It’s called learning from history, only in this case the history is still very much alive and has its teeth.

An overview of digital signal processing as applied to consoles will, as deeply as it is possible to go before nasty equations arise, give an insight into how these things work—at first blush it all seems black magic—really it’s just a lot of black chips each with a specific and usually straightforward purpose. Similar to the way that a real analog console design is dissected and explained in the following pages, a real digital console design is broken down for overview and analysis.

Parallel, and indeed prior, to the incursion of DSP audio was digital control of audio. Although DSP and digital control necessarily go hand in hand, digital control of analog techniques are overviewed here, too.

25.1.1 Console Development

The establishment of consoles was a slow and gradual process. Similarly, systems—or preorganized arrangements of devices—evolved slowly, too. In most audio work the two are now considered as almost synonymous; the greatest departure from this is the inclusion of a console as part of a system. But even then, there is no doubting that the console is the heart and substance of the system.

The history of consoles reaches back to the time when the recording process was purely mechanical, Fig. 25-1, followed by its electrical analog, Fig. 25-2, which included a source transducer (in this instance a microphone), a means of gain (an amplifier), and an output transducer (a disk-cutting head). It doesn’t take a staggering amount of imagination to extend this system to embrace other applications: public address, acoustic enhancement of natural sound by electronic means, Fig. 25-3; disk replay, Fig. 25-4; and broadcasting by replacement of a simple electromechanical transducer by a radio transmitter, Fig. 25-5. The objective of the
system is to facilitate the transfer of a signal from one source—be it a simple transducer or another system—to a destination.

Of course things get a bit more involved than that, and to demonstrate this complexity, the evolution of what is probably the most important subsystem to our industry—the recorder, mono, stereo, or multitrack—will be used to explain how it, almost single-handedly, made everything as complicated as it is today. Disks were permanent. You got it right or you didn’t. Tape at least gave the chance of one more take.

Mixing in the early days of system development was surprisingly easily achieved—just connecting the outputs of the various source input amplifiers together did it perfectly adequately. It’s important to understand that the technology of the day facilitated this simplicity far more, paradoxically, than today’s gear. Tube amplifiers, such as were then used, needed to be terminated at their outputs by a specific impedance for proper operation, which for reasons discussed later was universally 600 Ω floating balanced. By simply connecting amplifier outputs together, a mix of sources was achieved, provided each of the source amplifiers saw 600 Ω. It was only a very minor step for interspersed networks to become constant-impedance variable attenuators, usually in the form of rotary controls. The pot (from potentiometer) or fader was born. The ability to create a balance of sundry sources for the chosen destination is perhaps the most recognized feature of the console and its system. Convention and common sense rule this as the main signal path, and other paths are subsidiary or auxiliary to it.

25.2 Auxiliary Paths

25.2.1 Monitoring

Take the example of Fig. 25-6, where a single microphone is being laid on a recorder. It’s operationally necessary for the system operator to hear the signal going to the recorder with headphones or a control-room monitor loudspeaker. To facilitate this requirement, a parallel feed is taken off the machine input to the operator’s monitor. Monitoring is perhaps the most important of the auxiliary signal paths; upon it is based the qualitative decisions of the nature of the signal in the main path. It is the reference.

Fig. 25-7 applies a small extension to the basic monitoring path in the form of a source/replay switch, enabling operators to hear the aftermath of their efforts. If the recorder has separate record and play signal paths, they can even toggle between the two while actually recording for immediate quality assessment. The monitoring section is born.
25.2.2 Prefade Listen and Audition

When a multiple-source system is established (similar to Fig. 25-8), another monitoring requirement, *prefade listen* (PFL) and *audition*, is required. Imagine the case of a radio broadcaster, where the sources consist of disk replay units and microphones; it’s an obvious necessity to be able to listen to a source prior to its being put on air to check that:

1. The microphone is set at the correct position, level, or even working!
2. The required section of a disk or tape is cued up or ready to play.

There are two basic methods of arranging this prehear function, as shown in Fig. 25-9. They owe their existence primarily to slightly different operating practices on opposite sides of the Atlantic. The first, Fig. 25-9A, involves switching the signal immediately prior to the fader on the selected source path into the monitoring chain. This is called *prefade listen* (PFL). A useful but not immediately obvious virtue of this arrangement is that it is possible to listen to a channel’s contribution to a mix of which it is part without disturbing that mix. It is, therefore, a nondestructive monitoring function. The alternative method shown in Fig. 25-9B consists of removing the required channel (postfader) from the mix and placing it onto a second parallel mix facility, commonly called *audition* or *rehearse*; it is possible in this mix to emulate exactly what would happen in the real mix without upsetting the presently active mix. A disadvantage of this method is the inability to use the function when the channel is live because it disrupts that source and prevents it from going to the mix. It is a destructive monitoring technique. Each method has its virtues, though, and most modern consoles use both techniques to varying extent. That said, all but really small American broadcast consoles nowadays employ a PFL-type cue function, the audition/rehearse bus being arranged to be a secondary mix bus independent of but in the same vein as the program bus. The name often remains as an echo of its original function. Postfader monitoring, however, lives on in large production consoles as *in-place stereo* monitoring, described later.
25.2.3 Overdubbing and Foldback (Cue)

While broadcasting lends itself to explaining the need for individual channel monitoring, original material generation onto tape serves best to explain another crucial auxiliary signal path.

It didn’t take long before studios were using more than one tape machine in a technique known as overdubbing. Briefly, this involved recording a backing track (for instance a rhythm section) on one machine and then playing that back while vocalists sang or soloists played along with it; the whole was mixed together and recorded on a second machine (bounced) as shown in Fig. 25-10. This could be carried on until the subsequent machine-to-machine generation losses became too objectionable (although that never seemed to bother many early producers!). (Generational losses occur because the tape machines of the era were less than perfect, what came out of them being noticeably ropier than what went in!) Naturally, it was essential that the musicians in the studio were able to hear via loudspeakers or headphones that to which they were supposedly playing along; this is where foldback (cue) comes in. In its simplest form, it could be a straight derivative of the main mix output, since this output has basically everything necessary in it. This system, however, has a few shortcomings due primarily to conflicts between what the final mix is intended to be and what the artist(s) needs to hear to perform satisfactorily. A prime example of this dilemma is in the recording of the backup vocalists sections; usually they take a fairly minor part in a mix, being balanced well down. Contrary to this is the need of the vocalists to not only hear the track played back to them but to hear themselves sufficiently well—usually enhanced—to pitch and phrase themselves effectively. These conditions are next to impossible at the final mix. A solution lies in Fig. 25-11 where a separate balance of the relevant sources is taken and fed separately to the performers, giving them what they most need, a foldback mix. The takeoff for the foldback feeds is almost invariably prefader so that the artist’s balance remains unaffected regardless of what modifications may be necessary for the main mix.

25.2.4 Echo, Reverberation, and Effects Send

The move (regrettable as it may seem) from natural performing acoustic environments to the more cultured, drier, closer miced techniques brought with it many problems attendant to the advantages. How do you make a sound seem as though it was recorded in a great concert hall if it was done in a small studio? Reverberant chambers were an initial answer, being relatively small rooms acoustically treated to have an extended reverberation time (bathroom effect). Driven obliquely at one end or corner by a loudspeaker(s) and sensed by a microphone(s) at the other end, which is amplified and balanced into to the main mix, a fairly convincing large room reverberant effect can be achieved. Simplistically, all that’s needed to feed the loudspeaker in this room is
a derivation of the main mix, but similar to the problems with foldback mixes, artistic judgments dictate something more complex. Some instruments and sounds benefit greatly from being dry (most of a drum kit, for example), while others—vocals, in particular—sound quite dry, cold, and uninteresting. A means of adjusting the relative amounts of artificial reverberation due to various sources would be beneficial. Fig. 25-12 shows a small console system complete with an echo send mix bus (echo in this sense including reverberation); the echo return is brought back into the main mix just as any additional source would be. Echo feeds are nearly always taken postfader, keeping the reverberation content directly proportional (once set) to the corresponding dry signal in the mix regardless of the main channel fader setting.

Today, any number of foldbacks and effects sends are in use as toys (effects boxes) proliferate; long gone are the days when one of each feed was sufficient.

25.2.5 Communications (Talkback)

An often mentally mislaid but crucial console auxiliary path is talkback; that is, the ability of the console operator/producer to talk to various people involved in the recording. The primary need for talkback is to be able to communicate with the studio area that is necessarily acoustically separate from the control/monitoring room. Since there are already foldback feeds going to the studio area for performer cues, it makes sense to talk down these feeds, which is talk to foldback (talk to studio). Another useful function in this vein is slate. This curiously named facility allows the operator to talk into the main mix output and thus onto tape for track and take identification purposes.

25.2.6 Combined Auxiliaries

In summary, a usable console has to have several signal paths in addition to the main mix path. These include overall and presource monitoring, prefader adjustable foldback feeds, postfader artificial reverberation feeds, and communication (talkback) feeds as shown in Fig. 25-12.

25.3 Stereo Consoles

Stereo predated multitrack recording. Technically the required console techniques were not very far removed from those just described. Assuming the same bouncing (machine-to-machine overlay and transfer system described earlier in the section on overdubbing), stereo just means two of everything in the main signal path.

25.3.1 Panning

Panning is the technique of positioning a single monophonic source within a stereophonic image. It isn’t true stereo; true stereo can only be achieved from coincidentally aligned microphones. Instead, it is panned mono. Simply, the ear is deceived by pure level differences between the left and right paths of a stereo pair into perceiving differing image position; fortunately for the entire industry, this is a trick that works rather well and is quite simply realized.

Complementary attenuators (one increasing and one reducing attenuation, with rotation) feeding the L and R mix paths from a mono source is the most common method. Fig. 25-13A illustrates this system. The pan pot is usually inserted after the source fader. An alternative arrangement is shown in Fig. 25-13B. Here the pan pot is inserted prior to the fader; a ganged matched fader is required with this method. This arrangement can be useful when stereo PFL is required, although there are other ways of achieving stereo in-place monitoring for sources that will be described later.

25.3.2 Auxiliaries for Stereo

Auxiliary paths remain largely untouched by the upgrade to stereo of the main mix path; the monitoring section stays just the same in systemic function (but obviously with two paths instead of one to cope with stereo feeds). Both the prefader foldback and PFL take-offs are still in mono. The postfader echo-send feed is usually taken out before the main path pan pot, so they remain mono, but the returns pass through their own pan pots such that the reverberant image may also be spatially determined in the mix. It’s become normal practice to make echo-send feeds stereo in their own right, Fig. 25-14, via their own pan pots’ mixing to two outputs. Many reverberation rooms, plates, and boxes are capable of supporting a diffuse stereo field. The purpose of this is to excite the reverberant chamber (or plate or springs or little black box) spatially, conjuring a more solid and credible reverberative effect in the main mix. If a panned echo-send output isn’t available, it’s common to use a pair of separate postfader feeds and juggle the levels between them.
25.3.3 Multiple Effect Feeds

Currently, there is a whole gamut of electronic toys applied to mixdown to achieve specific sounds: Harmonizers®, delays, flangers, phasers, automatic panners, artificial reverberators of various sorts, and so on. These all need to be fed from their own effects mix paths. Similarly, studio foldback mixes have grown more profuse with changing music and increasing musician sophistication and awareness of studio techniques; consequently, the number of auxiliary mixes within modern consoles has risen quickly. A rationalization of this is to make those auxiliary mixes multipurpose, usually by allowing them to be switchable between prefader and postfader feeds on their appropriate sources. A smaller number of buses are needed in this way; during the recording process the emphasis is on many foldback (prefade) feeds for the musicians in the studio and maybe one or two toys to spice up the monitoring. On the other hand, during the overdubbing and mixdown phases very few foldbacks (if any) are needed but every bus will be set to postfade and laden with effects. Additionally, in broadcast it is commonly necessary to talk back down some or all of these mixes individually; such a feed is called an interruptible foldback, or IFB. Large modern consoles for live applications often have many stereo foldback auxiliaries, driven by the trend toward the (usually wireless) in-ear headphones beloved by performers.

25.4 Dawning of Multitrack

Multitrack operation is when a number of separate parts of the recording are laid onto separate tracks on a recording machine and subsequently remixed down onto another machine (be it mono or stereo) or even interim bounced onto spare tracks on the same machine.
Stereo recording using two-track tape technology seemed to many to be the zenith of professional audio. Many will argue the point even today. There is inescapable evidence of the validity of that opinion in that some of the finest stereo recordings, especially of classical and jazz works, were done using fundamental microphone techniques straight onto two track. Even in the field of pop records where things were bounced mercilessly the final master still represents the first generation of the last overdub. (In retrospect that is an advantage over contemporary multitracking where the master is at best the second generation of everything.)

Multitrack soon reared its head(s?) in the early 1960s—initially as three track and four track across 1 inch tape; there are those who regard that as the zenith. More tracks reduced the number of intermachine bounces, but they still added up! *Sergeant Pepper* is of the bounced four-track genre (although many parts were done on a pair of loosely sync'd machines for pseudo eight-track) and stands up rather well even today. It does put things in perspective. How much more technology is needed for what?

Three tracks afforded a great advantage over two tracks for modern music producers at the time. Two-track recordings were always hampered by the need to make sure that all the earlier things done in a bouncing sequence were right to begin with; there was no chance of subsequently altering them. Three-track recordings, typically in a Track/Vocals/The Rest format, took a little of that pressure away. Already producers and performers were taking advantage of the multilayered production approach to take the heat out of recording; it was no longer necessary for everyone from lead vocalist to third trianglist to be present all at once for a momentous occasion. Bits could be done one at a time. The extension to this given by multitrack is simple to see: the more tracks, the smaller those bits need be and the fewer things needed to be incontrovertibly mixed. Putting off the day of reckoning—the final mixdown—is one of the strongest appeals of multitrack. This, indeed, has led to a curious polarization in the business; *tracking*, the laying down of individual tracks, is typically done in entirely different studios or environments to *mixing*. And *remixing*, the construction of yet different mixes from the same basic tracks for specific genres such as dance mixes, has spun off into yet another subindustry. So much for making spontaneous music.

### 25.5 Grouping and the Monitoring Section

Each signal source in the console needs some routing to determine the machine track on which it is going to end up. It’s a situation that hardly existed previously, since it was pretty sure that the mono or stereo output of the console was going to go straight to the respective mono/stereo inputs on the tape machine(s). There were on a stereo console just two groups where all the sources were summed together; for multitrack as many groups as there are tape tracks are switch selectable from the sources—any source to any machine track. The alternative hard way, patching everything across on
a jackfield, was and is exceedingly tedious, messy, expensive, and error prone.

Four-track recording set the mold for console design for many years. The monitoring section evolved. Fig. 25-15 can be compared to the simpler back end of a stereo mixer in Fig. 25-12. The main difference can be seen as the addition of an entirely separate mixer within the console just to handle the multitrack monitoring. Fortunately, it’s a fairly bare-bones mixer; it’s all at high signal levels, and little, if any, gain is required except as makeup gain in the monitor mix bus.

While all these tracks are being laid, it’s necessary to hear what has been done previously in the control room and studio. In the same way that source/return listen of stereo machines was needed, so each individual track of a multitrack needed similar treatment. It grew, though. Initially, as the number of tracks per machine increased, the number of mixer groups increased correspondingly. Each group had its own A/B switch relating to that individual console track output and the associated machine return, with its own level and pan controls feeding an altogether separate stereo monitor mix. This new monitor mix appeared as another source on the main monitor selector. This, alas, was insufficient. Foldback prefade mix feeds no longer became a luxury but a necessity, since the desk stereo output or a derivation thereof could no longer be relied upon to be even roughly what the artist needed to hear. There was no proper console stereo output at any time other than mixdown. Foldback feeds were added to the monitor mix bus.

The monster has split itself amoebalike into two entirely separate signal-processing systems: the main mixer and a monitor mixer. A curious situation occurs: the mix used for monitoring during the original multitrack recording had to be transferred over to the main system entirely at some time for mixdown. Ordinarily, tape-machine returns are not only brought back into the monitoring section but are also tied to high-level line inputs on the main mixer section. The remix takes place using those channels into the main stereo mix bus.

Perhaps the first major rationalization (which occurred long after many conventional X-input, 24-group, 24-monitoring consoles had been made) was a result of the realization that few people actually needed 24-group faders sitting there full up, collecting dust. Losing them instantly avoids a normally unnecessary gain-variable stage in the signal path, which, if maladjusted, could upset noise or headroom performance.

Individual channel outputs together with a much smaller number of stereo mixing subgroups—usually four or eight pairs—which could again be routed to any of the multitracks, proved easily as flexible. But still there was duplication of monitor buses and main stereo mixing buses both with their attendant effects and foldback feeds rarely being used simultaneously. At last the dawning of the realization that the pair, that is, the monitoring and stereo mastering buses, could be one and the same thing. In-line monitoring recording
systems had come to fitful fruition. The in-line console includes all of a recording channel’s processing and all of a machine return’s monitoring controls within one channel strip; it allows efficient sharing of controls, processing, and mixes between those paths, maximizing their full utilization through the tracking, overdubbing, and mixing phases of a production. It also does away with the separate multitrack monitoring section, the mixer within the mixer that nearly doubled the physical width of conventional consoles.

We all have to be thankful for the cranks and visionaries along the way (often the same) who have manipulated or shocked the industry into grudgingly lurching back into step with technology’s capabilities. These developmental milestones represent significant plateaus of thinking that form the basis of today’s console concepts. In-line is a classic example.

### 25.5.1 Subgrouping and Output Matrices

Particularly in live applications (e.g., sound reinforcement or broadcasting) the ability to make a subgroup of related sources—say drum mics, bass, guitar, keys, backing vocals, lead vocal (each of which can have many sources themselves)—and then rebalance them together is a valuable addition. (This means that instead of having to gingerly pull down the 10 mics on a kit without destroying the previously hard-won balance, a single fader on that subgroup can be moved instead.) These are real subgroups, so called because a real mix of real audio sources is created, rather than a similar overall result happening by way of a VCA subgroup (described fully later) in which only the fader movements are tied. An output is available just containing the subgroup member sources, useful if processing (EQ, dynamics, etc.) is required over them exclusive to other sources such as auxiliary sends for the addition of effects solely to the subgroup and remixing. This latter is a particularly powerful use for these subgroups; feeding them as sources into a downstream mixer, often called a matrix mixer, from which an often large number of matrix output mixes are created.

Again using sound reinforcement as an operational example, the many performers on stage all need to hear both themselves and the rest of the performers either in monitor speakers or in personal earpieces; the trouble is, the balance that each of these people needs is typically entirely different! Using the individual remix capability on each matrix output fed by the earlier-created subgroups, many different mixes of the same few subgroups are possible, hopefully resulting in a calm stage.

### 25.6 Console Design Developments

Two distinct considerations interplay in determining the ability of a console to fulfill a given application. These two—the system and the electronics—have entirely differing parameters that need to be defined but are, nevertheless, completely indivisible.

The electronics, as much as being designed to perform required functions, must be very carefully designed not to be a major influence on the sound of the console. Most causes of sonic disturbance can be attributed or predicted, and still dubious circuit configurations can be avoided altogether. There seems to be a groundswell of designing sonic character back into studio electronics; this after generations of striving for accuracy and neutrality is a touch alarming. The good news is that consoles (unless otherwise eccentrically contrived) are still expected to be neutral, the color being acquired by the gallon in external rack boxes. To that end, unless specifically stated, the electronics described here are intended to be neutral sounding. To the shock of some purists, commonly available integrated circuit operational amplifiers are generally used throughout the designs in this chapter. The reasons why (other than the obvious convenience), together with the reasons why they acquired a bad reputation, are treated in depth in Section 25.7.

Operational amplifiers (op-amps) have, in recent years, revolutionized the concepts and systems capability of full-performance audio consoles. Their use allows system elements to be thought of, designed, and implemented as building blocks. This simplifies matters considerably, but it also entertains the valid criticism that console design can be relegated to a do-it-by-numbers routine. Fortunately, device idiosyncrasies, subtleties, and the entirely separate science of getting heaps of individual system elements to behave successfully as a total console prevent this.

Fortunately for the console industry, the large proportion of the current console manufacturers started off in life as small groups of musicians and studio engineers furtively constructing mixers for their own ends, resulting in grass-roots system design owing everything to immediate operational needs. Continuing in this vein in production, the manufacturers are listening to and, most importantly, relating to customer needs because they’ve played this game for themselves.

Not too long ago, systems and mixers as such didn’t exist. All the bits of electronics used in the control room
sat there with all their inputs and outputs accessible by way of a jackfield for the prosperous or by small screwdriver and sore knees for those who weren’t.

Mixing sources was accomplished by directly paralleling amplifier outputs (possible because all the old tube gear was designed with a particular termination impedance in mind, usually arranged to be a conventional balanced 600 $\Omega$) and either hoping or arranging that the destination had enough gain to make up accrued paralleling losses. Crude as that may seem today from an engineering viewpoint, it has a sheen of pure elegance. An amplifier was just that, a box that had a balanced 600 $\Omega$ source and termination impedance. It might also have an alternative bridging (> 10 k$\Omega$) input terminal and a selectable amount of gain offering universal application from microphone amplifiers through mixing amplifiers to headphone amplifiers. To do more things, more boxes were added. Equalizers and limiters, a treasured few if there were any, were similarly universally applicable. Variable-level control was again attained by true balanced 600 $\Omega$ source and termination, via studded rotary attenuators. The utter beauty of the systemless studio was that anything could go to anywhere via anything else and be mixed or distributed at any point on the way.

Soon enough amplifiers were hardwired to attenuators and designated specifically a microphone amplifier, and a system had been created. Some of these together with a mixing gain makeup amplifier were thrown in a box. The mixer was born.

It has been downhill ever since, with ever-increasing numbers of system elements being tied together in increasingly knotted manners in order to maintain some kind of flexibility. Perversely, a system can be defined as a means of reducing the ultimate versatility of its constituent parts.

Once a mixer was accepted as a system element itself, the problem set in further. There was no need to provide for convenient connection of its internal interconnections to the outside world, so the balancing transformers disappeared, and more economic alternatives to the stud attenuators operating at more convenient internal impedances evolved. By a more positive token, the electronics were gradually becoming optimized for the specific functions to which they were designated, such as the microphone amplifier and the mixing amplifier. (The question nags us whether a universal amplifier, by now all but obsolete, could be optimized for all the varying requirements, this is unlikely.) Still, at least all the inputs and outputs of the mixer were conventional. This held true until the slow demise of vacuum tubes in professional audio.

### 25.6.1 Transistors

Transistors were justifiably unpopular for a long time because of the numerous limitations they placed on design. The headroom was severely limited because of the low supply voltages that could be applied to the early devices. They were noisy. The lower operating impedances and differing modes to tubes took some getting used to and, when they clipped, they actually clipped rather than gracefully bending (characteristic of tubes that people had known, loved, and frequently taken advantage of even now). To realize a reasonably low stage distortion, many transistors in compound configurations using heavy amounts of negative feedback were used—a far cry from a single tube stage operating virtually wide open with little feedback. This gave rise to a peculiar phenomenon that sounded as if it hailed from science fiction—*zero impedance*.

The heavy negative voltage feedback employed around transistor circuits could be made to render the output of an amplifier insensitive to varying load impedances; they would deliver the same output voltage level almost regardless of their termination impedance. This eliminated termination problems with the attendant worry of compensating in level for differing load hookups. With the exception of long line feeds, 600 $\Omega$ terminations were as good as dead. High-level balanced inputs were now almost exclusively bridging; they had a sufficiently high impedance (usually >10 k$\Omega$) not to disturb the level of the source to which they were tacked on. For better or worse, it has become the conventional studio interconnection technology. It has taken until fairly recently for a distinction and separate level specification for the two technologies to be accepted.

### 25.6.2 Level Specifications

The original transmission line level specification referred to a power level of 1 mW regardless of impedance. This was 0 dBm. It was a universal specification applicable to any signal of any frequency being transmitted along any length of wire for any purpose at any rated impedance, and it is used extensively in radio-frequency work and other things entirely unrelated to audio. The dBm definition is sacred and can’t be changed. Zero dBm in a 600 $\Omega$ load works out to 0.775 Vrms; this was adopted de facto as the reference for use in general audio work. With zero impedance technology, although the working voltage is specified, the impedance isn’t. It can be anything, but the power (as measured in dBm) necessarily varies as a result; for instance, 0.775 Vrms across a 100 $\Omega$ load is +7.78 dBm.
while across 10 kΩ it would be minus 12.22 dBm. But it’s still 0.775 Vrms.

The reference level for zero impedance thinking is a voltage, and the one chosen is the familiar 0.775 Vrms with which everyone was historically used to dealing. That voltage is distinguished as 0 dBu. Some have tried to impose a universal reference based around a voltage level of 1 V called the dBV for audio, which is easily divided by 10 but has proved sufficiently confusing to anyone brought up on the dBm that it is now all but dead.

But wait! There’s more! The ubiquitous VU meter when implemented as intended imposes a nominal system level of +4 dBm (0 VU = +4 dBm at 600 Ω), and in territories and market segments where the VU reigned, +4 dBm (and latterly +4 dBu) is still a common reference. And try as one might, it is impossible to ignore that there is more semipro recording and audio gear in use than real audio equipment and that generally uses the domestic level of –10 dBu as a nominal reference. Glad that’s all cleared up, then.

25.7 Operational Amplifiers in Consoles

Consoles utilizing integrated circuit operational amplifiers (IC op-amps) have suffered from a curious syndrome, collecting in earlier days a (sometimes deserved) dreadful reputation, which has stuck. This section is an attempt to explain the history, shortcomings, and attributes of IC op-amps from conception to present day, to point out how some shortcomings are overcome and to provide reassurance that they are the future of consoles. It is also an example that this, along with most other technology, is well understood and quantified, the concepts if not the details having been defined many years ago, Fig. 25-16.

When ICs first came out (the Fairchild μA709, e.g., they were expensive, prone to oscillate, and had no short-circuit output protection.

At this stage in the game, discrete transistor circuitry ruled supreme in pro-audio while considerable vacuum-tube gear was still in use. Techniques expanded and ICs were tamed sufficiently to remain operationally stable, but little high-frequency loop gain remained to guarantee enough feedback to adequately reduce high-frequency distortion. Also, they were very noisy. Although their parameters could be set up to be acceptable for any set application and gain setting, the very nature of control in consoles is variable, so the devices almost inevitably ended up operating away from their optimum.

Figure 25-16. Basic op-amp configurations.
A new term entered the audio design vocabulary: *compensation*. Compensation is the brutal slowing down of the amplifier in order to stop rampant, screaming instability. Essentially it was accomplished by defining the bandwidth of the overall loop around the amplifier or a particular gain stage within the amplifier—or both. And typically robbing the device of its promise.

Hot on the heels of the μA709 came the now much loved and despised, but always revered μA741. Best known in its plastic encapsulated eight-pin dual-in-line configuration, it still took our industry many years to catch on to the fact that here existed a seemingly almost vice-free op-amp. Well, at least, it was free of some of the 709’s vices. It was heavily internally compensated to nominally guarantee stability, but the penalty for this was rapidly disappearing open loop gain with increasing frequency. There was just enough gain left to squeeze 20 dB of broadband gain safely over a 20 kHz bandwidth. Some IC manufacturers came up with good 741s, usably quiet and free of the grosser output offset voltage problems that plagued earlier devices. The 741 was also output-protected to the extent of being short-circuit proof, a relief to all.

Subsequent generations of op-amps to the 709 included the 748 (the uncompensated sister to the 741) and the 301, again, some versions being excellent for this class of device. That the 748 and 301 were user compensated did allow for more optimal parameter setting and in most circuits only required one capacitor to achieve this (as opposed to the necessary two resistor-capacitor networks for the 709).

Although on the surface this appeared to be of great convenience to the designer, it disguised the fact that far superior bandwidth and phase-margin performance could be obtained by carefully considering the nature of the compensation network. Rather than just a simple capacitor of sufficient value to hold the amplifier stable (which also turned the internal compensated transistor into a Miller integrator doing absolutely nothing for the speed of the device), a more complex network such as a two-pole resistance-capacitance network, Fig. 25-17E, improved matters greatly.

External feed forward, while in use as an inverting or virtual-earth mixing stage, also enabled a dramatic increase in bandwidth and speed over the more conventional compensation arrangements, as shown in Fig. 25-17.

### 25.7.1 Slew-Rate Limitations

All these early devices had one great failing that has been leaped on vigorously by the hi-fi fraternity and

---

**Figure 25-17.** Various op-amp compensation techniques.
audio engineers alike. Slew rate is the speed (measured usually in volts per microsecond, V/μs) at which an amplifier output shifts when a step source of extremely high speed is applied to the input. All the early-generation op-amps had slew rates on the order of 0.5 V/μs, but no one really understood it or its implications or effects then, and it was not the issue it is now.

Why is slew rate a problem? If the audio signal that the device is attempting to pass has a rise-time that exceeds the amplifier's slew rate, then obviously distortion is created—the amplifier simply cannot react quickly enough to follow the audio. Slew is an issue at high frequencies (rapid transitions) and high levels (a quiet signal is moving at fewer V/μs than the same signal louder). This by happy accident means that a lot of program material that does not contain high amplitudes at high frequencies can be passed by slow, low-slew-rate devices with impunity. Unfortunately, a lot of sources found in recording studios or on stages don't fit that bill; they're loud and have serious high-frequency content.

The speed limitation was nearly always in the differential and dc level-shifting stages of the devices. It is quite difficult to fabricate on an IC wafer ideal classes of transistors in configurations necessary to improve matters without compromising other device characteristics (such as input bias current, which affects both input impedance and offset performance).

Feed forward, in which a proportion of the unslewed input signal is fed around the relatively slow-responding lateral pnp stages, improving slew rate and bandwidth appreciably, is used to great effect in the LM318; a slew rate of some 70 V/μs is achievable by this technique. It was in this area of slew rate, combined with a significantly improved noise performance (again another parameter suffering from difficulty in fabricating appropriate devices in a relatively dirty wafer), that the next major breakthrough occurred in devices commonly used for audio applications—the Harris 911. Although dramatically improved, the slew rate was still not fast and was also asymmetrical (+5 and −2 V/μs).

25.7.2 Bipolar Field Effect Transistors (BiFETs)

A breed of op-amps called BiFETs, or bipolar field effect transistors, emerged. These devices have a closely matched and trimmed field effect transistor input differential pair (hence, the typically unimaginably high 10 MΩ input impedance) and a reasonably fast 13 V/μs structure. These devices are typified by the TLO series from Texas Instruments, Inc. and devices such as the LF356 family from National Semiconductor Corp. Selected versions can, when source impedance is optimized, give noise figures better than 4 dB at audio frequencies, which is thoroughly remarkable for units costing very little more than a 741.

The speed of the devices has been achieved by the replacement of the conventional bipolar transistor differential input and level-shifting circuitry with FET configurations. Incidentally, the intrinsic noise characteristic of these FET front ends is significantly different from that of bipolar and seems perceptually less objectionable.

There are currently a few devices designed specifically and optimized totally for inclusion in high-quality audio equipment. With a quoted noise figure of better than 1 dB at audio, a slew rate of 13 V/μs, and the ability to drive a 600 Ω termination at up to +20 dBm, the Signetics Corp. NE5534 (or TDA1034) was in the vanguard of these; many nice devices have since followed.

These are all somewhat more expensive than the BiFET types, but none is prohibitively so, unless the target design is extremely cost sensitive. Today's designer is spoiled by the ability to choose appropriate devices for each application almost regardless of cost, and as will be shown, sometimes the less grand and glorious parts are sometimes the better choice.

Noise in any competently designed and operated console can be attributed mostly to two sources:

1. Mixing amplifiers with an appreciable number of sources and, hence, a lot of makeup gain
2. The input stage, especially a microphone amplifier with a fair amount of gain in it

Once a background noise level is established from the front-end stage (at a level obviously dependent on the amount of gain employed there), the difference in noise contribution further down the line between an amplifier with a typical unity gain noise of −120 dBm and one of −115 dBm is for the vast majority of considerations totally insignificant. Concentration on these two hot spots will define the noise performance of an entire console.

In circumstances where extremely low system noise floors are actually necessary (rather than just deemed a good idea) and where such a noise level isn't being totally swamped by the source (which it usually is), then devices like the 5534 make sense elsewhere. Not so much that they are that much quieter within themselves but that their substantial output driving capability allows circuit impedances to be reduced, resulting in a worthwhile difference to noise floor. It's nice to know that there is also maybe a chance of chucking enough current at capacitors in filters for them to work properly at high frequencies and high levels. Using the 5534 as a
microphone amplifier far outweighs the hassle of a similarly performing discrete transistor design, which in this specific area is still its main close rival. Every design case demands a long cool look to determine what sort of device makes most sense; there is no one-fix cure-all technique, or device. For the most part, the designs here are based on TLO-class or 5534-class devices, determined mostly by whether low-noise, high-output drive capability or high-input impedance driving criterion. Modern devices (for a mature technology, new op-amps do seem to pop up almost weekly) that fulfill these specific or other niche parameters would of course be applicable.

25.7.3 Discrete Operational Amplifiers

The JE990, designed by Deane Jensen of Jensen Transformers and manufactured by Hardy Co. of Evanston, Illinois, is an example of an encapsulated discrete amplifier module. Many fascinating solutions to op-amp internal-design problems (some of which even IC designers evidently haven’t realized existed) are implemented in this design whose features demand a total reappraisal of contemporary audio circuit design and philosophy. Optimum input source impedance (normally about 10 kΩ with most IC and discrete amplifiers) is reduced to about 1 kΩ by the use of an IC multiparallel input transistor differential pair. Small inductors in the emitters provide isolation from potential high-frequency instability due to the gain-bandwidth characteristic of the first differential stage shifting with varying source impedances. Unity-gain noise is a quoted staggeringly low −133.7 dBu, while the output is capable of delivering full voltage swing into a 75 Ω load. This permits the use of exterior circuit elements of far lower impedance, reducing thermal noise generation. This elegant device inevitably carries a high price tag. Its many attributes point to the direction for design. It is well ahead of any devices available in IC form and also, to the author’s knowledge, of any universal discrete circuitry elements used to date in console manufacture. This device begs the question of the wisdom of the complex multiamplifier, multistage mixer configurations versus true minimum-path circuit philosophy.

25.7.4 Instability

An unexpected thrill facing designers as they upgraded to newer, much faster devices was the tendency for all their previously designed circuits to erupt in masses of low-level instabilities even in what had been perfectly tame boards. Layout anomalies, such as track proximity, were a major contributor toward the stability problems, so new layouts had to be generated with a whole new set of conditions added to the already hazardous game of analog card design. However, the real roots to this problem are with the devices themselves and a lack of appreciation of the relationship between their internal configurations and the outside world. Everyone who had been brought up designing around 741s had become too used to treating them in a somewhat cavalier fashion and for good reason. It was very hard work to make them misbehave or even show a hint of oscillation. People got used to treating ICs as plug-in blocks of gain with little consideration for the fact that inside was a real, live collection of electronic bits that still had all the problems real electronics always had. The reason the 741 was relatively impervious to user-inflicted problems is analogous to the fact that it’s quite difficult to get anything that is bound, gagged, and set in molasses to not behave itself.

Mistake number one with the new devices was believing that they were unity gain stable because the data sheets said so. What that really means is “does not burst into oscillation at unity gain (under these circumstances ...),” which is not the same thing at all.

25.7.5 Phase Margin

It is important to maintain as large a margin as possible between the internally structured gain-bandwidth rolloff set for open loop and the rolloff around the external circuitry determining the closed loop gain. This is to preserve sufficient phase margin at all frequencies for which the circuit has gain. Failure to do this can result in the feedback being shifted in phase sufficiently to become reverse phase to that intended (positive feedback) with oscillation resulting. Even if the phase isn’t shifted quite that far, the feedback tends toward positive and damped ringing when transients hit the circuit ensues. Also, these resonance effects are extremely high in frequency, typically many megahertz, so any radio signal that gets as far as the circuitry will absolutely adore an amplifier that is critically resonant at its frequency! A reasonable phase margin to aim for at all gain frequencies is better than 45°. In practice, a compromise between desired circuit bandwidth traded off against the need to tighten that bandwidth for the sake of phase margins can be fairly easily reached with the newer devices, provided the need to do so is recognized.

There seem to be two schools of thought on bandwidth versus stability phase margin. First there are the
Pragmatists, who close down the bandwidth of an amplifier as rapidly as possible outside the required passband, maximizing stability phase margin and RF neutrality. Then there are the Purists, who maintain circuit gain as far out and as high as possible, walking the tightrope of stability—usually in deference to the in-band phase linearity.

The normal, easiest, and most flexible way to determine the closed loop roll-off of a circuit is by means of a feedback phase-leading capacitor across the main output-to-inverting-input feedback resistor. A typical arrangement is shown in Fig. 25-18. Generally, the need to properly define the bandwidth of a gain block by just such a means automatically takes care of the matter, although it’s dangerous design practice to assume that the two requirements—phase-margin determination and bandwidth limitation—are always mutually satisfiable.

A fairly common eroder of phase margin and progenitor of instability is stray capacitance from the inverting input of the amplifier to ground. This capacitance, a combination of internal device, pinout, and printed-circuit layout proximity capacitances, reacts against the feedback impedance to increase the closed loop gain at high frequencies. In normal circuits, even the typical 5 pF or so is enough to tilt up the closed loop gain parameters, threatening stability. Far worse is the situation where the inverting input is extended quite some distance along wiring, and worse yet, a bus—as in a virtual-earth mixing amplifier—hundreds, and sometimes thousands, of picofarads may be lurking out there. It can arise that despite a sizable time constant being present in the feedback leg, none of the expected high-frequency roll-off occurs since it is merely compensating for the gain hike created by bus capacitance. Ensuring required response and phase characteristics using any virtual-earth mixer can only be done properly with at least two orders of compensation around the mix-amp and with the finished system up and running completely, since any additional sources modify the impedance presented by the bus.

To define just how much this unwanted gain can rise, a small limiting resistor may be added as close to the amplifier inverting input terminal as possible; this is at the expense of the virtual-earth point now having a minimum impedance based on the value of that resistor. The resistor, incidentally, is also a measure of protection against any radio-frequency signals on the bus being rectified by the input stage junctions. Better yet, a small (real!) inductance in series with the summing amplifier input provides another means of out-of-band gain reduction and RF immunity.

25.7.6 Time-Domain Effects

There is invariably a finite time taken for a signal presented at the input of any amplifier to show an effect at the output of the amplifier—the so-called transit time. Every tiniest capacitance and consequent time constant in the internal circuitry of the amplifier make this inevitable; electronics takes time to do things. This transit time becomes an appreciably greater proportion of the wavelength of the wanted signal as the frequency increases, and as such it has to be taken into account. Fig. 25-19 shows how the fixed transit time becomes more relevant to increasing signal frequency. Ultimately, of course, the transit time will become half the time necessary for a wavelength of the signal frequency. At that stage what emerges from the amplifier will be a half wavelength or 180° out of phase. Before this point, its detraction from phase margin with increasing frequency can start to cause serious problems; at this point...
ultimate state, though, the negative feedback on which the amplifier depends for predictable performance is now completely upside down. Now it’s positive feedback. Now the amplifier oscillates.

TID is a direct result of the servo nature of an amplifier with a large amount of negative feedback. The feedback is intended to provide a correction signal derived as a difference between the amplifier output and the applied input signal. It is a simple concept: any difference between what goes in and what comes out is error in the amplifier. All we need do is subtract the error. However, it is not so simple. Since there exists a time delay in the amplifier, the circuit has to wait for that amount of time before its correction signal arrives. The output during this time is uncontrolled and just flies off wildly in the general direction the input tells it to. Once the correction arrives, the amplifier has to wait again to find out how accurate that correction was and so forth, see-sawing on and on until the amplifier output settles. Fortunately, this all takes place rapidly (depending on the amplifier external circuitry), but it still represents a discrepancy between input and output. It is an effect peculiar to amplifiers with large amounts of negative feedback (typical of most contemporary circuitry), frequently displaying itself quite audibly—especially in power amplifiers where transit time is quite long with the usual huge, slow output devices.

Amplifiers that rely on their own basic linearity—such as tube amplifiers—rather than on a servo-type nonlinearity correction system, are often held to be subjectively smoother. A whole subindustry thriving on the virtues of feedbackless circuitry has evolved. Nowadays, though, with device speeds improved as they are, settling times are becoming insignificant in relation to the signal transients with which they are expected to cope, pushing the frequency area at which TID could manifest itself far, far beyond expected audio excitation.

25.7.8 Output Impedance

A lot of devices, particularly the TLO series of BiFETs, have a quite significant open-loop output impedance. This is because the IC designers obviously considered that instead of an active output current-limiting circuit (standard on most op-amps up until then), a simple resistor would suffice. Although this built-in output impedance—by virtue of the enormous amount of negative feedback used—is normally reduced to virtually zero at the output terminal, it is still present and included as part of the feedback path, Fig. 25-20. Any reactive load at the output is going to materially affect the feedback phase and phase margin.

Any capacitance from the output to ground will form a feedback phase-lagging network. This shifts the phase

---

25.7.7 Transient Intermodulation Distortion (TID)

The TID effect, if not fallout from and overwhelmed by the effects of insufficient slew rate, is due to amplifier transit times. Not surprisingly, as is nearly always the case with fad problems (as was TID during the 1970s), TID has been known and appreciated for as long as there have been negative feedback amplifier circuits—the twenties. It is and always has been totally predictable.

---

Figure 25-19. Transit time effects with increasing signal frequency.
inexorably toward the point where the total amplifier and network phase shift reaches 180° at the inverting input (that’s a full 360° total), and the circuit oscillates. The frequency at which it oscillates is inversely relative to the capacitance value. It isn’t unusual, with small values, to find oscillations right at the edge of the high-frequency sensitivity of an oscilloscope. Hanging a long piece of wire on the amplifier output (especially shielded cable with its high shield to inner capacitance) is a surefire guarantee of instability for this very reason. It has the added complication that there is a measure of inductance there, too. It is conceivable that a long cable might start to look like a mismatched tuned stub at a frequency where the amplifier still has some gain, creating a creditably good, stable RF generator.

What this extra resistance-capacitance output circuit is in effect doing is to add dramatically to the transit time of the amplifier where actually the termination problem is creating far more delay than could possibly exist within the device itself. That the cures for the two ills are similar shouldn’t be a surprise. Fortunately, a simple fix for this instability is to buffer away the load from the output feedback termination with a small resistor of typically 33–150 Ω. This usually does it, but at the expense of head room loss due to the attenuation from the buffer resistor against the load termination. Provided the load is greater than about 2 kΩ, which it would really have to be in order to prevent getting close to current drive saturation in the IC output stage, this head room loss should be well less than 1 dB. A better way is to buffer off with a small inductance, giving increasing isolation with frequency; a phase-shifting characteristic opposite to that of the (normally) capacitive load provides a total termination that is phase constant at the higher frequencies. At the lower audio frequencies, of course, the inductive reactance is very low, and the load sees the very low dynamic output impedance of the amplifier. The buffering inductance becomes virtually transparent.

Both of these techniques also provide a measure of protection against the possibility of RF signals finding their way into the amplifier by means of rectification in the output stage or inverting input. Very often output stages are more prone to RF field detection than inputs.

Some devices with a quite low output impedance before applied feedback (i.e. those with unbuffered, complementary emitter-follower output stages) are not likely to be fazed as much by these effects (pun totally intentional) but it is just as well to design in these considerations habitually. Emergency replacement, device upgrades or IC internal design changes can evoke this problem unintentionally.

### 25.7.9 Compensating Op-Amps

Op-amps generally have a couple of pins dedicated for compensation, which can be taken as a less than subtle message from the manufacturer that their product isn’t stable under certain conditions of usage and needs external kludging. Usually this is at low closed loop gain where the bandwidth is at its most extreme. The classic solution is to shrink the bandwidth of the amplifier by slowing the amplifier down. Among other things, this wrecks the slew rate that’s been handsomely paid for.

The most ordinary means of slowing down the devices is to slug an internal gain stage, leaving the other stages intact. On the bright side, if it is this internal gain stage around which the external compensation capacitor is hung that is tending toward instability, the capacitor should cure it. Sadly, it rarely is that stage. If a previous stage, say, the input differential amplifier, is unstable, all the capacitor will do is slow up the amplifier and reduce the slew rate to the extent that the oscillation is no longer visible at the output. It does not cure the instability. It’s still in there, hiding. Often the only external manifestations are supposed dc offset voltages that won’t go away and a poor-sounding amplifier.

There is a moral to this tale of compensation: don’t use op-amps that require compensation if at all avoidable. Stability should be ensured by the circuit as a whole, and if speed is to be preserved, the op-amp should not be used below the gain at which it’s happily stable. 

Compensation achieves stability by masking a symptom and not by tackling the cause.

The previous precautions, in addition to the feedback phase-leading capacitor, are now required circuit practice for using the newer, fast devices in many op-amp configurations. It should be said here that because there is no facility for implementing phase leading around the
standard voltage-follower configuration and that this is the most critical configuration for stability, it is not a preferred circuit element. The manufacturer will have designed the IC to be just stable enough at unity gain to be able to say so unblushingly, but with probably little real-world margin to spare. Hanging a compensation capacitor across the appropriate pins will slow up the slew rate and not necessarily make the whole amplifier any less unstable. It is better not to tempt fate.

25.7.10 Input Saturation

The use of a standard voltage follower implies that in order to maintain the same system head room in that stage, the input has to rise and fall to the same potentials that the output is expected to. It can’t. In most op-amps, especially those with bipolar inputs, the differential input stages saturate or bottom significantly before the power supply rails are reached and certainly before the output swing capability is attained. This limited input common-mode range means that the follower not only will cease to follow but will also spend a considerable amount of time in unlatching from one swing extreme or the other. Once an amplifier internal stage has latched, the feedback loop is broken; the stage has no assistance from the servomechanism to unstick itself. Once the loop is reestablished, it has to settle again as if from a hefty transient before it can resume following. Basically, this is an ugly scene. Uglier yet is the propensity of some devices when the input common-mode range has bottomed for the output to lunge to the opposite rail. Talk about “sonic character.”

IC manufacturers commonly specify the common-mode input voltage range and it is precisely this limit that would be exceeded in use as a follower. For reference they are: ±13 V for the 5534, ±11.5 V for an LM318, and +15 V to −12 V for a typical BiFET.

All fall far short of the power supply maxima. Provided enough gain is built around the amplifier to prevent these common-mode limits from being reached, there should be no latching hangups; the feedback network also provides some substance to hang closed-loop compensation around in addition to enabling the full output voltage swing of the amplifier to be utilized.

Similar settling-time problems occur any time any stage is driven into clipping, but given the high power-supply voltages and consequent large head-room common today, clipping should be rare.

In short, not only for this good reason, the standard voltage-follower configuration is pretty bad news.

25.7.11 Front-End Instability

Altogether the most obscure potential instability-causing effect relates directly to the behavior of the input stage in bipolar front-end op-amps. The gain-bandwidth characteristic of the input differential stage is greatly dependent on the impedance presented to the input, the gain-bandwidth increasing with reducing source impedance. There is the possibility that given an already critical circumstance, the erosion in phase margin due to this effect can cause overall instability. This instability can be mitigated by limiting the gain-bandwidth excursion by means of a resistor (typically 1 kΩ) and/or some inductance in series with the input. Ordinarily, this would have little effect on circuit performance but may, especially in microphone amplifiers, detract from noise performance. Noise performance is largely dependent on the amplifier being fed from a specific source impedance, and 1 kΩ would be a sizable proportion. However, it’s usually fairly easy to arrange in the design stage such that the IC doesn’t have a zero impedance at either of its inputs.

Fortunately, because of the far greater isolation between the FET gates and their channels, this is a problem that FET-input op-amps do not have. A similar approach to that proposed for output isolation (i.e., an inductor rather than a resistor) in series with the affected input seems, on the surface, an equally good idea. The impedance of the inductors would be low at audio frequencies (so not affecting noise criteria significantly) and high at radio frequencies where the low source impedance phenomenon does its work. Unless the value is critically defined, an inductor of sufficient value to provide a usefully high reactance at RF also could be self-resonant with circuit stray and its own winding capacitances at a frequency probably still within the gain-bandwidth capability of the amplifier. Takes a bit of care.

Those who have experienced design with discrete circuitry will not be surprised that this source impedance instability effect is also the reason emitter followers are the most instability prone of the three basic transistor amplifier configurations. The cure is the same. Not only does the series impedance limit the source impedance before zero, it also acts together with any pinout and base-emitter capacitance as a low-pass filter helping to negate further external phase shift that may detract from stability. This base source-impedance instability is quite insidious in that it can either contribute to instability of the amplifier loop if it is already critical or it can be a totally independent instability local to the affected devices with nothing whatsoever to do with the characteristics of the external loop.
25.7.12 Band Limiting

One of the first great superficially appealing results of using the enormous feedback inherent to op-amps at the relatively low gain requirements of the audio world was a close approach to dc-to-light frequency response. The author remembers well the hysterical peals of laughter as the response of a new mixer was measured as still 0 dB right to the end of the testing ranges of the oscillator and the badly disguised puzzled looks and worried glances when we put real audio through and actually listened to it.

Many audio signals, especially live ones from microphones, analog tape-machine returns with a high vestigial bias content, keyboards, and a range of other sources, have a fair amount of ultrasonics present. If an analog remix of a digital recording takes place (it happens) many digital-to-analog (D/A) converters have an embarrassment of out-of-band noise that is of no program relevance whatsoever. A good microphone is going to hear all manner of stuff in a space: TV/computer scan whistles, motion alarms, switch-mode power supply or light-dimmer inductor screechings just for a start, none of which can be pretended to be musical. Depending on how good a following A/D convertor implementation may be, some of these may well get aliased down into the audible frequencies to less-than-subtle effect.

There is a proverb: the wider the window, the more muck flies in. Returning focus here just to analog signal processing, it would be perfectly all right if the following circuitry were capable of dealing with signals much higher than the audio band; sadly at the time (and to a lesser degree even now) that is not so. The root of the difficulty is the worsening open loop gain of the individual op-amps; as it drops off at 6 dB/octave with increasing frequency, there remains less closed loop feedback available to maintain the op-amp’s linearity. In other words, the circuitry becomes less and less linear as the frequency increases and the feedback dwindles.

Fig. 25-21 is representative of the open loop (no feedback) input-output transfer characteristic of an op-amp—i.e., what comes out in relation to what goes in. Not at all linear. In fact, rather nasty. (Incidentally, most big power amps have similar curves.) The good in-band linearity and low distortion of op-amps come from the application of monstrous amounts of negative feedback. Take the case of a noninverting 741-type amp with 40 dB of gain around it, Fig. 25-22. At 100 Hz there can be 60 dB of feedback, which is great nonlinearities are being corrected by roughly the tune of 1000:1! However, the open loop gain plummets above this frequency, leaving a still respectable 40 dB of feedback at 1 kHz (100:1). (This figure of 40 dB is widely regarded as the lowest amount of feedback for good performance from an op-amp.) At 10 kHz it’s down to 20 dB; it is 14 dB at 20 kHz; and at an ultrasonic 40 kHz, there is a bare 8 dB! There is still gain, though, and the amplifier is quite capable of supporting and amplifying a signal up at those frequencies; it’s just not very good at it.

![Operational amplifier open-loop gain curve](image1)

**Figure 25-21.** Operational amplifier open-loop gain curve typical of a bipolar device.

![Test circuit](image2)

**Figure 25-22.** A 741 with 40 dB gain.

Harmonic distortion of ultrasonics that would be generated by passing through a transfer function like Fig. 25-21 is unimportant; the frequencies would be even more ultrasonic. The problem lies in the intermodulation of two or more signals, products of which more often than not fall into the audible band; even reciprocal mixing with noise results in in-band noise products. A whole slew of intermodulation products are produced. It is no wonder that early op-amps sounded bad.
So much for the expected result of improved transient response through having a wide-open frequency response. As is now obvious with hindsight, deliberately limiting the input frequency response of the mixer to a little more than the audio band results in an amazing cleanup of the sound. By removing a lot of the inaudible signals that cross modulate within themselves and with in-band signals, the cause of much of the lack of transparency and mush that had become the trademark of early-generation IC op-amp consoles is eliminated.

Despite improved devices with greater open loop gains at far greater bandwidths, this approach remains valid today. By band limiting the program signal to reduce inaudible signals as early in the chain as possible, there is far less chance of their generating unwanted audible products. A front-end low-pass filter, operating in conjunction with all the other low-pass effects of feedback compensation arrangements throughout the console, should provide adequate minimization of these products in modern devices.

Purist arguments about the undesirability of any deliberate filtering seem rather futile in a world of real devices—all but a very few transducers and what they hear/reproduce are an embarrassment above 20 kHz, and final signal destinations—like anything digital, or otherwise inherently band limited. However, with 96 kHz digital sampling threatening to become mainstream, widening the window to at least utilize some of the fabulously hard-won bandwidth may be in order in systems where such is likely. Band limiting, to whatever sane degree, is a particularly powerful tool for obviating funny noises and lack of sonic transparency, and its use shouldn’t be abdicated without a fight.

### 25.7.13 Slew-Rate Effects

Slew-rate limiting occurs when the fastest signal rise time the amplifier is expected to pass exceeds the speed of the fastest stage in the amplifier; the input transient becomes slurred to as fast (or slow) as the amplifier’s capability. It is a level-dependent effect; at low levels the input signal’s transient may be well within the amplifier slew envelope and escape unmutolated, but as the input gets larger the transient’s slope can equal or exceed that of the amplifier.

Slewing gives rise to intermodulation effects that are dependent upon both frequency and signal level. The louder and faster the input transient, the worse the damage. A common subjective result of this limiting is for the high end of a drum kit to change in character of sound with differing levels of the lower-frequency instruments on which it is riding. Another favorite is the “disappearing snare drum” in which, again, the sound radically alters with changing level.

### 25.7.14 Device Idiosyncrasies and the Future

Many circuits rely somewhat on the extremely high input impedances of the BiFET devices and their very low required input bias currents. Using bipolars everywhere may result in unavoidably generated output offset voltages that could manifest themselves in extreme instances as switch clunks and scratchy pots. Also, the feedback phase-leading compensation may or may not be appropriate for devices other than BiFETs, especially with some bipolars with less than ideal internal poles. If there’s a temptation to use more conventional bipolar devices, particularly those in multiple packages, it is also worthwhile examining their characteristics when inputs or outputs are taken above or below the power supply potentials. If the device structure under such circumstances is unprotected and turns into a silicon-controlled rectifier that deftly shorts the power supply with a bang, you are possibly better off using something else. In short, if a device is chosen specifically for an application and support circuitry designed for it, adding another device for the sake of adding it is usually nonproductive and often a step back. Op-amps and their surrounding components should be regarded holistically.

The proliferation of amplifier elements in modern console design has mushroomed further in recent years with the availability of compact and extremely low-cost IC op-amps. Increasingly complex functional blocks are becoming increasingly commonplace. If, in order to improve their electrical and sonic characteristics, it would mean an increase in size and cost of well over an order of magnitude, would they still be quite as popular? In the good old days of tubes, it was not through any lack of expertise that equalizers even of today’s complexity did not exist; it was just the size and cost would have made even the reckless shudder. Also, it is to be noted, they were not really thought necessary.

By way of history repeating itself, though, the astounding complexity of many digital audio algorithms (e.g., the use of as many as nine biquads to achieve not a whole EQ, just a single section, which alone would require a mere 27 op-amps to emulate) makes concerns about analog technology overkill seem a touch quaint.

### 25.8 Grounding

A human working visualization of anything electronic soon becomes impossible without a mental image of the
solid, infinite, immovable, dependable ground. It has many other names too: earth, 0 V, reference, chassis, frame, deck, and so on, each of differing interpretation but all, ultimately, alluding to the great immovable reference.

Electrons could not care less about all this. They just go charging about as potentials dictate; any circuit will work perfectly well referred to nothing but itself. (Satellites, cars, and flashlights work, don’t they?) Ground in these instances is but an intellectual convenience.

Interconnection of a number of circuit elements to form a system necessarily means a reference to be used between them. To a large degree, it’s possible to obviate a reference even then by the use of differential or balanced interfacing, unless, of course, power supplies are shared.

So, having proved that ground is seemingly only a mental crutch, why is it the most crucial aspect of system design and implementation?

25.8.1 Wire

Fig. 25-23A shows a typical, ordinary, long, thin length of metal known more commonly as wire and occasionally as printed-circuit track. However short it is, it will have resistance, which means that a voltage will develop across it as soon as any current goes down it. Similarly, it has inductance and a magnetic field will develop around it. If it is in proximity to anything, it will also have capacitance to it.

A. Long, thin length of wire.

B. The wire actually has resistive and distributed reactive components.

Figure 25-23. What is a length of wire?

So Fig. 25-23A actually looks more like Fig. 25-23B with resistive and distributed reactive components. Admittedly, these values are small and seem of little significance at audio frequencies, but clues have already been laid (particularly in Section 25.7 on op-amps) that believing the world ends at 20 kHz is not so much myopic as naive.

A radio engineer looking at Fig. 25-23B would mumble things like “transmission line,” “resonance,” or “bandpass filter,” maybe even “antenna.” RF technology and thinking may seem abstruse and irrelevant to audio design until it is considered that active devices commonly used nowadays have bandwidths often dozens, sometimes hundreds of megahertz wide. An even more frightening realization is the enormous quantity of RF energy present in the air as a consequence of our technological being; never mind the gigawatts of broadcasting bombarding us, the proliferation of walkie-talkies, cellular phones, and business radio all beg mischief in our systems. It even comes from other continents; the aggregate field strength of international broadcasters clutched loosely around 6 MHz, 7 MHz, 10 MHz, and 15 MHz is truly phenomenal.

A more obscure collection of equivalents is shown in Fig. 25-24. Fig. 25-24A represents a wire into a bipolar transistor input; Fig. 25-24B shows a wire from a conventional complementary output stage; and, for reference sake, Fig. 25-24C shows a basic crystal-set radio receiver. It may seem quaint, but for the presence today of wildly more volts per meter RF field energy compared to the heyday of wireless it works just the same. In all the three circumstances, radio frequencies collected and delivered by the antenna are rectified (hence, demodulated and rendered audible) by a diode (the base-emitter junctions in Figs. 25-24A and B). As contrary as it may seem for demodulation to occur at an amplifier output, it is perhaps the most common detection mechanism with the demodulated product finding its way back to the amplifier input by means of the conveniently provided bypassed negative feedback leg.

Making our length of wire fatter and thicker has the effect of lowering the resistance and inductance while increasing capacitance (greater surface area exposed to things nearby). So, although the resonant frequency of the wire stays about the same, the dynamic impedance (hence, Q) reduces. Although in general this is deemed
a good thing, in some instances it can merely serve to improve the matching and coupling of the RF source to the resonance.

Carried to an extreme, even a console frame constitutes a big fat resonant tank at a surprisingly low (mid-VHF) frequency while frame resistance, however heavily it may be constructed, cannot be disregarded and cannot be treated as a universal ground path.

For the purposes of practical design, these considerations perhaps become a little better defined. The reactive elements of capacitance and inductance with the attendant effects of resonance and filtering are concerned with less obvious aspects (such as electronic stability and proneness to radio demodulation), while resistance gives rise to most of the horrors usually lumped under the collective term grounding problems.

25.8.2 Earth Ground

The closest most of us get to earth is the fat pin on an ac power plug. Fortunately for most purposes, it is adequate, provided just the one point is used as the reference. Other points are likely to have slightly differing potentials due to dissimilar routing and resistances. Compared to a technical earth ground (e.g., a copper water pipe or, alternatively, a fortune in copper pipe hammered into the earth), conventional earth grounds can have a surprisingly high potential, a volt or two, considering it is principally a safety facility not ordinarily carrying current. Any potential implies resistance in the earth path, which is bad news about something intended as a reference while also detracting from the safety aspect.

Practically, though, it does not matter too much if everything is waving up and down a bit provided everything, including even unrelated things in proximity, are waving up and down in the same manner. The potential is usually small, meaning that the ground impedance is reasonably low to the extent it may be considered insignificant.

25.8.3 Why Ground Anything to Earth?

With all our component system parts tied together by a reference ground and everything working as expected, the question arises as to why it is necessary to refer our ground to earth. If the internal grounding is completely correct, our system will operate perfectly, quietly, and tamely regardless of to what potential (with respect to earth) it is tied. If not tied, it will derive its own potential by virtue of resistive leakages, inductive coupling, and capacitance to things in its environment. For an independently powered system (i.e., batteries), these leakages and couplings will be of very high impedance and, hence, easily swamped by human body impedance to earth.

If, as is most often the case, most of the system is powered off the ac lines, this floating ground potential becomes of far lower impedance and consequently is much more capable of dragging current through a human load. That’s you or me. (It’s the current that kills, not the voltage.) A telltale sign is a burring, tingling feeling as you drag a finger across exposed metalwork on something that is deriving its own ground potential.

The mechanism for this lower impedance is fairly straightforward. Power transformers are wound with the optimum transfer of energy at 50–60 Hz and very high flashover voltages (several kilovolts) in mind; the finer points of transformers such as leakage inductance, interwinding, and winding imbalance capacitance are all but disregarded.

Being far greater in scale than ordinary ambient reactive couplings, they primarily dictate the floating ground potential to be anything up to 240 Vac above ground or whatever the power lines happen to be locally.

It used to be that some units were fitted with bypass capacitors from each supply leg to chassis ground, partly in the fond hope that this would help prevent any nasty noises on the ac mains from entering the hallowed sanctum of audio within. Ungrounded, this guaranteed the chassis floating at half the supply rail from a fairly low impedance. Ouch. But it gets worse. With the near universality of switch-mode power supplies, and with nearly everything containing digital electronics to some degree or other, there is the imperative of ensuring any nasties that the supply/digits generates don’t find their way out of the box and up the power lead! Some reversal of fortunes there. This is required not so much from the altruistic desire to not pollute but that the box likely wouldn’t pass emissions testing (FCC Part 15, CE and the like) and wouldn’t be able to be sold. Typical supply-side filtering as a minimum in such supplies is a π filter of common-mode inductors and parallel capacitors—including capacitors to chassis ground.

The result is that if the chassis is not directly earthed, it rides at (in the case of both lines having tied capacitors) half the line voltage. The capacitor values grossly swamp transformer and ambient leakages and give the chassis floating potential an uncomfortably (literally) low impedance. The chassis tingle changes from “Mmm—interesting” to vile oaths with attendant flailing limbs.
A system composed of many separately powered units will almost certainly hum, buzz, and sound generally uneasy if not earthed, which is seemingly in direct contradiction to the earlier statement that “the system will operate perfectly regardless of what potential it is tied to.” Being tied to a lot of different self-generated potentials at a lot of different points along a system path is definitely not in the recipe.

Each different power transformer will have different amounts and permutations of leakage and, hence, propagate different potentials and degrees of power-line-borne noise into our otherwise perfect grounding path. Assorted ground potentials mean assorted ground currents, meaning assorted noises.

Tying the entire grounding path to earth is the best shot at “swampout” of leakage impedances. A connection to a (nearly) zero impedance makes nonsense of most other potential-creating paths, most of which have reactances in the kilohms.

Regardless of earth termination in such a multisupply circumstance, significant currents exist along the ground reference lines. The resultant interelement noise and hum voltages (developed across the inevitable line resistances) quickly become intolerable in unbalanced systems. Any wobbling of the ground reference becomes directly imposed upon the desired signal.

Balanced, or pure differential, transmission helps to obviate these perturbances by rendering them common mode in a system that is (theoretically) only sensitive to differential information. In reality, practical transformers can afford a good 70–80 dB common-mode isolation at low audio frequencies. They deteriorate in this respect at 6 dB/octave with increasing frequency up to the winding resonance frequencies unless considerable effort is made to fake a more accurate balance externally. Although transformer balancing does effect a dramatic improvement in noise levels, it is far greater for fundamental hum (50–60 Hz) than it is for other power-line-borne noise. This explains why in tricky systems, lighting dimmer buzz, motor spike noise, or any source with a high-frequency energy or transient content is so persistent.

The golden rule is to treat the grounding of any balanced system as if it were unbalanced. This minimizes the inevitable reference ground currents.

There is one overarching good reason only glanced by earlier for grounding to earth. The consequences of a piece of the gears’ chassis becoming inadvertently at the power-line potential are obvious. We would much rather see death to a fuse or breaker than to one of us.

### 25.8.4 Console Internal Grounding

Let us assume that the grounding for the studio control room is all sensible and that our console has a solid earth termination. What about the intraconsole grounding paths? For most console builders this is perhaps the ultimate unbalanced signal path.

Conventional amplifier stages rely on a voltage difference between their input and reference in order to produce a corresponding output voltage (referred, naturally, to the reference of the input). If the input is held steady while the reference is wobbled, a corresponding (amplified) inverted wobble will appear at the output.

It is plain that any signal the reference sees that is not also common to the input (e.g., ground noise) will get amplified and summed into the output just as effectively as if it were applied to the proper input. The obvious (and startlingly often overlooked) regimen to render extraneous noise unimportant is to ensure that the point at which an amplifier source is referred is tied directly to the reference, while that amplifier output is only taken in conjunction with the reference. Successive stages daisy chain similarly—source reference to destination reference, and so on. This philosophy is called ground follows signal.

#### 25.8.4.1 Ground Follows Signal

“Ground follows signal” is a classic maxim and one that has dictated the system design of nearly every console built. It was particularly true in the era of discrete semiconductor design, where ground was often not only audio ground but also the 0 V power-supply return; ideally the audio and supply grounds should be separate. As an added complication, the power-supply positive lines, being heavily regulated and coupled to ground, were an equal nightmare as they too became part of the grounding path. This could be fairly simply avoided by spacing each circuit element away from the supply line by an impedance considerably greater than that offered by the proper ground path—achieved by either separately regulating or simply decoupling by a series resistor, parallel capacitor network, as shown in Fig. 25-25. This actually gives the lie to the notion that single-rail supply systems are easier than differential rail arrangements; to do them properly results in almost indistinguishable numbers of parts and degrees of effort.

Accelerating technology has for once actually made life a bit simpler—specifically, the trend toward IC op-amps with their required differential (+V_c and −V_c) power supply. This, thankfully, removes electronic operating current from the audio system ground, while
individual stage supply decoupling is rendered a nicety rather than a necessity by the excellent power supply noise rejection ratio of most popular op-amps.

Nevertheless, correct grounding paths still apply; the removal of supply current just exposes and highlights audio ground subtleties.

Unfortunately, although op-amps have simplified matters in one respect, their ease of use and versatility have been largely responsible for the creation of enormous systems with so many stages, break points, mix buses, and distribution networks that the simple daisy chaining of ground follows signal becomes unwieldy, if not unworkable. Alternate grounding schemes, such as star grounding where every ground path and reference is taken to a central ground or earth, play increasingly important roles.

In practice, a necessary compromise between these two prime systems occurs in most console thinking. Daisy chain applies mostly to on card electronics (e.g., in the microphone amplifier sections), while systems switching and routing rely on star connections.

25.8.4.2 Ground Current Summing

A principal grounding-related manifestation is crosstalk, or the appearance in a signal path of things that belong elsewhere. Other than airborne proximity-related reactive crosstalk, the most unwanted visitations are by the common-impedance or resistive ground path mechanism. In Fig. 25-26A, $R_1$ represents the load of an amplifier output (whether it’s the 10 kΩ of a fader or a 600 Ω line termination is immaterial for the present). The resistor $R_G$ represents a small amount of ground path wiring, loss resistance, and so on. It is quite apparent that the bottom end of the termination is spaced a little way from reference ground by the wiring resistance, and the combination forms a classic potentiometer network. The fake ground has a signal voltage present of the amplifier output voltage attenuated by $R_1$ into $R_G$.

Practically, with a 600 Ω termination ($R_1$) and a ground loss ($R_G$) of 0.6 Ω, the fake ground will have a signal voltage some 60 dB down. The use of the fake ground as a reference for any other circuitry is a surefire guarantee of injecting −60 dB worth of crosstalk into it.

Two identical terminations sharing the same fake ground, Fig. 25-26B, happily inject a small proportion into each other by generating a common potential across the ground loss $R_G$.

Should the second termination be far higher in impedance (the 10 kΩ of a fader), its contribution to the common fake ground potential will be far less (−86 dB) since the ground impedance is much smaller in relation to the source. Correspondingly, though, this higher impedance termination is more prone to be crosstalked into from the lower impedance contributors to the common ground.

25.8.4.3 Typical Grounding Problems

Here is a fairly unusual (but definitely not unknown) grounding anomaly resulting from inattention to the grounding paths. In Fig. 25-27 A2 is a line amp feeding a termination of 600 Ω into a lossy ground of 0.6 Ω
resulting in a fake ground potential 60 dB below the output of the amp. An earlier stage in the chain A1 (in this example, a microphone amplifier, with a considerable amount of gain) has its feedback leg (amplifier reference) tied to the same fake ground. Its input ground reference (here lies the problem) is taken from a separate bus supposedly to provide a nice, clean ground. This it does admirably, the bus being tied straight to reference ground and having no sources of great substance going to it.

![Feedback and oscillation via poor grounding.](image)

Any signal present on the fake ground is duly amplified by the microphone amplifier (in its inverting mode) and is attenuated at the line amplifier output back into the fake ground. Naturally, as soon as the microphone amplifier gain exceeds the output attenuation, the entire chain bursts into oscillation.

A very similar mechanism was responsible for an owner’s criticism of his well-known console that whenever he attempted to use the track routing on any channel modules, the sound of that channel discernibly altered. It was found that ordinarily nothing in the channel drew much current; all ground impedance requirements were quite light. Light, until the track routing line amp with its load of routing resistors and a terminated output transformer was accessed, demanding a relatively large ground current. This output stage current shared the only ground access point of the module (two paralleled connector pins) with all the rest of the module electronics, with the notable exception of the microphone and line input transformer ground returns. The resultant feedback, although nowhere near enough to promote oscillation, did by virtue of the phase shifting of the output transformer at both high and low frequencies result in distinct coloration.

A purist answer to these fake and loop problems is to choose one grounding point for the entire console and to take every reference and ground return directly to it through separate ground wires.

A few less than minor problems would ensue. The enormous number of ground lines would soon outstrip the capacity of the module connectors, and the mass of wiring would cause apoplexy from the wiremen and aggravate an already critical world shortage of copper. Fortunately, a working compromise suggests itself based on separating the different classes of ground requirements by impedance.

Bucket grounding refers to tying fairly high-impedance sources to a common ground point, bus, or line (since the ratio of their impedances is so great that resultant fake ground potentials can hopefully be made low enough to ignore). Anything that is likely to draw current (any kind of output or line amplifier stage) should go directly to ground, will not pass through any bus, and will not collect shared ground paths on the way to the bucket.

Any ground bus will have a measure of resistance and must, therefore, be fake to a certain degree. If we do our sums right, ground bus signal levels can be kept acceptably low, below −100 dBu.

Smugly, we can expect to ignore figures like that until we (almost inevitably) amplify them up.

25.8.4.4 Ground Noise in Virtual-Earth Mixers

A virtual-earth mix-amp unavoidably amplifies ground noise. Fig. 25-28A tells the story. For instance, a multitrack mix-amp can typically have 32 sources applied to it; the through gain from any source is unity (assuming the source resistors equal the feedback resistor), but the real electronic gain of the circuit is 33 or a touch over 30 dB. Redrawing the circuit slightly in Fig. 25-28B shows exactly what this 30 dB is amplifying. Consider as a clue that which is directly applied to the noninverting input of the op-amp—the ground! True, it is amplifying the noise due to the resistors and the internal noise mechanisms of the device, but for our argument here, it is amplifying ground. In any reasonably sized console, providing no sources are grossly out of proportion to the majority, ground noise is pretty random and noisy in character. The result is that, on being amplified up, it serves to make the mix-amp apparently much noisier than would be expected from calculation. In suspect systems it has been found to be the predominant noise source. It is no accident that the real electronic gain of a mix-amp is also known as its noise gain.

It is truly astonishing what attention to virtual-earth mixer grounding can have on bus noise figures. For mix-amps, practical noise performance has little to do with the device employed and nearly everything to do with grounding.
25.8.4.5 Reactive Ground Effects

Noise generation due to grounds is not limited to the resistance predominant in the ground wiring at audio frequencies. At radio frequencies (well within the bandwidths of modern op-amps) even fairly short ground wires and buses can have very significant reactances, dramatically raising the effective ground impedance. This not so much reduces the isolation between the various stages as directly couples them together. All the inherent RF noise and instabilities of the stages become intermodulated (by the nonlinearity of the device at those frequencies) to make their presence felt as yet more audible and measurable noise.

A good “shock horror” extreme example, though described in simplistic theoretical terms, manifests itself sometimes dramatically in practice and can be called the standing on one leg effect.

The box in Fig. 25-29 represents a device that relies on a wire to be connected to the ground mass. It looks all right, and so it is, apart from the fact that at certain radio frequencies the wire is electrically ¼ wavelength or an odd multiple of ¼ wavelength. In accordance with transmission-line theory our innocuous bit of wire turns into a tuned line transforming the zero impedance of the ground to an infinite impedance at the other end. The result is that the device is totally decoupled from ground at those frequencies. Practical consequences of this, of course, vary, from instability at very high frequencies on cards with long supply and ground leads to painful, unreasonable susceptibility to RF in otherwise wholesome items of equipment.

25.9 Signal Switching and Routing

Signal routing within the channel and other areas of the system is a touchy affair that has always been an area of much discontent for console designers, especially since the advent of in-line consoles and remotable and assignable systems. There are always standard relays, but these have lost, justifiably, a lot of appeal in the light of ac technologies.

25.9.1 Relays

Unless they are of the expensive miniature IC package variety, relays tend to be big, heavy, eventually unreliable, mechanically noisy, and a nuisance to implement electronically. They also demand support circuitry such as back-emf protection diodes and drive transistors for a realistically operable system. The coils, being inductive in nature, draw a surprisingly large instantaneous on current and release an equally surprisingly large amount of back-emf energy when deactivated. Both of these—through mutual-inductance coupling, dubious common ground paths (even as far back as the master ground termination in separated supply systems), soft power supplies, and even mechanical microphonic effects—tend to impinge themselves on audio signal paths as clicks, splats, pings, and other assorted bumps. Of course, it’s possible to have silent relay switching. However, after designing in separate ground unrelated power supplies of considerable heft, spatially separating the relays from the audio (preferably on another card), working out the drive interfaces, and liberally sprinkling the whole issue with diodes, resistors, and capacitors to
tame the spiky transients, the circuit becomes very complicated.

Certain routing applications do implicitly require relays and their lack of concern about the amount of dc and either common-mode or differential signals of absurd quantities that may accompany the audio in balanced networks. Such circumstances are to be found anywhere a telephone line is used.

This is almost specifically a broadcaster’s concern, where many external high-quality sources appear down phone lines and need to be routed before hitting either the internal distribution amplifier system of the station or perhaps even a console line input directly. Outside source selection, as it’s called, does not fortunately have the same splat-elimination constraints as intraconsole switching, since the signal is nearly always of high level, balanced, and riding with at least a little dc (which will unavoidably click upon switching); most importantly the selector is very unlikely to be switched while actually live on air.

25.9.2 Electronic Switching

The wish list for an audio switch is simple:

1. It has an infinite off impedance.
2. It has a zero on impedance.
3. It has a control signal that is isolated from and does not impinge on the through signal path.
4. It costs nothing.

In the real world, of course, some leeway has to be given, but, fortunately, the tradeoffs are more in subtleties than in these basics.

Transistors are out of the picture right away despite their high on-off impedance ratios, because they are essentially unidirectional in current flow, and the control port (the base) is actually half of the signal path as well. In certain circumstances they have been used in the place of relays as a soft output muting clamp as in Fig. 25-30A.

Diodes, Fig. 25-30B, are used extensively for signal routing in RF equipment, with the required signal riding on a relatively large dc bias that overcomes the diode forward voltage drop making it a low-impedance path, and correspondingly turned off by a large back bias. Considering that in some audio design cases getting rid of a handful of microvolts dc can be an ordeal, somehow a couple of dozen volts hurling about lacks a certain appeal. Typically, switching diodes for RF with a PIN structure are chosen; their very small capacitances are considerably less parametric with respect to varying reverse bias, so minimizing automodulation and consequent distortions.

FETs have been and still are used extensively for signal switching. They again have a high on-off ratio, and the control port (the gate) is of extremely high impedance and well isolated from the signal path, but the gate on-off voltage levels are a bit awkward for interfacing with logic control signals. They also define signal head room through the switch, based on the gate on-off biasing voltage range. It is bidirectional, its channel path being essentially just a voltage-controlled resistor, but the on resistance tends to vary with the varying audio voltage across it (auto modulation); distortion in the more basic FET switching configurations can be a problem. However, they are workable, Fig. 25-30C.

25.9.3 MOSFETs and CMOS

Closely related to FETs are metal-oxide-semiconductor field effect transistors (MOSFETs). They have a different chemical structure and physical construction but have essentially similar characteristics with the exceptions that the gate is of even higher impedance, and the control voltage swing required is easier to deal with. Complementary MOSFET (CMOS) elements,
connected back to back to form close to ideal bidirectional analog transmission gates, are manufactured in all manner of variations and packages by IC manufacturers. At extremes of performance minor control-port breakthrough (charge injection) can rear its head and be taken into consideration.

Early versions of CMOS transmission gates had some rather untoward vices. They were raw CMOS elements, and one of their main attributes, the extremely high impedances in their off states and of their control ports, made them liable to destruction by normal amounts of static electricity. Also, they tended to latch up easily if any of the MOS junctions inadvertently got reverse biased into conduction (this happened easily if the signal voltage passing through a gate even momentarily exceeded the supply voltage). Most present devices are now gate protected to prevent static blatting, and the worst that happens with the audio signal exceeding the switch supply voltage by a small amount is that the switch breaks over (i.e., conducts audio momentarily). It does not result in the fatal consequences it once did.

Perhaps the best-known and most-used switch of this kind is the 4016 (and its younger brother the 4066, which is essentially identical but for a lower on resistance). It is a 14-pin dual package containing four independently controllable CMOS transmission gates. Each gate can pass up to the IC’s supply voltage (typically 18 Vdc) into a load exceeding 10 kΩ with a distortion of about 0.4% in rudimentary switching formats. Obviously, both the distortion figure and the head room availability of 18 dB above 0.775 V (for an 18 Vdc supply) are both woefully inadequate by today’s expected console standards. Another less obvious pitfall is the decreasing switch isolation at high frequencies due to leakage capacitance across the gate.

Fig. 25-31A gives a typical representation of the variation of the on resistance of a CMOS transmission gate with signal voltage applied to the gate. This variation in resistance is, of course, the source of the distortion. If we could restrict the signal voltage to within that (linear) bit in the middle, or better still virtually eliminate the signal voltage altogether, our problem would go away.

Placing the switching element right up against a virtual-earth ground point, as in Fig. 25-32A, achieves this signal voltage elimination; the switch now behaves as a two-state resistor. When closed, the on resistance variation, which will be small anyway because of the very low voltage swing across it, will be effectively swamped by the (relatively) much larger series resistance. When open, the off resistance extends the total series resistance to a value approaching infinity. In practice, the on-off ratio is not really adequate. Capacitance across printed circuit tracks and in the device encapsulation itself, combined with common-ground current and other essentially flat-response crosstalk mechanisms, results in a cross-switch leakage characteristic ultimately rising 6 dB/octave against frequency. Also, despite the fact that the distortion problem is now largely resolved, there still remains a head room problem when the switch is open. If the source voltage presented to the series resistor exceeds that of the power supply of the CMOS gates, the gate will break over, turning on for that excessive portion of the input waveform.

Attenuating the source signal by the needed amount before it hits the gate skirts this hangup. Unfortunately, this worsens the noise gain of the virtual-ground amplifier by the amount of that attenuation. In Fig. 25-32B dropping an equal-value resistor to the series resistor to ground from its junction with the gate is a working approach. The maximum signal that can be present across the gate when off is now half that previously, which is usually more than enough attenuation to prevent breakover. This 6 dB loss is magically made up for in the on mode because the source resistance of the signal into the amplifier is now halved (series resistance effectively in parallel with the dropped resistor).

Incidently, the crosstalk improves as a consequence by almost 6 dB—less signal voltage actually within the chip. For many practical purposes, this switching configuration, with its performance limitations as defined, is quite adequate. For instance, the
noise and crosstalk characteristics are a good order of magnitude superior to any analog multitrack recorder, so this element can be a good choice for an inexpensive track assignment routing matrix.

**25.9.4 Potentiometric Switching**

A refinement of this element—in fact, really an extension of the same principle—is shown in Fig. 25-32C. Here, a second analog transmission gate replaces the dropped resistor and is driven through an inverter from the control line for the original gate, arranging for it to be on when the other is off and vice versa. When the original gate is on, there is very little potential across either of the gates (they’re both at virtual ground from the op-amp). Similarly, there is little potential across either of the gates when the second gate is on, since it is tying the series resistor to ground and the open gate is between ground and virtual ground. Crosstalk is dramatically improved when the element is off because any signal present at the series resistor faces the double attenuation of the series resistor tied to ground by the on second gate followed by the off original gate into the virtual-earth input of the op-amp. In the on mode of the element, there is no input attenuation; hence, there is no gain and no extra noise contribution from the amplifier. The only limitation now to the cross-switch leakage characteristic of this switching element is printed-circuit card layout and grounding arrangements. Given a good home, this element is virtually unmeasurable.

It does, however, have one quirk that may preclude its use in some places. Unless a great deal of care is used to arrange complementary on-off switching timing for the two gates, they are both momentarily partially on together during a switching transition. This, for an instant, ties the virtual-earth amp input to ground via the quite low half-on impedances of the two series gates, creating an instantaneous burst of extremely high gain from the amp; this shows as a transient of noise or worse still as a splat if any dc offset is present at the virtual-earth point. It can be minimized, or at least the extent of the transient defined, by a small value resistor ($R_{SS}$) in series with the input, Fig. 25-32C. This will, of course, increase the signal voltage across the gates and increase the distortion, so a compromise has to be struck to suit the given application. Even so, excessive distortion owing to this has never shown itself to be a problem.

**25.9.5 Minimizing Noise**

To reduce the thermal noise contribution as part of the circuit noise performance, the resistances involved in switching should be as low as practically possible consistent with device limitations and the ground current arrangements. The feedback resistor around the virtual-earth stage is limited by the output drive capability of the op-amp, bearing in mind it has to drive its load, too. Fig. 25-31B demonstrates a typical channel resistance variation of a CMOS switching element with through current. It behaves linearly until about 40 mA, which actually compares more than favorably with the output drive current capability of an op-amp. (FETs are excellent constant-current sources, self-limiting in nature.) As a rule of thumb then, the resistors used around analog gate switching circuits can be as low as 2.2 kΩ without exceeding device limitations; the high-output current capability of the 5534 can be used to good effect here if the drive for lowest possible thermal noise is that important. Generally, ground-borne noise generously provides a noise floor well before this theoretical limit is attained; the whole lowest-imped-
ance question becomes self-defeating eventually. The more current is chucked around, the worse the ground noise is going to become.

25.9.6 Practical Matrix Example

The 4000 series of CMOS devices, which are very commonly used, have one important feature at odds with general mixer technology—their maximum supply voltages. The earlier 4000A series were limited to a 15 Vdc total (as compared to the 30 Vdc or 36 Vdc total commonly used in console design), while the more recent buffered B series can stand 18 Vdc. More recent families (HC, e.g.) nearly always adhere to the common digital electronics supply of 5 V (actually 7 V max). An advantage of the earlier series was that a separately regulated 5 V supply wasn't necessary. Nowadays, though, there is nearly always 5 V running around for this, that, or the other and it is not a difficulty to create a sufficiently well-regulated and quiet 5 V supply for HC switches. Given the virtual-earth switching technique described, this diminution of supply is immaterial.

Most CMOS families have a wide range of switch configurations available; some specialist devices integrate quite large arrays. By way of example, Fig. 25-33 shows one mixer channel’s worth of a digitally assigned 32-track routing matrix, designed around a pair of Harris HI506A 16-way multiplexers. This part, for example, contains 16 analog transmission gates tied to one common output (which we will rename input). Each of the free ends of the gates ties directly to a mix bus. They all share a common series source resistor via the input port. Since only one of these gates can be open at a time (the one corresponding to the binary 4-bit address code on the address inputs), there is no possibility of two or more buses being inadvertently shorted. The device manufacturers proudly point out the break-before-make delay in switching, meaning that a newly selected gate waits until the previous one has delatched, so there is no momentary switching short.

25.9.8 16-Track or 32-Track Routing

The switching card described above may be configured merely by changing two wire links in two different routing formats. The first enables a stereo pair of signals (i.e., the panned outputs of a channel) to be routed to adjacent odd/even pairs of outputs (i.e., 1 and 2, 7 and 8, 27 and 28, and so on), where the odd numbers represent left and the even numbers represent right. Either odds or evens may be accessed singly by suitable feeds to the odds enable and evens enable control inputs. Quite obviously these also facilitate disabling (turning off completely) the routing.

A 4-bit binary control bus selects which pair of the possible 16 pairs may be accessed, so these six control lines are all that need to be extended to the channel module where simple switching performs all routing requirements.

When the aforementioned wiring links are made in the fashion shown in Fig. 25-33, the card becomes configured as a 1-source-into-32 destination switcher, necessitating some control function changes. Evens enable becomes the additional highest significant bit of the destination address code (5 bits are needed for 32 combinations), while odds enable turns into the enable/disable control of the switcher. (The benefit, in both modes, of disabling the switcher when not actually in use is that it removes the feed totally from the destination buses. Their performance is not impaired at all, and a preselected routing setup on the address lines is not disturbed.) With the same signal applied to both the audio inputs, it is now possible to access any one of the 32 buses singly.
### 25.9.9 Processor Control

The seemingly great mass of logic circuitry enclosed in the dotted lines allows the card to be controlled by a computer or microcontroller’s I/O lines (depending on the scale of the system). Very little additional decoding is necessary to allow this interface to hang straight onto a CPU bus. It’s really just six flip-flops acting as memory elements (so that the card can remember what the CPU has told it to do) and six tristate buffers that, on request, tell the CPU what the card is actually doing. This memory both saves the CPU from having to store the matrix routing information somewhere else and also acts as a very useful diagnostic aid to help find out what isn’t doing what, where, and why.

For ordinary direct operation, this logic can be left off the card completely and linked across (between the Xs on the diagram). The NAND gates in the top left-hand corner merely organize the CPU bus information to fire the appropriate clock, enables, and resets to the memory elements.

CMOS 4000 series logic operating at 5 Vdc is not the fastest logic family in existence and is too slow for most microprocessor CMOS to drive directly. The circuitry shown here will operate successfully from a microcontroller running at a MHz or two, which is very slow in the computer world. This slowness is not a problem in reality, since the practical way of dealing with this is to hang the entire switching matrix logic system off a bunch of the CPU input/output ports, masquerading as a local address/data/control bus system at a fairly leisurely software-controlled rate.

A convenient 16 input-output (I/O) line is required (two lots of eight, handy for PCs). A single 8255 or 6850 Peripheral Interface Adapter (PIA) would handle this matrix. Being software controlled, the I/O lines may be timed a little more gently than the hardware-determined processor buses.

A separate address decoder card however takes many of the card address bits that are required (5 for 32, 6 for 64, 7 for 128) and generates the decoded feeds for the card enable (CE) on each matrix card. This is very simply accomplished with a daisy chain of 4028 binary-to-decimal decoders, Fig. 25-34.

This slow interface has the single benefit that it is fully featured; it is common with faster and more capable processors with plenty of cheap memory aboard to not require the readback facility; nearly all the interface logic can be replaced by parallel bus latches such as HC373s with suitable address decoding. HC of course will operate at reasonably high clock rates, even directly off a processor’s data buses. FPGAs, the ultimate octopus of peripheral handling, can handily absorb all the described interfacing.

### 25.9.10 Audio Path

In the bottom left-hand corner of Fig. 25-33 is an analog mix-amp and line amp, which are the group output stages for the channel to which the particular matrix card is relevant and they are as close as they can get to the buses.

The mix-bus input is tied on the back of the edge connector in the card frame to the bus it is responsible for sensing. This ensures card replaceability and redundancy; individually doctored cards are the kiss of death from a maintenance standpoint since there is no means of getting a given path going again (in the event of a failure) without actually fixing the fault. The old standby of swapping cards wouldn’t work; it is always best to keep individualism off the cards.

Note that no values are attributed to the feedback capacitor around the mix-amp, since this not only has to compensate for the amplifier’s own tendency to instability but for the added irritation to this of the bus impedance—an unknown until actual construction. Also note a capacitor across part of the switcher input series resistance. This provides a variable high-frequency kick, which can be of assistance in sorting out frequency and phase response quirks in problematic bus systems. This is, fortunately, very rarely needed and is provided just in case.

Fig. 25-35 shows the audio path through the switcher, devoid of frills. The 1 kΩ resistor RS, which does not appear in Fig. 25-35, is internal to the H1506A, appearing on each of the switch inputs. Although a minor nuisance in this application, which means the CMOS switches are not actually switching a zero impedance, they are part of the device’s internal protection against, principally, static electricity damage—a worthwhile sacrifice.

The total source impedance before the bus is about 9.9 kΩ, which with the addition of the 100 Ω buffering resistor becomes 10 kΩ before the virtual-earth input of the mix-amp. A 4.7 kΩ gain-trim preset in series with 8.2 kΩ gives a gain determining feedback resistor swing of approximately 8.2–12.9 kΩ, which corresponds to a swing of −1.7 dB to +2.2 dB.

The line amp is a simple beefed-up inverting amplifier necessary to maintain the absolute input-output phase relationship.
Figure 25-33. Processor-controllable matrix routing circuit.
Figure 25-33. Processor-controllable matrix routing circuit. Continued.
25.10 Input Amplifier Design

A console is expected to accept signals of wildly varying input level and impedance while producing a uniformly consistent output capable of being deposited in the tightly defined container that is a recording track, or similarly defined output.

Fortunately, industry standards provide at least some clues as to what mixers are likely to have applied to them. Nevertheless, these standards can obviously do nothing to alter the physics of the operation of the assorted transducers and sources in common use; the disparity in the treatment required between a dynamic microphone and a recorder output totally precludes a universal input stage.

Mixer front-end design tends to be a little like working on a grown-up jigsaw puzzle where all the important pieces perversely refuse to fit. It’s delightful to discover or cultivate some that fit nicely, like in line-level input stages. This euphoria is chipped away by the problems inherent in other areas, notably microphone input stages.

Optimizing input noise performance in a dynamic microphone preamp is quite an operation, juggling a
Consoles 859

seemingly endless number of variables. A dynamic microphone may be represented (a little simplistically) as a voltage source in series with a fairly lossy inductance representing a midband impedance typically of 150–300 Ω, Fig. 25-36. Being a transducer and, of necessity, mechanical in nature, many complex varying motional impedance effects contribute to the overall scene, as do the effects of matching transformers used in many microphones. For most design purposes, however, this simplistic electrical analog can suffice. The low impedance commonly and conventionally used is primarily to mitigate high-frequency attenuation effects due to inevitable cable capacitance. Despite the fact that the characteristic impedance of microphone cable is not too far removed from that of our typical sources, the runs are so short in wavelength terms that transmission-line “think” is not really applicable and the cable just looks like a distributed capacitance. This, in practical circumstances, amounts to a large value of capacitance that the transducer must drive along with its load. Unfortunately, the impedance is not low enough that it may be treated as a pure voltage source; therefore a tiny signal at a finite impedance must be ferreted out and treated with care for optimum performance.

25.10.1 Power Transfer and Termination Impedance

Textbooks on electrical theory state that to extract maximum power from a given source the optimum load is equal in value to the source impedance. In the dynamic microphone, it is of doubtful (if any) value. We’ve squeezed all the energy possible from the generator, but to what end? Given that most electronic amplifiers of the type useful in low-noise applications are of relatively high-input impedance (i.e., voltage amplifiers), then the terminating resistance that largely defines the load of the microphone would, in fact, dissipate most of our hard-won power. It is the output voltage capability of the source that is of greatest use here, not the power. So, as can be seen in Fig. 25-37, matching source and load impedances does a very effective job of sacrificing 6 dB of signal level that has to be made up in the succeeding amplifier. This does not imply that the noise performance is 6 dB worse than possible, since the source impedance as seen by the (assumedly perfect) amplifier is now a parallel of the microphone and its matching load; hence, it is about half the value of either. The thermal noise generation of this combined source is consequently 3 dB less; so although the voltage is down 6 dB the noise performance is only degraded 3 dB by such a termination. Still, it is better not to throw away a good 3 dB before even starting to hassle with the amplifier itself.
Another good reason for not terminating with an equal or any fairly low resistance is the effect on microphone response and subjective quality. Having an inductive characteristic, the dynamic microphone capsule has an impedance that steadily rises with frequency, becoming predominant at high audio frequencies where the inductive reactance of the source is large with respect to the coil-winding resistance. When terminated with a relatively low resistance, the complex impedance of the capsule and the termination resistor form a single-order 6 dB/octave low-pass filter, gracefully rolling off the high-frequency output of the microphone. Not too useful.

With a fairly hefty cable capacitance, the system is no longer graceful; the complete network now looks like a rather rough second-order filter. There isn’t too much to be done about that; regardless of termination method, cable capacitance is here to stay and is always a consideration unless the preamp is remoted to or close to the microphone itself.

25.10.2 Optimizing Noise Performance

Amplifiers are not perfect. For noise criteria, the first device that the signal hits in the amplifier is the key one, since the noise it generates usually masks—by a large margin—noise from all succeeding stages.

All practical amplifying devices are subject to a variety of internal noise-generating mechanisms, including thermal noise generation. When measured, these give rise to some important values; namely, the input noise voltage, the input noise current, and the ratio between those two that is in effect the input noise impedance. This becomes all important in a little while. For the most part, bipolar transistors—either standard or more usually large-geometry and sometimes multiparalleled—are used as front-end devices both in discrete designs and op-amp IC packages in this application so much of the following relates to both packages.

These noise voltages and currents alter in both individual magnitude and ratio to each other with differing electrical parameters, especially collector current. Predictably, as this current decreases, so does the noise current (most of the noise is due to minor random discontinuities in device currents); the ratio between the noise voltage and current—or noise impedance—may be altered in this fashion.

Thermal noise generation is common to all resistive elements. The amount is related to both the temperature and the bandwidth across which it is measured; an increase in either will increase proportionally the noise power generated. Under identical circumstances, the noise power that is generated by any values of resistance is the same. Differing resistor values merely serve to create differing ratios of noise voltage and noise current; the product of the two always equals the same noise power. This particular noise phenomenon, thermal noise or Johnson noise, is totally unavoidable because the nature of atomic structure is such that when things get hot and bothered, they grind and shuffle about randomly, creating electrical disturbances white in spectra (i.e., equal energy per cycle bandwidth).

Even the real (resistive) part of the complex impedance of a dynamic microphone generates thermal noise; this ensures that there is a rigidly defined minimum noise value that cannot be improved upon.

25.10.3 Noise Figure

The difference between the noise floor defined by thermal noise and the measured noise value of a practical system is known as the noise figure (NF) and is measured in decibels (Noise Figure = System Noise – Theoretical Noise). The noise output from a resistor or the real part of an impedance is calculable and predictable—Herr Boltzmann rules. A direct comparison of the noise voltage measured at the output of an amplifier due to a resistor applied to the amplifier input versus the noise voltage expected of the resistor on its own is possible just by simply subtracting the measured gain of the amplifier. This is a measure of NF.

An interesting effect occurs when, with any given set of electrical parameters set up for the amplifier front-end device, the source resistance is steadily changed in value. A distinct dip in the NF occurs, Fig. 25-38, and the value of the resistor at which this dip occurs changes as the device parameters are changed (collector current primarily). For the usually predominant noise mechanism (thermal noise), a minimum NF occurs with a tiny amount of collector current (5–50 μA) and a high source resistance (50 kΩ up). Without diving into the mathematics, the nulling is a balancing of interaction between the external noise source and the internal voltage and current noise generators.

25.10.4 Inverse-Frequency Noise

There is another major noise mechanism inherent to semiconductors. It is the low-frequency (inverse level with respect to frequency) noise—a burbly, bumping-type noise caused by the semiconductor surface generating and recombining sporadic currents—most prevalent in dirty devices but present to a degree in all. It is subjectively apparent and has to be
considered. Measured alone, low-frequency noise has its own set of collector current and source resistance nulls, usually far higher in current and lower in resistance than for thermal noise.

Commonly known as 1/F noise—implying its predominance at very low frequencies—it is often specified by way of the frequency at which it is contributing the same amount of noise as the device’s effective thermal noise. Below this knee frequency 1/F noise predominates. A good clean device will have a knee frequency below 10 Hz; judicious filtering along the signal path can render 1/F noise unimportant within a system, but it remains a serious consideration within each individual amplifier stage.

25.10.5 Optimum Source Impedance (OSI)

A compromise has to be struck. To make a generalization, a 100 μA collector current and a 10 kΩ source impedance for a typical low-noise pnp transistor seem about right. (Pnp transistors are commonly used in this area due to slightly better low-frequency performance figures over npn types.) The source resistance value is that at which the device is optimally quiet for audio purposes and is known as the optimum source impedance (OSI). Incidentally, this impedance has absolutely nothing to do with the kind of circuit configuration in which the device may be. Whether it be in a common-base amplifier with an input impedance of 50 Ω or in a totem-pole front end with bootstrapping and a consequential input impedance of over 10 MΩ, it doesn’t matter. The source impedance for optimum noise performance stays at 10 kΩ, or whatever, provided that the collector current is the same in all cases. Optimum source impedance has nothing to do with input impedance.

This optimum impedance varies depending on the type of input device used. For an FET, the noise figure typically obtainable drops to an amazingly low value but, unfortunately, at a substantially useless impedance of several dozen megohms. Even supposing it were practical to provide a source impedance of that magnitude, the whole arrangement would be so sensitive to any electromagnetic fields (such as RF) that even tiny amounts present would obliterate the noise advantage. The design and construction of capacitor microphones using FET front-ends highlight the hazards; the end results often show such capacitor microphones can be several dB noisier than a dynamic microphone/front-end combination.

Good bipolar transistors have OSIs in the region of 5 kΩ to 15 kΩ, whether discrete or as part of an IC amplifier package. Fortunately, these values closely coincide with the source resistance value that provides for optimum flatness of device transfer characteristics. This helps a long way toward best frequency versus phase linearity, which translates to enhanced stability in a typical high negative-feedback amplifier configuration.

Fig. 25-39 shows the effect of altering the source impedance into such an amplifier (using a conventional bipolar transistor input device) on output frequency response. The droop is due to the excessively high source impedance reacting against the device base-emitter, board, and wiring capacitances to form a low-pass filter. The high-frequency kink is a practical effect of the curious mechanism; when a bipolar transistor is fed from an impedance approaching zero, its high-frequency gain-bandwidth characteristic extends dramatically, radically altering the phase margin and, consequently, the stability of an amp designed and compensated for more ordinary operating circumstances. The kink is a resonance within the amplifier loop caused by erosion of phase margin resulting from this mechanism. It is but an uncomfortably short step from oscillation.

As can be seen from the graph in Fig. 25-39, the response is maximally flat at a source resistance of around 10 kΩ, about the same value as the OSI for optimum noise performance for the same configuration. A problem to reconcile is that our practical source impedance is nominally 200 Ω for a dynamic microphone, whereas the OSI for the best conventional input devices is around 10 kΩ. How do we make the two fit?

25.10.6 Microphone Transformers

There are some horrible stories about how bad transformers are. Properly designed and applied, however,
they do offer a good to excellent solution to impedance matching and sundry other problems facing input stage design. Simplistically, a transformer is a magnetically soft core around which are two windings, the voltage ratio between the two being equal to the ratio of the number of turns on each. The impedance ratio is the turns ratio squared (e.g., a 10:1 turns ratio corresponds to a 100:1 impedance ratio) because power output cannot exceed power input. If the voltage is stepped up ten times, the output current must be stepped down ten times. Impedance, which is the ratio of voltage to current, is consequently the square of the transformed voltage or current ratio, see Chapter 11.

Given this, it is a simple matter to calculate the ratio necessary to match the microphone impedance to the amplifier OSI that is realistically achievable. Since few people are intense enough about the whole affair to bother measuring individual microphones, the convention that 200Ω is a good midpoint for source impedance serves well. Variations between actual microphones make trivial differences in the larger scheme of things. The assumption that most bipolar input amplifiers have an OSI of between 5 kΩ and 15 kΩ indicates that the transformer ratio should lie somewhere between 1:5 and 1:8.7.

Many consoles use higher ratios (typically 1:10), probably in the naive belief that the noise advantage of a step-up input transformer stems from the free gain it affords. Although on a basic level it would seem to make sense that the less electronic gain needed the quieter the system must be, this fallacy is completely belied by the truth that the transformer merely allows you to choose and alter the source impedance for which the amplifier is optimally quiet. Increasing the turns ratio beyond this easily defined optimum can and will actually render the amplifier noisier.

In practice the free gain can be more of a nuisance than a benefit. It is not unusual for microphone inputs to receive transients exceeding +10 dBu and mean levels of –10 dBu, especially in a rock-and-roll stage or recording environment. Even dynamic capsules can deliver frightening levels that can pose head room problems in the mixer front end. A typical 1:5 transformer has a voltage gain of 14 dB (20 dB for a 1:10 ratio), which would mean that even with no electronic gain after the transformer, normal mixer operating levels are being approached and possibly exceeded. These circumstances make worrying about a dB or two of noise performance total nonsense to be sure; it just serves to point out that our microphone front end has to be capable, if not perfectly optimized, for elephant herds as well as butterflies.

25.10.6.1 Transformer Characteristics

Transformers have numerous limitations and inadequacies resulting from their physical construction that make their actual performance differ (in some respects radically) from that expected of a theoretical model.

The heart of the transformer is the magnetically pliable material into and out of which energy is induced. Virtually any material—nickel, steel, iron, ferrous derivatives, and substitutes—have the same basic limitations. They saturate at a magnetic level beyond which they are incapable of supporting further excursion, and exhibit hysteresis—a crossover like nonlinearity at low levels responsible for a significantly higher distortion at low levels than anything else likely to be found within a well-designed modern-day signal path.

These two effects at opposite ends of the dynamic spectrum mean that all transformers have a well-defined range within which they must be operated and this range is less than the range of levels the microphone amplifier (mic-amp) is expected to pass. This is especially true at low frequencies, where the core is prone to saturation far earlier. Optimization begins here. Is it to be designed for minimum hysteresis (butterflies) or with plenty of material to be tolerant of monstrous (elephantine) signal levels?

Windings are made of wire, which has resistance. Resistance means loss and decreased efficiency and noise performance. By the time there are enough turns on each of the windings to ensure the inductive reactances are high enough not to affect in-band use, winding resistances can no longer be ignored.

Capacitance exists between things in close proximity and that includes transformer windings—between each other, between adjacent turns and piles in the same winding, and from the windings to ground. In this given instance it is nothing but bad news. Capacitance
between windings means unwanted leakage and imperfect isolation, while winding self-capacitance reacts with the winding inductances to form resonances. Resonances, even if far outside the audio band, invite response trouble, and disturb in-band phase linearity. Combinations of these capacitances greatly affect one of the greater advantages of transformers, common-mode rejection (CMR).

25.10.6.2 Common-Mode Rejection

For a transformer to work and transfer wanted information from one winding to another, a current must be made to flow through the primary; this is ideally achieved just by the opposing polarity (differential) signal voltage applied across it. Again ideally, any identical signals on the two ends of the windings (common mode) should not cause any current to flow in the winding (because there is no potential difference across the winding to drive it) and so no signal transfer can be made into the secondary. So much for ideal.

Common-mode rejection is the ability of the transformer to ignore identical signals (in amplitude and phase) on the two input legs and not transfer them across the secondary as differential output information.

Principally, it is imbalanced distribution of capacitance along the length of the two windings, both with respect to each other and to ground that makes CMR less than perfect. Co-winding capacitance has the effect of directly coupling the two wiring masses permitting common-to-differential signal passage, which worsens with increasing frequency at 6 dB/octave. Electrostatic shielding (a Faraday shield) between the windings can alleviate co-winding capacitance coupling.

Further CMR worsening can be expected even if the two windings are perfectly balanced with respect to each other, if the primary winding is not end-to-end capacitatively matched with respect to ground. Any common-mode signal from a finite impedance source (almost always the case) when confronted with such a capacitatively unbalanced winding sees it as being just that—unbalanced (becoming more so with increasing frequency). Again, input common-mode signals are transferred across to become output differential information indistinguishable from the wanted input differential source.

Broadcasters particularly are concerned with winding balance, not only on microphone transformers but also on line-output transformers, reasoning that common-differential transference is as likely to occur at a source as at an input.

25.10.6.3 Microphone Transformer Model

Fig. 25-40 gives a better idea of what the small signal of a dynamic microphone has to suffer. The winding capacitances (\(C_p\) and \(C_s\)) form lovely resonances with the inductances, while the transformed up primary winding resistance (\(R_p\)) added to the resistance of the secondary winding (\(R_s\)) merely serves to increase the effective source impedance of the microphone producing loss and resultant inefficiency.

A frequency response of a less-than-ideal transformer fed from a 200 \(\Omega\) source and measured at high impedance across the secondary looks something like Fig. 25-41, where the low-frequency droop is attributable to one or both of the winding inductive reactances becoming comparable to signal impedances, while the high-frequency peak is an aforementioned secondary winding self-resonance. Usually the primary self-resonance is fairly well damped by the source impedance, but occasionally added cable capacitance can play cruel tricks here, too.

![Figure 25-40. Transformer coupling model showing major elements.](image)

![Figure 25-41. Typical transformer transmission response.](image)

The mic-amp itself, as discussed, has a high-input impedance (hundreds of kilohms and up) while its optimum source impedance is defined at around 5–15 \(k\Omega\).

It’s good engineering practice to consider how the circuit behaves when the operating impedances are no longer defined by the microphone (i.e., when it is unplugged). Ordinarily, the circuit of Fig. 25-40 with the microphone disconnected would probably oscillate, as would any circuit with a high-gain, high-
input-impedance amp terminated only by the collection of vile resonances and phase-shifting elements that are an open-circuit transformer. An open-circuit impedance-defining resistor \((R_o \text{ in Fig. 25-42})\) with a value 10 or 20 times that of the amp OSI, helps tame this. It also marginally tames the secondary resonance.

There are a variety of techniques for dealing with this resonance. They vary from pretending it doesn’t exist to actually using it as part of a front-end, low-pass filter to keep ultrasonic garbage out of the electronics. Minimization of the high-frequency bump is attempted as much as possible passively, prior to the amp; the taming network in Fig. 25-42 represents a typical approach. Here, a series resistor-capacitor combination in conjunction with the open-circuit impedance-defining resistor is used. The values are calculated to produce a step-type response, Fig. 25-43, which when combined with the hump at the high-frequency end of the transformer response, produces a more acceptable roll-off characteristic. Naturally, the interreaction between this network and the complex impedance of the transformer is not quite that simple. The network capacitance reacts heavily with the transformer inductance, shifting the resonance frequency in the process. It is this fact that has led to the misconception that the capacitance somehow magically tunes out the resonance.

Open-circuit stability is dramatically improved, Fig. 25-43. The network takes an even larger slice out of the overall high-frequency response, keeping impedances at the top end comfortably low.

25.10.6.4 Bandwidth

Providing the compensating high-frequency roll-off around a subsequent amplifier, in the form of exaggerated feedback phase-leading around the mic-amp itself in this case \((C_F)\), has the advantage that the noise performance of the combination at higher frequencies remains unimpaired by an impedance mismatch resulting from a passive network.

Problems result in several areas. Compensation around the mic-amp becomes limited when the electronic gain approaches unity, while compensation around a late fixed-gain stage means that all stages prior to it, including the mic-amp, have head room stolen at the frequency of the resonance and to a degree of the magnitude of the resonance. This may or may not be a problem depending on how far the lower side of the resonant curve invades the audio band.

The passive method reduces the magnitude of the resonance. The ultimate low-pass roll-off slope is that of the high-frequency side of the resonance, which more accurately is a lightly damped inductance-capacitance, low-pass, 12 dB/octave filter. The active method uses an additional 6 dB/octave curve in the compensation making a total of 18 dB/octave, but it relies on the resonance being of a manageable degree to begin with. A measure of both techniques is usually required; their balance and relationship are an experimental process to optimize for each different type of transformer.

This enforced filtering is of considerable advantage, helping to keep all sorts of unwanted ultrasonic noise from finding its way into the mixer. It also represents a major advantage of transformer inputs over solid-state varieties.

A further advantageous filtering is the falling source impedance seen by the amplifier at extreme low frequencies. This is due to the fact that the winding inductive reactance reduces with frequency. This is a definite help in combating the generation of excess low-frequency noise in the first amplifier.

25.10.6.5 Common-Mode Transfer

There are two different amplitude response curves to be considered. The first, the normal differential input, has been fairly thoroughly determined. The second, by virtue of its mechanism, relies on imperfections within the main filter element itself (the transformer) rides over and oblivious to our carefully calculated filter.

![Figure 25-42. Basic microphone preamplifier with compensation components.](image-url)
Consoles 865

responses. Common-mode unrejected signals still appear at the amplifier input as if nothing had happened.

25.10.6.6 Input Impedance

As determined earlier, we would end up with better noise performance and cleaner sounds if the microphone looked into a high, preferably infinite, impedance. Preferences apart, we have already had to define the reflected load (input), impedance by the resistor needed to keep the front-end stable under unplugged conditions ($R_0$), but at least it is an order of magnitude or so above working impedances, so its effect is small. It does, though, act as part of an attenuator of input signals along with the source impedance and winding losses, Fig. 25-44. This is the major factor responsible for worsening front-end noise performance using transformers. Any attenuation before the optimized amp directly degrades the noise figure, typically between 1 and 6 dB, depending on the transformer.

A good rule of thumb is that the midband input impedance should exceed ten times the source impedance, or about 2 kΩ for a dynamic microphone. Any wild variation in this impedance is obviously going to result in frequency and phase response aberrations, which are probably the greatest single drawback to transformer front ends. Things aren’t quite as bad as they seem; examples of performance shown here have been deliberately of a marginal transformer to highlight the illeffects, notably in response and impedance flatness; good transformers from good reputable manufacturers such as Jensen, Lundahl, and Sowter generally show much nicer results, but the design criteria to eke the best from them remain nonetheless.

25.10.6.7 Attenuator Pads

Attenuator pads, regrettably necessary in many instances to preserve head-room and prevent core saturation with elephantine sources, should maintain expected operating impedances when introduced. The transformer primary should still be terminated with a nominal 200 Ω, while the microphone should still look at 2 kΩ or above. Departure from these will cause the microphone/amplifier combination to sound quite different when the pad is thrown in and out, as would be expected from altering source and load impedances in and around complex filter characteristics. A significant downside to pads is that although the differential (desired) signal is being attenuated to the expected degree, any common-mode signal isn’t.
25.10.6.8 Transformerless Front Ends

Bringing the amplifier optimum source impedance down to that of conventional dynamic microphones is possible by means other than transformers. Reducing the ratio of amplifier-inherent voltage and current noises has this effect. Two main techniques, either alone or in concert, are used:

1. Large-geometry devices have innately lower noise impedances. Even power-amplifier drivers have been used (e.g., 2N4918, BD538) but these tend to suffer from low transit frequencies (bandwidth) and beta (gain), which can lead to additional complexity in the circuitry.

2. Paralleling multiple identical input devices, and so proportionally increasing the noise current in relation to the noise voltage, reduces the ratio between them (i.e., noise impedance).

PNP transistors, as mentioned elsewhere, have less surface-recombinant noise/lower base-spreading resistances than NPNs and are favored in this application.

The usual technique is to place two of these large and/or multidevice input front-end amps—preferably accurately matched—ahead of an electronic differential amplifier, as shown in Fig 25-46. All the amplifier gain is made within the first pair of stages, differentially cross-coupled. This gain arrangement, rather than referring to ground, can afford reasonable common-mode signal rejection. Differential input signals are amplified since the reference for each of the two amplifiers is the other amplifier, tied to an identical signal of opposite polarity.

If the input signals to the two amps are identical in phase and amplitude (common), the references for each of the amplifiers are similarly waving up and down sympathetically to the signal. There is no voltage difference for the individual amplifier to amplify; consequently, there is no gain. For ordinary differential input signals, the amplifiers operate conventionally, their ground reference being a zero voltage point half-way along the gain-determining variable resistor. This point is a cancellation null between the opposite sense polarity swings of the two amplifiers.

These amplifiers feed a conventional electronic differential amplifier running usually at unity gain. In order to maintain stage noise as low as possible, the resistors are made as low in value as the devices can sensibly stand. This arrangement is unmistakably a bastardized instrumentation amplifier—a well-documented circuit configuration; the only thing of remark is the pair of low-impedance optimized front-end stages.

A criticism (rightly) leveled at some implementations of this, including earlier-generation integrated parts, is that the noise performance is significantly worse at low amounts of gain than at high gains, where
the (hopefully) optimized input pair reigns. This is mostly down to the impedances chosen around the op-amp differential amplifier; some resistor values here have been seen as high as 25 kΩ, guaranteeing a high invariant noise floor for much of the gain range; bizarrely, some implementations attempt gain around this stage, too. The lesson earlier learned of keeping the circuit impedances as low as circumstances permit is salient here.

There are few reasons now for hand-knitting discrete versions of this input arrangement, and good ones not to, primarily suitable input devices: the much-favored 2SB737 is sadly becoming difficult to procure, and the excellent integrated matched transistor sets such as the THAT 320 are relatively expensive. Relative, that is, to the cost of a purpose-designed IC! There are a few integrated versions of this kind of arrangement offering very acceptable performance in the convenience of a little package; the Burr-Brown INA103 or 163 and the THAT Corporation’s 1510 have multiparallel input transistor stages presenting OSIs about perfect for nominal microphone impedance, the latter part taking to heart the op-amp differential stage noise issue, with excellent results. Texas Instruments/Burr-Brown’s PGA2500 is a digitally gain-controlled version of this configuration, which works very well indeed with fine gain steps and inaudible gain-change (zipper) noise, solving a major headache for digital console designers and others desirous of remote control of mic gain. They have proved themselves worthy with ribbon microphones, the ultimate front-end-noise torture test.

With this configuration, although potentially offering far higher and flatter input impedances than transformer inputs, there are, as always, snags. Common-mode signals directly gobble up head room in the first pair of stages even if they are operating as followers; that this common-mode stuff is substantially canceled in the following differential amplifier is a bit of a stable-door and bolted-horse routine. There is also the great danger that common-mode signals (in addition to normal differential signals) can exceed the input swing capability of the input devices. At best this will block the input stage, at worst—if the common-mode signal is big enough and at a low enough impedance (think ac line grounding fault here)—serious destruction can result. A transformer input would blithely ignore such.

Radio frequencies simply adore base-emitter junctions, and this configuration has them in abundance. Successfully filtering microphone inputs sufficiently without sacrificing noise performance or input device high-frequency gain (increasing high-frequency distortion and so on) is not a trivial task; it makes the self-filtering properties of an input transformer seem rather appealing.

Fig. 25-46C details the kind of helmet-and-armor with which one has to attire electronic microphone front ends to survive the fray:

- The π L/C filters and additional coupling to ground at high frequencies help against RF. The inductors can either be single pieces, one in each leg, or preferably a pair of windings around a common (usually toroidal) core. This has the twofold advantages that the choking effect is concentrated on common-mode signals—the most common (so to speak) interference method—and that the inductances of the two windings essentially cancel for differential signals, so that there is much less effect of the RF protection impinging on the desired audio.
- The input dc-decoupling capacitors have to be pretty huge in value to maintain low-frequency integrity and at the same time have a high enough voltage rating to handle typically 48 V off-load phantom-power voltage.
- The parametric varactor capacitance of the clamping diodes has little to no effect on the audio but are vital to protect the device front end from the very healthy whack as the phantom voltage is turned on or off. Even so, clamped or no, good common-mode rejection or no, phantom ramped or no, these transitions are not exactly subtle. These diodes may help protect the input from other nasties, too, but the aforementioned major ground fault would render all this toast anyway. The good news: such are rare but in the real world of touring sound not unthinkable.

25.10.6.9 Line Level Inputs

The reader is referred to Chapter 11 for Bill Whitlock’s excellent further coverage of real-world interfacing.

High-level balanced interconnections and systems for the most part have been largely relegated to outside world and intersystem interfacing; internal interconnects are left unbalanced except within a very few completely balanced console designs. The wisdom until quite recently was that balancing implied transformers and their performance limitations.

Transformers—good ones at least—are expensive, large, and heavy. Not so good ones are still relatively expensive, large, and heavy and represent a weak link in a modern signal path, with their low frequency distortion, hysteresis, and high/low frequency/phase response effects. Transformers are best used only where their impedance transformation capabilities, innate filtering,
and excellent isolation properties are really needed. And then only really good ones. Most high-level interfacing applications within the confines of a studio environment justify neither their capabilities nor drawbacks.

The search was on for electronic equivalents to transformers for both input and output applications, a moderate degree of success being achieved early on for input stages with classic circuits such as Figs. 25-47 and 25-48. These are simple differential input amplifier and instrument amplifier configurations using op-amps.

Line inputs are commonly differential amplifiers, similar to the one used in the transformerless mic-amp, but with the resistor values elevated to bring the differential input impedance up to over the 10 kΩ required of a bridging termination, Fig. 25-47. The noise of these stages is directly attributable to these resistor values, so the lower resistor values are better. An instrumentation amplifier configuration would seem to offer possibly better performance for noise (the differential amplifier resistor values may be kept small) but it entails the use of undesirable voltage followers (see Section 25.7) with potential stability problems, input voltage swing limitations, and unprotected (for RF) input stages. At least with a simple differential amplifier the impedances are comfortably low and the inputs buffered by resistors from the outside world.

The dc-blocking series capacitors must, unfortunately, be large in value to maintain an even input impedance and sensibly flat phase response at the lowest used frequencies. Also, being necessarily unpolarized, they are physically large and expensive. This is a small price to pay, though, for such a simple but important circuit element.

The instrumentation amplifier presents very high, nonground-referred differential and common-mode terminations and has the great advantage that gain may be easily invoked between the two input amps at no cost to the excellent common-mode rejection, Fig. 25-48. Integrated line receivers are typically of this configuration.
A pair of inverting amplifiers, shown in Fig. 25-49, provides a simple, hardy, easily defined differential (but not true floating balanced) input stage. A fascinating circuit known as the Superbal input is depicted in Fig. 50; this is a balanced differential virtual-earth amplifier, referred to ground solely by one op-amp input and capable of very good common-mode rejection, limited by the tolerance of the components from which it is constructed. Accepting any lopsided input signal, it delivers a differential output perfectly symmetrical to ground, making it an exceptionally useful input conditioning amplifier.

The capacity of both these circuits to be differential virtual-earth points makes them ideal for use in balanced mixing bus systems.

25.10.6.10 Electronic Balanced Outputs

The simplest balanced outputs configuration is given in Fig. 25-51. This is a pure, no-nonsense, inverter-derived differential feed. For many internal interconnections and especially in differential balanced mixing systems it works well, but it should not be used to connect to the outside world.

Ideally, there must be no discernible difference in characteristics between the output circuit and an ideal transformer. After all, the fate of signals in the real world on a balanced transmission line won’t alter in your favor simply because you’ve chosen not to use a transformer. If transformers are being supplanted it had better be with devices capable of affording similar benefits to the system and its signals. Regardless of applied reverse common-mode potential, the differential output potential must not change. Also the output should be insensitive to any imbalance in termination, even to the extent of shorting one of the legs to ground. This is the floating test. For example, the simple inverter circuit of Fig. 25-51 fails the floating test since, if one leg is shorted to common, the overall output has to drop by one-half (6 dB). (The question of what happens to ground noise with a shorted amplifier bucketing current into it will be sidestepped here.) Two basic circuits have emerged as being close approximations to a transformer. Not only are they fairly closely related, but most balanced output topologies are also derived from them. They both depend on cross-coupled positive feedback between the two legs to compensate for termination imbalance.

In Fig. 25-52 a unity-gain inverting stage provides out-of-phase drive for the two legs, each output leg of which is a −6 dB gain inverting amplifier with error sensing applied to its reference (positive) inputs. Under normal operation, there is no error-sensing voltage; the two inverse outputs cancel at the midpoint of the equal sense resistors. The two amps invert a differential feed.
voltage equal to the unbalanced input voltage appearing between their outputs. (Two -6 dB quantities sum to make zero gain.) Take the case of one output, the upper one being shorted to ground. An error potential is derived of such a phase and level on the error-sense line that positive feedback increases the gain of the unshorted amp by 6 dB, while matching on the positive input of the shorted one the signal on the negative input, canceling its amplification. Closing the shorted amp down prevents ground-current problems; therefore, any measure of output termination imbalance is reasonably dealt with by this arrangement.

A major problem with any circuit depending on high levels of positive feedback such as these is their potential instability. Both these circuits are right on the edge of instability—they have to be in order to work accurately; a measure of margin has to be given for peace of mind and component tolerances. This backing-off compromise affects primarily common-mode rejection and output level against lopsided terminations. A loss of about 0.5 dB in differential output level can be expected when one side is shorted to ground, although tight component tolerances can improve on this. Component tolerance imbalance—even if constructed with 1%
resistors—manifests itself also as sometimes quite substantial dc offsets that will likely have to be trimmed to not eat up too much head room.

Curiously, instability tends to show itself as common mode. This fault manifested itself to the author for the first time (too) early one installation morning; a peak program meter (PPM) across such an output read nothing, listening elicited a little bit of hum, but a scope on either leg to ground showed 10 Vp-p square waves, driving the tape machine to which the output was connected into shock.

Integrated versions of the cross-coupled circuit such as the SSM 2142 have the great advantage of extremely closely matched/trimmed resistor values, and hence far more predictable performance than discrete versions.

25.10.7 A Practical Microphone-Amplifier Design

Optimizing front-end sound is nothing more than shrewd judgment in juggling the nearly endless electronic operating conditions so that adequate performance is obtained over the wide range of expected and common input signals. Any wrinkles should be arranged to exert influence only under quite extraordinary operational conditions.

The microphone amplifier example described here, Fig. 25-53, is a somewhat developed version of a basic front-end design and is in grave danger of becoming an industry standard.

Initially most striking is the manner in which a single-track potentiometer is used to vary simultaneously the gains of two amplifying elements—the front-end (noninverting) stage and the succeeding inverting amplifier. Since the first stage is (as far as its inputs are concerned) a conventional noninverting amplifier, transformer input coupling is no more problematic than with simpler microphone amplifiers (e.g., Fig. 25-41, a standard generic microphone amplifier).

With maximum gain distributed between two stages, large gain is possible without any danger of running out of adequate steam at high frequencies for feedback purposes in either of the two amplifiers. This, incidentally, also makes for reasonably simple stabilization of the amplifiers, something not easily accomplished with simpler single-amplifier circuits achieving the same gain swing. Other than the obvious simplicity and economy of one-pot gain control, two nice features inherent in the design are interesting from the points of view of system-level architecture and operation.

25.10.7.1 System-Level Architecture

System-level architecture is largely concerned with operating all the elements of a system at the optimum levels and/or gain for noise and head room (i.e., at a comfortable place somewhere between the noise floor and clipping ceiling). Where gain is involved, it’s important that the resultant noise be due primarily to the gain stage that has been optimized for noise (or rather lack of it) such that it can then mask all subsequent and hopefully minor contributions. At no point in the gain swing—particularly at minimum gain—should it be necessary to attenuate unwanted residual gain. This amount of attenuation gets directly subtracted from overall system head room. What good is 24 dB of head room everywhere else, if you have only 16 dB in the front end?

In this respect circuits similar to Fig. 25-53 score well, and the graphs of Fig. 25-54 show why. Fig. 25-54A represents the gain in dB of a simple noninverting amp varying with the percentage rotation of an appropriately valued linear pot in its feedback leg. This is like the gain/rotation characteristic of the first amp of Fig. 25-53. Similarly, Fig. 25-54B is the gain/rotation plot for a linear pot as the series element in an inverting amp, such as the second gain stage of Fig. 25-53. For the first half of the rotation, the first stage provides all the gain swing and most of the gain; only about 6 dB is attributable to the inverting stage at midpoint. Toward the end of the rotation, this position reverses with the front end remaining comparatively static in gain; the extra swing and gain come from the inverting stage. Noise criteria are met, since the first (optimized) stage always has more than enough gain to swamp any noise it might have; only about 6 dB is attributable to the inverting stage at midpoint. Toward the end of the rotation, this position reverses with the front end remaining comparatively static in gain; the extra swing and gain come from the inverting stage. Noise criteria are met, since the first (optimized) stage

\[
\begin{align*}
R_1 &= R_2 = 22 \text{ k}\Omega \\
R_3 &= R_4 = 620 \text{ k}\Omega
\end{align*}
\]

Figure 25-53. Shared-gain two operational-amplifier input stage.
really quiet!). The impedances around the second stage largely determine the noise performance of the amplifier, and this is such that it need not be considered in relation to input noise at any sensible gain setting. Head room is satisfactory because no attenuation after the first gain stage is needed for any gain setting. The two gain stages operate nicely complimentarily.

An operational advantage can be gleaned from Fig. 25-54C. This is the combined gain/rotation curve for the entire two op-amp circuit. Note that for a very large percentage of rotation around the middle of the gain swing (where it’s most often used) the dB gain change per rotation is as good as linear. It gets a bit cramped at the top and bottom, but you can’t win them all. For reference a little later on, it may be noted that there are two available resistors \( R_2 \) and \( R_3 \) that may be used to modify the gain structure independently of the potentiometer.

### 25.10.7.2 Input Coupling

As a microphone amplifier, the fairly high optimum source impedance of the op-amp used in Fig. 25-55 (a Signetics NE5534, or AD797) needs to be matched to the likely real source impedance of some 150–200 \( \Omega \). No apologies are offered for the use of transformer input coupling, as grossly unfashionable as this may currently seem. Transformers still offer outstanding advantages—especially simplicity, impedance step-up, protection, and filtering—over electronic inputs in this application.

Many circuit values (marked with an asterisk in Fig. 25-55, with some in quite unexpected places) are dependent on the specific transformer type in use. Several differing transformers can be very successfully used provided their differing ratios are taken into account in level calculations; a ratio of 1:7 is optimum to match the OSI of the input device employed. Phase and response trimming values will vary significantly. For example, with the Jensen JE-115-K, it is simpler than with the Sowter 3195 around which this circuit was originally developed. Despite the apparent simplicity of the circuit, a lot of effort has gone into defining the front-end bandwidth and straightening out the phase response at audible extremities. Taming the high-frequency transformer resonance in particular is quite tiresome.

On the front of the transformer hang the usual components to make the microphone amplifier useful in this world of capacitor microphones: a 20 dB input attenuator and 48 V phantom power via matched 6.8 k\( \Omega \) resistors per leg carried common mode along the microphone line. Further to earlier discussions, the component values in the pad are chosen such that the microphone still sees the same general impedance whether or not the pad is inserted, while the mic-amp still sees about a 200 \( \Omega \) source to keep all the transformer-based filtering in trim. It is essential the 6.8 k\( \Omega \) phantom resistors are
matched; poor matching is a very easy way to wreck carefully won common-mode performance.

25.10.7.3 Line Level Input Facility

A line-in option is brought in via the transformer also. It features far stiffer input attenuation (about 36 dB) while simultaneously disabling much of the gain swing of the first amp. The resultant gain swing of 35 dB (between –25 dBu and +10 dBu input level) with a bridging-type input impedance of some 13 kΩ should accommodate most things that the microphone input or machine-return input differential amp can’t or won’t. A small equalization network is used in the attenuator to bolster the extreme low-frequency phase response.

An alternative and in many ways preferable line-in arrangement might be to use either a discrete or integrated instrumentation amp-style stage, switched into the second stage of the mic-amp. In Fig. 25-55 this would come in where “from B-check Diff-Amp” is marked. This would avoid the necessity of using the transformer with attenuators, which of course does no favors to the common-mode rejection ratio.

25.10.7.4 Common-Mode Rejection Ratio

Common-mode rejection ratio (CMRR) in the transformer is dependent mostly on the physical construction of its windings. The Sowter, in common with many other transformers, may be in need of compensation by deliberately reactively unbalancing the primary winding.
to match the inadvertent internal characteristics, Fig. 25-56. Jensen transformers are uncannily good in this respect—no tweaks usually being necessary. There are external circuit influences that can and will upset the maximum obtainable common-mode rejection. The accuracy of the phantom-power resistors is one; any input pad, regardless of accuracy, is another. Assuming any reactive (i.e., rising with frequency) common-mode response has been trimmed out, unequal phantom legs will enforce a lopsided flat common-mode response while true floating input pads instantly reduce the CMRR by nearly the amount of their attenuation. Why? They do this because they only attenuate the differential (wanted) signal and not the common-mode one. A halfway solution is to centrally ground reference the pad. Given all that, less than perfect common-made response shouldn’t cause any ill manifestations in a typical recording environment with fairly short input leads. A high electromagnetic field of any sort, or an application with very long leads (or worse yet, a multicores), is far more likely to create problems with untrimmed inputs than with those properly balanced; vulnerability is greatly increased to all types of common-mode problems including noise on the phantom power-supply feed. Indeed, this is a common compounding of faults on a console that exhibits consistently noisy inputs.

At minimum gain though, the first stage in Fig. 25-55 is operating almost as a follower with an output load of 770 Ω, with the remaining feedback path to ground. That’s safe and easily within the amplifier’s driving capability. It would be better though if this small resistance were still smaller because it is contributing a little unwanted thermal noise to the otherwise beautifully optimized front end. The calculated degradation is only minor points of a dB and in practicality is easily lost in the gray mist that always surrounds the marriage of calculation with practical noise measurement.

The idea of using a front-end stage that turns into a follower under operating conditions has proved stable without any obvious trace of ringing within its bandwidth. This is probably because it is only being asked to look into safe, unreactive loads. Things that will make any unstable circuit squeal have not affected it. Among the instruments of torture have been a pulse generator/storage scope and an RF sweep generator/spectrum analyzer. The 10 pF compensation capacitor is more an act of conscience than a practical necessity. No compromise comes from its use here, since at maximum gain the first amp is working 30 dB below system level (an implied slew rate of nearly 200 V/μs!). At minimum gain the incoming signal level is such that it’s most likely coming from a line source of certainly much more limited speed than the front end.

Down from the nether world of megahertz, the microphone amplifier is totally stable for audio, even with the microphone unplugged and input unterminated; the input network (of RG and CG) is designed to work in conjunction with the fairly low-input impedance of the 5534 (150 kΩ nominal).

25.10.7.6 The Limiter

Elaboration on the simple two op-amp mic-amp element consists of arranging an automatic gain control element in the feedback loop of the second amplifier and following that with a variable turnover frequency high-pass filter, Fig. 25-55.

A photoresistor device has its resistive end strapped across the normal gain-determining feedback resistor. Its resistance drops in value from very high (megohms) in inverse relation to the photodiode current to a limit of around 300 Ω at about 20 mA diode current. This resistance swing in the second amplifier is easily adequate for use in a peak limiter arrangement. The resistance change is close to exponential versus diode current, which could be of use in a gentler compressor, but here as a limiter the resistance change is quite sudden once that point is reached.

![Figure 25-56. Input common-mode “tweak.”](image-url)
The limiter side chain is true symmetrical peak detecting, selectable to be able to pick off from either the high-pass filter output (as an input limiter) or from after the post-equalization breakpoint downstream (as a channel limiter). A positive-going and a negative-going level-detecting comparator are adjustable between clip detection (0.67 dB before system head room) or program level (nominally) +8 dBu.

A bicolor LED blinks red to indicate limiting in action, and it blinks green when the limiter is disabled to signify that the selected level (clip or program) is being reached or exceeded. In this indicate mode, the limiter integration time constant is deliberately shortened to make the green flashing similar in character to the red flashing in limit.

The difference is due to the nature of servo loops, of which a feedback limiter such as this is an example. In limit, the loop is self-regulating, the gain-control element holding back the audio level so that it’s just tickling and topping up the side chain. In indicate, the loop is broken, and there is no such regulation. The green light stays on whenever the threshold is exceeded and tends to hang on while the time-constant capacitor discharges. With even a minor overdrive, this hangover could extend for quite a few seconds; hence, the shortened time constant.

This limiter is not subtle. The comparators deliver a full-sized, power-supply wallop to the integrator upon threshold, softened a bit by the attack preset in conjunction with the output impedance of the comparators. This rather unusual approach is to help wake up the photore-sistor that has a relatively leisurely response time. The combination can be adjusted to be slow enough such that it doesn’t clip yet fast enough to prevent an audible snap. Overshoot is generally within 1 dB on normal program, given a release time long enough to prevent pumping.

As a rough guide, if it’s intended to use such a limiter for sporadic transient protection, it’s best to aim for short attack and release times, bearing in mind that such settings will behave more as a clipper to the lower frequencies. For continual effect use, longer time constants will be less gritting and more buoyant. This side-chain arrangement certainly behaves differently from more conventional FET or voltage-controlled amplifier (VCA) linear proportional systems and needs a slightly different approach in setting up.

25.10.7.7 High-Pass Filters

Constructed around the line output amplifier of the front end in Fig. 25-55 is a second-order high-pass filter. It is a completely ordinary Sallen-Key type filter, arranged to use a dual-gang equal value potentiometer to sweep the 3 dB down turnover frequency from between 20 Hz and 250 Hz. A click-stop switch at the low-frequency end (counterclockwise) negates the filter, replacing it with a very large time-constant, single-order dc decoupler. These are both tied to reference in order to minimize clicks. Fortunately, the BiFET op-amp in the filter barely uses any input bias current, so there is little developed offset voltage from that source to worry about.

Being an equal-value filter, the Q or turnover would be very lazy indeed if the feedback were not elevated in level to compensate for the upset resistor ratio. Here a compromise is struck. A low Q gives a very gentle roll-off (which is sonically good), and high Q results in a much more rapid attenuation beyond the cutoff frequency at the expense of a more disturbed in-band frequency response—pronounced bumps—and frantic temporal and phase responses exhibited as ringing and smeared transients. Luckily, the majority of control-room monitors exhibit far worse characteristics at the low-frequency end.

A maximally flat response midway between the two extremes is chosen by an appropriate amount of elevated feedback (around 4 dB). This gain is taken across the filter as a whole, with the second stage of the microphone amplifier arranged to sustain a 4 dB loss to compensate. It all works out in the end, with no compromise of head room. With minimum gain set, there is still unity electronic gain front to back. An added convenience of gain is that it provides a better chance of shoring up feedback phase margin, which is quite important in a line amp that may have to drive a lot of heavily capacitative cable. Also, it provides yet another single-order low-pass pole to help smooth out the high-frequency resonance of the microphone transformer.

25.11 Equalizers and Equalization

The term equalization is strictly a misnomer. It was originally utilized to describe the flattening and general correction of the response of systems in which by a matter of course or design had deviated from the original shape (e.g., telephone lines and analog tape machines). (In the latter case, equalization refers to the adjustment tweaks to the preemphasis and deemphasis curves—not necessarily the curves themselves.)

In search of a name for the deliberate modification of amplitude and phase versus frequency responses for taste
and the occasional genuine creative effect, the contraction EQ is well understood as both a noun and a verb.

This sonic mutilation uses frequency response curves and shapes in degrees that have grown through an uneasy mixture of operator needs and technical expedience/feasibility. One of today’s multiparametric console channel EQs would have needed a rack full of tubes in the fifties and sixties. Funny, they didn’t seem to need such EQs then.

The delight (and maybe curse) of IC op-amp design is that active filter (hence, EQ) implementation and techniques have blown wide open, limited only by economics, the largeness of the printed circuit board and the smallness of the user’s fingers.

EQ curves can be roughly lumped into three user categories: garbage disposal, trend, and area. High-pass, low-pass, and notch filters that eliminate air-conditioning burble, mic-stand rumble, breath noises, hum, TV monitor line-frequency whistles, and excessive electronically generated noise are obviously in the business of garbage disposal. Fig. 25-57A shows the sorts of responses to be expected from these. Gentle hi-fi-type treble and bass slopes and similar shelving curves establish response trends shown in Fig. 25-57B, while resonance like, bell-shaped lift-and-cut filters manipulate given areas of the overall spectral response, Fig. 25-57D. These are used to depress unwanted or irritating aspects of a sound or, alternatively, to enhance something at or around a given frequency that would otherwise be lacking. As the curves differ, so do the design techniques required.

25.11.1 Single-Order Networks

You can’t build a house until you have the bricks, so they say. Fig. 25-58 has those bricks in the form of combinations of basic passive components with a rough guide to their input-output voltage transfer functions (essentially the frequency responses). Assumptions are that the $V_{in}$ source impedance is zero and the $V_o$ termination is infinite impedance.

Capacitative reactance decreases with increasing frequency, working against the resistance to increasingly short the output to ground with increasing frequency in Fig. 25-58A, while in Fig. 25-58B the capacitance steadily isolates the output from the input with reducing frequency (rising reactance).

Inductors have entirely the opposite reactive characteristics. Inductive reactance is directly proportional to frequency, so the curves in Figs. 25-58C and D will be of no surprise at all, being complementary to those involving capacitance.

25.11.2 Single-Order Active Filters

Further useful curves are derived when the passive $R$, $C$, and $L$ elements are wrapped around an op-amp in the classic inverting and noninverting amplifier modes, as shown in Figs. 25-58E to $L$. All the curves in Fig. 25-58 are normalized to unity gain and the same center
Figure 25-58. Single order filters.
frequency at which the curve departs significantly from flat.

Standard arithmetic formulas normally consider or obtain a frequency at which the curve has departed 3 dB from flat (the 3 dB down point) being usually also where the phase has been shifted 45°. This is only partially useful in the design of filters for use in practical EQs; the departure point, or turnover frequency, is generally more relevant.

25.11.3 Changing Filter Frequency

With any of these filters, moving the frequency at which the filter bites can be achieved by altering any of the R, L, or C values. Making any value smaller moves the frequency higher, while making the value larger moves the frequency lower.

There are an endless number of combinations of element values to create the same curve at the same frequency. In Fig. 25-58A if the value of the capacitor were reduced (increased in reactance), the filter curve would shift up in frequency. A corresponding proportional increase in the series resistor value would result in the original turnover frequency being restored; we have an identical filter with a different resistor/reactor combination. What does remain the same is the ratio or relationship between the two elements. It is only the filter impedance (the combination of resistance and reactance) that varies.

With the exception of a few, the operation of any active filter can eventually be explained by referring to these basic single-order filter characteristics in Fig. 25-58.

There is one particular combination of two reactive elements (capacitance and inductance) that is of prime relevance to the construction of EQs. This, a series-tuned circuit, Fig. 25-59, is where things really become interesting.

25.11.4 Reactance and Phase Shifts

In, for example, the context of a simple resistor/reactor filter (Fig. 25-58A), the reactance not only causes an amplitude shift with frequency but also a related phase shift. A fundamental difference between the two types of reactance (C and L) is the direction of the output voltage (V_o) phase shift with respect to the source (V_in).

More specifically, the capacitor in Fig. 25-58A causes the output voltage phase to lag farther behind the input as the roll-off progressively bites to a limit of −90° at the maximum roll-off of the curve, while the inductor of Fig. 25-58C imposes an increasing voltage phase-lead as the low-frequency roll-off descends with a limit of +90° at maximum attenuation.

The two reactances, in their pure forms, effect phase shifts of +90° to −90° to an ultimate extent of 180° opposed; they are in exact opposition and out of phase with each other.
Referring again to Fig. 25-59, a slightly different light shines. The two reactances are working in direct opposition to each other with the inductive reactance trying to cancel the capacitative reactance and vice versa. Arithmetically, it is surprisingly simple with the two opposing reactance values directly subtracting from each other; the combination network behaves as a single reactance of the same reactive character as the one predominant in the network.

For example, if for a given frequency, the inductive reactance is a $+1.2 \, \text{k}\Omega$ (the $+$ indicating the phase shift character of inductance) and the capacitive reactance is $-1.5 \, \text{k}\Omega$, then the effective reactance of the entire network is that of a capacitor of $-300 \, \Omega$ reactance.

### 25.11.5 Resonance

Resonance is the strange state where the reactances of both the $L$ and $C$ are equal. For any inductor-capacitor pair at resonance, the two reactances will be equal. If you subtract two equal numbers, the answer is zero. So, for the series tuned-circuit arrangement of Fig. 25-59A at resonance, there is no impedance. The two reactances have canceled themselves out. It is a short circuit at that one frequency of resonance, disallowing component losses and is, in effect, a frequency-selective short circuit. Either side of that frequency, of course, one or the other of the reactances becomes predominant again.

### 25.11.6 Resonant $Q$

Like the single-order networks, there is an infinite number of combinations of $C$ and $L$ at any given frequency that will achieve resonance (i.e., the two reactances are equal). Similarly, it is the scale of impedance that alters with such value changes; the magnitude and rate of change of reactance on either side of resonance (off tune) hinges on the chosen combination.

At resonance, although the two reactances negate each other, they both still individually have their original values. Off resonance, their actual reactances matter. If each of the reactances is $400 \, \Omega$ at resonance, then $10\%$ off tune either way they are going to become $440 \, \Omega$ and $360 \, \Omega$, respectively. A $10\%$ change in this instance equates to about a $40 \, \Omega$ change either way, up or down. Now imagine that a smaller capacitor and a larger inductor were used to obtain the same resonant frequency. Their reactances will be correspondingly larger. If they’re five times larger with reactances of $2 \, \text{k}\Omega$ each, then at $10\%$ off tune their reactances will become $2.2 \, \text{k}\Omega$ and $1.8 \, \text{k}\Omega$ or $200 \, \Omega$ change each. The higher the network impedance, the more dramatic the reactance shift off tune.

On its own, the series-tuned circuit with whatever impedances are involved doesn’t amount to much; however, in relation to the outside world, it becomes rather exciting. In Fig. 25-59C the series-tuned circuit is fed via a series resistor with the output being sensed across the tuned circuit. Fig. 25-58D shows input-output curves for three different tuned-circuit impedances based on low, medium, and high reactances with the series resistor kept the same in all cases. The detune slopes are steeper with higher reactance networks than with lower ones. In other words, higher reactance networks have a sharper notch filter effect, less bandwidth, and are said to have a higher $Q$ (quality factor) than lower reactance networks. In all cases, the output sensed voltage would be the same as measured across a single reactance of the appropriate and predominant sort; there is no magic about a series-tuned circuit other than the curious subtractive behavior of the two reactances.

### 25.11.7 Bandwidth and $Q$

There are direct relationships between the network reactances, the series resistance, the bandwidth, and the $Q$. $Q$ is numerically equal to the ratio of elemental reactance to series resistance in a series-tuned circuit ($Q = X/R$); on a more practical level, the $Q$ can also be determined as the ratio of filter center frequency to bandwidth ($Q = f/BW$). Bandwidth is measured between the $3 \, \text{dB}$ down points on either side of resonance (and usually where the phase has been shifted $\pm45\degree$). If a tuned circuit has a center frequency of $1 \, \text{kHz}$ and $3 \, \text{dB}$ down points at $900 \, \text{Hz}$ and $1.1 \, \text{kHz}$ (pedantically $905 \, \text{Hz}$ and $1.105 \, \text{kHz}$), the bandwidth is $200 \, \text{Hz}$ and the network $Q$ is $5$ (frequency/bandwidth). The greater the $Q$, the smaller the bandwidth.

The filter resonant frequency may be altered by changing either the inductance or capacitance. $Q$ is subject to variation of the resistor or simultaneously juggling the reactances in the inductance-capacitance network, while maintaining the same center frequency.

### 25.11.8 Creating Inductance

It is most efficient (electrically and financially) in the majority of console-type circuitry for inductance to be simulated or generated artificially by circuits that are the practical implementation of a mathematical conjuring trick. These are known generically as gyrators.
A true gyrator is a four-terminal device that transmutes any reactance or impedance presented at one port into a mirror image form at the other port, Fig. 25-60A.

![Diagram of a true gyrator](image)

Figure 25-60. Gyrators.

A capacitor on the input (with its falling reactance versus frequency) creates inductance (with a rising reactance versus frequency) at the output port. The scale of inductive reactance generated may be easily and continuously varied by altering the internal gain-balance structure of the gyrator in Fig. 25-60B by changing the transconductance of the back-to-back amplifiers, creating a continuously variable inductor.

Real inductors have a justifiably bad name for audio design, sharing transformers’ less pretty attributes. They are big and heavy and they saturate easily. Their core hysteresis causes distortion, and they are prone to pickup of nearby electromagnetic fields (principally power line ac hum and RF unless well screened, which makes them even bigger and heavier). The windings and terminations are prone to break. And they are expensive.

It is quite easy to see why it is popular to avoid using real inductors. Naturally, the simulated inductive reactance is only as good as the quality of the capacitative reactance it is modeled upon and the loading effect of the gyrator circuit itself. Degradation of the inductance takes the general form of effective series lossy resistance, the $Q$ of the inductors suffering ($Q = X/R$). Leakage resistance across or through the image capacitor is partially to blame here. Fortunately, for the purposes of normal equalizers, very large $Q$s are neither necessary nor desirable, so selecting capacitor types to this particular end is hardly necessary.

An obvious extension of the continuously variable inductor is the continuously variable bandpass filter formed by adding a capacitor either in series or parallel with the gyrated inductor, forming series- and parallel-tuned circuits to make notch and peak filters, respectively. Although ideal for fixed-frequency filters with the $Q$ of the network or sharpness defined by a resistor in series with the gyrator resonator, the idea falls down when the resonance frequency is moved.

If the frequency is moved higher by altering either the $L$ or $C$, the reactances of the element at resonance become lower; consequently, the ratio of the reactances to the fixed-series resistor (this is the ratio that determines the $Q$) becomes smaller, and the bandwidth of the filter becomes broader in response. In order to maintain the same $Q$ over the projected frequency variation, the series resistor has to be ganged with the frequency control, which is not easy. Should it be necessary to make the $Q$ a variable parameter also, as in a parametric-type EQ section, it would mean devising quite a complex set of interactive variable controls. For this reason parametric-type EQ sections are ordinarily constructed around second-order, active-filter networks, not individual tuned circuits whether real or gyrated.

### 25.11.9 Gyrator Types

Let us not write off gyration for functionally variable filters immediately. As we’ll see, they form in one way or another the second reactance in many active filters.

True gyrators of the back-to-back transconductance amplifier variety are difficult to make, set up, and use. Fortunately, there are simpler ways of simulating variable reactances—if not pure reactances at least a predictable effect of a reactive/resistive network.

### 25.11.10 The Totem Pole

Fig. 25-61 performs the magic transformation of the single capacitor $C_1$ into a simulated inductance between the terminals. Although emulating quite a pure inductance when set up properly, it is precisely that setting up that is not altogether straightforward. In fact, it is high on a list of circuits most likely to do undesired things.
25.11.11 The Bootstrap

The simplest fake inductor is shown in Fig. 25-63A, with typical values. It relies on a technique called bootstrapping. The principles are shown in Fig. 25-62. A 1 kΩ resistor with 1 V across it will pass 1 mA. Without changing the source potential of 1 V, the bottom end of the resistor is tied to 0.8 V. There is 0.2 V across the resistor, and so a current of 0.2 mA flows through the resistor. The source (still at 1 V) sees 0.2 mA flowing away from it, the amount of current it would expect to see going to a 5 kΩ resistor value (1 V/0.2 mA = 5 kΩ). It thinks it’s looking at a 5 kΩ resistor! Continuing this, stuffing a potential of 1 V (not the same source) at the bottom end of the resistor means there is no voltage across the resistor, so there is no current flow. Our original source thinks it’s seeing an open circuit (infinite resistance) despite the fact that there is still a definite, real, physical 1 kΩ resistor hanging on it.

This phenomenon holds true with any source voltage, ac or dc, provided the instantaneous bootstrap voltage is the same as the source. Any phase or potential difference creates an instantaneous potential difference across the resistor; current flows and an apparent resistance materializes.

This fake inductor works on frequency-dependent bootstrapping, the terminal being almost totally boot-
 strapped to high impedance via the 150 Ω resistor at high frequencies and the bootstrap voltage reducing (together with its phase being shifted) with falling frequency. At very low frequencies the capacitor behaves as a virtual open circuit. No bootstrap exists, so the terminal is tied to ground via the 150 Ω resistor and the effectively zero output impedance of the voltage follower. The circuit emulates an inductor reasonably well; it has a low-impedance value at low frequencies, increasing with frequency to a relatively high impedance.
A minor failing with this simple circuit is that at high frequencies a parallel impedance (consisting of the variable resistor and capacitor chain) hangs directly from the terminal to ground. Buffering the chain from the terminal by a follower eliminates this, Fig. 25-63C.

Fig. 25-63A creates an analog of an inductor with the losses shown in Fig. 25-63B. The series resistor is the 150 Ω bootstrap resistor; after all, a proper inductive reactance tends to zero at low frequencies, not 150 Ω. The resistor is in series with the faked inductance tending to make it seem somewhat lossy or have a lower \( Q \) than a perfect inductor. If a fake inductor can be said to have winding resistance, this is it! The \( R/C \) network across the lot represents, again, the high-pass filter impedance, which on the addition of the follower disappears to be replaced in Fig. 25-63D by the much greater input impedance of the follower, which is high enough to be discounted.

As a short footnote to this gyrator epic, consider what happens to either Fig. 25-63C or F if the high-pass resistance-capacitance filter is replaced by a low-pass filter by swapping \( R \) with \( C \). It may seem a bit strange to use circuitry to imitate a capacitor, but imitating a continuously variable capacitor does make sense. Real variable capacitors of the large values needed in EQs (yet easily created by gyrators) simply don’t exist otherwise.

### 25.11.12 Constant-Amplitude Phase-Shift Network

A constant-amplitude phase-shift (CAPS) circuit of previously little real worth (other than for very short time delays) is shown in Fig. 25-63E. Bearing more than a little resemblance to a differential amplifier, this circuit can rotate the output phase through 180° with respect to the input, around the frequency primarily determined by the high-pass RC filter. Additionally the input and output amplitude relationship remains constant throughout.

How? This is dealt with in Figs. 25-63G and H where the simplistic assumptions that a capacitor is open circuit at low frequencies and a short at high frequencies show that at low frequencies the circuit operates as a straightforward unity-gain inverting amplifier (−180° phase shift), while at high frequencies it operates as a unity-gain noninverting amplifier (0° shift). The mechanism for the latter mode is interesting. The op-amp is actually operating at gain-of-two noninverting; this is compensated for by the input leg also passing through the still operating unity inverting path, which naturally subtracts to leave unity gain, noninverting.

### 25.11.13 Simulated Resonance

Detailed up to here are all the variables needed to create single- and second-order filters. Higher-order networks can be made with combinations of the two. Tracking variable capacitors and inductors allows the design of consistent \( Q \) bandpass filters irrespective of frequency. This eventually leads to a dawning of understanding in how the much-touted integrator-loop filters such as the state variable actually operate. The clue lies with the 180° phase-shift circuit of Fig. 25-63E. Connecting two such filters (with the variable resistor elements ganged) in series produces a remarkably performing circuit. At any frequency within the design swing, it is possible for the circuit output voltage to be exactly out of phase with the source (−180° phase shift). By summing input and output, direct cancellation at that frequency and at no other is achieved. In short, a variable-frequency notch filter with a consistent resonant characteristic results. Alternatively, bootstrapping the input from the output actually changes that input port into something that behaves exactly like a series-tuned circuit to ground, Fig. 25-63J. The circuit is continuously variable in frequency with a consistent \( Q \) by virtue of the simultaneously tracking simulated inductor and capacitor maintaining exactly the same elemental reactances at whatever the selected operating resonant frequency. This creates the same source resistance, same reactance, same \( Q \).

### 25.11.14 Consistent \( Q \) and Constant Bandwidth

The same \( Q \) definitely does not imply the same filter bandwidth. As the resonant frequency changes, the bandwidth changes proportionally. Bandwidth is, after all, the ratio of frequency to \( Q \). Some active filters, such as the multifeedback variety, exhibit a constant bandwidth when the resonant frequency is changed: a 10:1 variation of center frequency, a 10:1 variation of \( Q \). This, of course, is rarely useful for real EQ; it is noteworthy though in that the change in \( Q \) with frequency happens in the opposite sense to that expected from a normal variable tuned circuit. The \( Q \) sharpens with increasing frequency. It is a perfect example of a constant-bandwidth filter.

### 25.11.15 \( Q \), EQ, and Music

The near insistence on resonant-type filters being constant in \( Q \) when varied in frequency is not through an industrywide collective lack of imagination or desire to keep things tidy. It stems from psychoacoustics, from
the way humans react to audible stimuli, and also from the way nature deals with things acoustic.

If something is acoustically resonant, it will need a similar electrical resonance response shape to compensate for, extract, or imitate it in the console. Acoustics are defined by exact analogs of the first- and second-order filters and the time-domain effects that we’ve been delving into here in EQ.

Differing wall coverings have absorption coefficients paralleled very closely with shelving-type EQ curves. Apertures and partly enclosed spaces big and small act like second-order resonances identical to electrically resonant circuits. The physical size of a room determines the lowest frequency it can support just as a high-pass filter would. Initial and other major room reflections effect precisely the same changes on audio as deliberately introduced electronic delays; the frequency-dependent propagation characteristics of air are emulatable with slope filters.

25.11.16 Bandpass Filter Development

Methods of filtering come thick and fast once the basics are established. The development of a popular bandpass filter arrangement is shown in Fig. 25-64. It starts as two variable passive single-order filters of a common crossover frequency point, ganged so that they track. Reconfigured slightly, Fig. 25-64B, to minimize interaction, they are shown with their drive and sense amplifiers. Wrapping the two networks around an inverting amp isolates them completely from each other, improving the filter shape. The bandpass $Q$ is rather low, well under one, leaving it rather limited in scope for practical applications. Positive feedback from the amplifier output back to the noninverting input sharpens the $Q$.

Yes, it does look rather like a Wein Bridge oscillator. Attempting to get the $Q$ too high proves the point unquestionably!

25.11.17 Listening to $Q$

This raises the problems of excessive $Q$s. Fortunately, extremely high $Q$s (greater than ten) are unnecessary or unusable for EQ purposes. The higher the $Q$ becomes, the less actual spectral content of the signal it modifies, so despite the fact that its peak gain or attenuation is the same as a lower $Q$ filter, it seems to do subjectively less. Judicious care is required in setting up the filter to enhance or trim exactly what is required. Accidental overkill is easy.
There comes a breakpoint with increasing $Q$ where you are not so much listening to the effect of the filter as to the filter itself. Resonant-tuned circuits are essentially ac electrical storage mechanisms, where energy inside the circuit shuffles backward and forward between the two reactive elements until the circuit losses waste it away. The greater the $Q$ (and by definition the lower the included losses), the more pronounced this signal storage is.

Think of a high-$Q$ circuit as a bell, which is just an acoustic version of the same thing. If the bell gets booted either physically or by being excited by audible frequencies at its tuned pitch, it will ring until its natural decay. It’s the same with a filter. A transient will set it ringing with a decay time related to the filter $Q$. Music containing energy at the filter frequency will set it off just as well; a listener will hear the filter ringing long after the original transient or stimulus has stopped. Despite being good for a laugh, extremely high $Q$s and the resultant pings trailing off into the sunset are of no value whatsoever in a practical EQ. A transient hitting such a filter fires off a virtually identical series of decaying sine waves at the frequency of the filter.

Square waves sent through audio paths are good for kicking resonant ringing off at almost any frequency. It’s a convenient means of unearthing inadvertent response bumps, phase problems, and instabilities. The breakpoint—where filter ringing is as audible as signal—is quite low, a $Q$ of between five and ten depending on the nature of the program material.

### 25.11.18 Push or Retard?

It is not too difficult now to appreciate that resonant circuits and oscillators are very close cousins—often indistinguishable, except for maybe an odd component value here and there. There are two fundamental approaches to achieving a resonant bandpass characteristic using active-filter techniques.

The first is to start off with a tame, poorly performing, passive network and then introduce positive feedback to make it predictably (we hope) unstable. The feedback exaggerates the filter character and increases the $Q$ to the desired extent. A perfect example of this is the Wein Bridge development of Fig. 25-64. The major disadvantage of such methods is that the $Q$ is disproportionately critical with respect to the feedback adjustments, especially if tight $Q$s are attempted.

The second approach is to start off with an oscillator and then retard it until it’s tame enough. This is the basis of the state variable, the biquad, and similar related integrator-loop-type active filters.

### 25.11.19 The Two-Integrator Loop

This, for better or worse, and a variety of reasons, is by far and away the most popular filter topology used in parametric equalizers. Three inverting amplifiers connected in a loop, as shown in Fig. 25-65, seem a perfectly worthless circuit and, as such, it is. It’s there to demonstrate (assuming perfect op-amps) that it is a perfectly stable arrangement. Each stage inverts ($180^\circ$ phase shift), so the first amplifier section receives a perfectly out-of-phase (invert, revert, invert) feedback, canceling any tendency within the loop to drift or wobble. Removing $180^\circ$ phase shift would result in perfect in-phase positive feedback; the result is an oscillator of unknown frequency determined predominantly by the combined propagation times of the amplifiers.

Arranging for the $180^\circ$ to be lost only at one specific frequency results in the circuit being rendered unstable at just that one frequency. In other words, it oscillates controllably. Creating the $180^\circ$ phase loss is left to two of the inverting amps being made into integrators, Fig. 25-65B, so called because they behave as an electrical analog of the mathematical function of integration.

The integrator you may recognize from a single-order filter variation in Fig. 25-59. It’s not so much the amplitude response that’s useful here as the phase response, which at a given frequency (dictated by the $R$ and $C$ values) reaches $-90^\circ$ with respect to its input. Two successive ganged-value integrators create a $180^\circ$ shift.

Retarding the loop to stop it from oscillating can be achieved in a variety of ways:

1. Trimming the gain of the remaining inverter. This is unduly critical like the Wein Bridge for $Q$ determination.
2. Doping one of the integrator capacitors with a resistor, Fig. 25-65C. This in essence is the biquad filter (after biquadratic, its mathematical determination). The $Q$ is largely dependent on the ratio of the capacitive reactance to the parallel resistance; consequently, it varies proportionally with frequency. For fixed-frequency applications the biquad is easy, docile, and predictable.
3. Phased negative feedback. This is not true negative feedback but taken from the output of the first integrator ($90^\circ$ phase shift). It provides an easily managed $Q$ variation, is constant, and is independent of filter frequency, Fig. 25-65C. Forming the basis of the state-variable filter, this has turned out to be “the active filter most likely to succeed,” if the majority of current commercial analog console designs are to be believed.
A. Three-inverter loop (stable).

B. Introducing 180° phase shift via two integrators.

C. Introducing loss to temper the Q to usability.

D. CAPS – variable filter, Q determined as for state variable.

E. Ganged potentiometer simultaneously altering Q and input attenuator.

F. State-variable filter with single pot Q adjust.

Figure 25-65. Loop filters.
Loop filters, such as described in Fig. 25-65, have a number of inherent problems that are usually glossed over for the sake of the operational simplicity and elegance of the design.

25.11.20 Stability and Noise Characteristics

Each amplifier within the loop has a finite time delay, which together add up to significant phase shifts within the open loop bandwidths of the amplifiers. Some simply add to the delay imparted by the integrators, but the total time discontinuity around the summing amp can promote instability in the multimegahertz region. Compensation for this around the summing amplifier can introduce further phase shifts, upsetting the filter performance at high frequencies.

Two major problems are due to the nature of the integrator arrangement itself. They come to light at the extremes of the feedback capacitive reactance (i.e., at very low and very high frequencies where, respectively, the reactances are virtually open circuit and short circuit).

Open circuit at low frequencies means the op-amp is infinitely amplifying external resistor noise and internally generated thermal and (mostly) low-frequency 1/F noise, plus any low-frequency noise presented to the input along with the signal. There is a lot of generated and circulating low-frequency noise.

At high frequencies, the reactance approaches a short circuit, connecting the output back around to the inverting input. This arrangement, zero closed loop gain, is about as critical in terms of device instability as it can get. It is directly analogous to a grounded-input follower (see Section 25.7 for inherent problems), since there is no possible way of further externally defining the closed loop characteristics beyond those of the integrating capacitor itself. For typical audio frequency EQ the integration capacitor value can be quite sizable, up to 1 μF. Two further aggravations:

1. Current limiting. Is the current output capability of the op-amps sufficient to charge such a size capacitor instantaneously? If not, this will result in low maxima of signal frequency and signal level before op-amp slew-rate limitation sets in. The amplifier just might not be able to deliver enough current quickly enough.

2. Finite device output impedance. There will almost certainly be another foible related to the open loop output impedance of the op-amp; this corresponds to a resistor in series with the device output that forms a time constant and a filter with the integrator capacitor, in addition to the intended one. Another time constant means more time delay in the loop, causing a seriously degraded (maybe already critical) stability phase margin. At best it adds a zero to the integrator, reducing the integrator’s effectiveness at high frequencies.

Integrators ask a lot of device outputs; not only do they have to cope with a vicious reactive load (with which many op-amps are ill equipped to cope) but they also have to drive other circuitry, such as the next stage. A mad drive to bring circuit impedances down for noise considerations can soon outstrip even the best op-amp’s capabilities.

As tame as it may superficially seem, the state variable is not an unconditionally or reliably stable arrangement, with out-of-band dynamic problems potentially degrading its sonic performance. It is an amazement that these filters work as well as they do in many commercial designs.

With the exception of inevitable loop effects (usually time related), most of the undesirable things about the state variable can be eliminated or mitigated by replacing the integrators with constant amplitude, phase-shift elements, Fig. 25-65D. This results in what could best be known as a CAPS-variable filter. Here, all the constituent elements are basically stable, and there are provisions for independent device compensation. There is no undefined gain for any of the spectrum. This seems to be a far healthier format to start making filters around.

There is another way of looking at the state variable/CAPS-variable filters that will suddenly resolve the previous discussions on gyrators, L and C filters, series-tuned circuits, and so on with the seemingly at-odds approach of active filters.

Resonance depends on the reaction of the two reactances of opposite sense, 180° apart in phase effect. Rather than achieve this in a differential manner, one element +90° with the other −90° at a given frequency, these active filters achieve the total difference by summing same-sense phase shifts (−90° + 90°)−i.e., still 180° apart. Two reactive networks are still involved; it is still a second-order effect. At the end of the day, the principal difference is that such loop-type active filters have their median resonance phase displaced by 90° from their input as a result of both reactive effects being in the same sense, as opposed to the nil phase shift at resonance of a real LC network.
25.11.21 Q and Filter Gain

Pretty much every resonant-type active filter has the characteristic of its gain at resonance being at least related and often directly proportional numerically to the Q of the filter. This means a filter with a Q of 10 usually has a voltage gain of 10 (20 dB) at resonance. Naturally, this does not make the building of practical equalizers any easier. Nothing much does. Even specifying a maximum Q of 5 (14 dB gain) only helps by losing 6 dB of boost with respect to a Q of 10.

That represents a very sizable chunk of system head room stolen at the filter frequency, which also makes the sum-and-difference matrixing necessary to provide the usual boost-and-cut facilities difficult to configure. The obvious solution is to attenuate the signal going into the filter by the same amount as the gain and Q expected of the filter. Arranging a continuously variable Q control that also attenuates the signal source appropriately is not a conspicuously simple task, at least with most filters. Perhaps the most straightforward example is shown in Fig. 25-65C, a state-variable-type filter with an attenuator in the retard network altering the Q ganged with an attenuator ahead of the input/summing amplifier. Within reasonable limits this holds the resonant peak output constant over a considerably useful range. A much neater and more commonly applied solution is shown in Fig. 25-65F: a single potentiometer at the noninverting input of the summing amp that would serve both purposes—filter Q and input level—complementarily and simply.

Most other filters are not so obliging in terms of continuously variable Q. Switching between a few values of Q while substituting appropriate input attenuation is quite often a practical and operationally acceptable solution, applicable to nearly any filtering technique. Fig. 25-64E illustrates a further development of the Wein Bridge arrangement using this method to provide three alternative Qs. The attenuator values are necessarily high in impedance to prevent excessive loading of the source, a factor that in some practical EQ circumstances can be important.

25.11.22 High-Pass Filters

Two basic single-order high-pass filters are shown in Fig. 25-66. The keys, for the purposes of high-pass filtering, are the reduction of inductive reactance to ground with reducing frequency in Fig. 25-66F and the increasing of capacitative reactance with reducing frequency in Fig. 25-66G.

How about combining the two and omitting the resistors as in Fig. 25-66A? As expected, the combining of the two opposing reactances causes an ultimate roll-off twice as fast as for the single orders; however, they have also resulted in a resonance peak at the point of equal reactance. Resonance Q is the ratio of elemental reactance to resistance; deliberately introducing loss in the circuit in the form of a termination resistor tames the resonance to leave a nice, flat, in-band response, Fig. 25-66B.

Substituting a basic gyrator or simulated inductance for the real one, Fig. 25-66C naturally works just as well and even better than expected. The filter output can be taken straight from the gyrator amplifier output, eliminating the need to use another amplifier as an output buffer. Further, we can automatically introduce the required amount of loss into the inductor by increasing the value of the bootstrap resistor and get the resonance damping right. (Refer to the discussion of gyrators in Section 25.11.9.)

Further yet, we can easily change the turnover frequency of the filter by varying what was the tuning resistor. In doing this, of course, the elemental reactance-to-loss ratio will change, causing damping factor (and so the Q) to change with it. The frequency change and required damping change are directly related and in the same sense and may be simultaneously altered with a ganged control—even, if we do our sums right, with the two ganged tracks having the same value!

A slight redraw of Fig. 25-66C gives Fig. 25-66D, a more conventional portrayal of the classic Sallen-Key high-pass filter arrangement. As the Sallen-Key filter evolves, it turns out that an equal value filter (where the two capacitors are equal and the two resistors are equal) results in a less than adequate response shape. An expedient method of tailoring and smartening up response to become Butterworth-like (working on the assumption that a couple more resistors are cheaper than a special two-value ganged potentiometer) is to alter the damping by introducing gain into the gyrator buffer amplifier (providing also a healthier mode of operation for the amplifier—followers are bad news), see Fig. 25-66E. A side effect of this technique of damping adjustment (which, incidentally, is independent of filter frequency) is that an input-output in-band gain is introduced. The 4 dB gain introduced necessary to render the filter frequency response maximally flat could be included in overall system gain, or alternatively a compensating attenuator could be instituted ahead of it. This could as well be arranged to be a fixed-frequency, band-end, single-order, high-pass filter to accelerate the roll-off slope out of band; a further alternative is to make the
filter input out of two capacitors such that the input signal is attenuated by the needed amount yet the combined capacitance value is the correct value for the filter—this can be a bit of a nightmare to drive adequately, though. For many applications the free 4 dB or so isn’t a problem—it can simply be assimilated as part of the system-level architecture.

The 4 dB thing can be a nuisance. Where it is, or in particular where an inverting filter stage is either convenient or necessary, the multifeedback configuration works well; indeed, lacking the problems of a near-follower as in the case of the Sallen-Key it uses the op-amp well. At high values of $Q$ or extremes of frequency, some component values can get far from the ordinary midimpedance values seen elsewhere in the EQs and filters described here, and one should be aware of possible noise or op-amp current-drive limitation issues as a consequence. Unlike the Sallen-Key described, it is not readily possible to continuously vary the turnover frequency, and it uses three capacitors as frequency-determining components rather than two. Otherwise, for fixed frequency filters this is a very friendly topology.

### 25.11.23 Second or Third or More Order?

Without delving too deeply into psychoacoustics, the ear notices easily third or more order filters being introduced for much the same reasons as a high-$Q$ bandpass filter is obvious. There are severe modifications to the transient response of the signal path and ringing-type time-related components are introduced into the signal spectrum.

An application where this effect is not overly objectionable is where the filters are defining bandwidth at high and low audible extremes. Within the audible band though, the ear is quite merciless toward such artifacts. The transient response modification and time-domain effects are not the end of the story; the relationships between instrument fundamentals and their harmonics in the turnover area of the filter are likely to be interpreted as unnatural, especially should the fundamental be attenuated with respect to the harmonics.
Second-order filters, assuming moderate filter $Q$s associated with Bessel or Butterworth characteristics, score well in both respects. There is less transient response disturbance and less tonal characteristic modification. There are few who would dispute that they sound more natural and musical than tighter filters. A small wrinkle is to leave a small controlled amount of underdamped bump in the filter frequency response. This has two consequences: one is the slightly more rapid out-of-band roll-off, but the other, a subjective effect, is that the extra program energy introduced by the hump serves to help offset the loss of energy below the turnover frequency. The perceived effect on introducing the filter is more of a slight change in sound rather than a direct drop in low-frequency response and strikes a better subjective compromise than techno-striving for the ultimately flat, perfectly measuring filter.

25.11.24 Equalization Control

Achieving bare response shapes of whatever nature—high-pass, low-pass, bell-shaped bandpass, or notch—does not really constitute a usable EQ system. The shape, even if variable in frequency and bandwidth, is either there or not, in or out, no subtleties or shades; some means of achieving control over the strength of effect is vital to the cause. By far the most common (but certainly not the only) control requirement and one easily understood by operators is lift and cut, where the frequency areas relevant to the various filters are required to be boosted or attenuated by any variable amount within given limits. Determining these limits alone is good for an argument or two, dependent on such disparate considerations as system head room, operator maturity, and, obviously, application. An EQ created specifically for wild effects is not a stable device. An adjustment of 20dB is not unknown (and not, unfortunately, unheard); a 6 dB adjustment, in contrast, is often far more than enough particularly for spoken voice. A general median accepted by most manufacturers is to provide between ±12 and ±15 dB level adjustment on channel-type EQs.

25.11.25 The Baxandall

Hi-fi-type tone controls needed similar basic operational high-frequency and low-frequency boost-and-cut facilities, and a design for this dating from the 1950s by Peter Baxandall has since been an industry standard in assorted and updated forms. A development of the Baxandall idea is represented in Fig. 25-67 based

![Development of Baxandall-style equalizer.](image-url)
Consoles

around today’s more familiar op-amp technology rather than discrete transistors or tubes. Fig. 25-67A shows a virtual-earth-type inverting amplifier with the gain (being equal to the ratio of the feedback resistor RF to the series resistor RS) continuously variable from near-infinite loss (min) to near-infinite gain (max) with unity in the middle. If a fixed-gain-determining leg is introduced and the variable leg is made frequency conscious, as shown in Fig. 25-67B (in this instance by crude single-order high-pass filters—the series capacitors), the gain swing only occurs within the passband of those filters. The through gain for the rest of the spectrum is determined by the two fixed resistors. If this fixed chain is replaced by a second frequency-conscious network that does not significantly overlap the original one in bandwidth, the two chains independently modify their frequency areas, Fig. 25-67C. The fixed chain is only necessary where the gain is otherwise unpredictably defined by a frequency-conscious network.

The belt-and-braces low-pass arrangement (for low-frequency boost and cut) of Fig. 25-67C can be rationalized into the more elegant circuit of Fig. 25-67D. This circuit more closely resembles the definitive Baxandall circuit. Rather than isolating the low-frequency boost-and-cut chain with increasing inductive reactance, the control is buffered away with relatively small resistances and bypassed to high frequencies by capacitance. The control takes progressively greater effect at lower frequencies as the rising capacititative reactance reduces the effective bypass. A further refinement is a pair of stopper resistors, small in value, that define the maximum boost and cut of the entire network.

Naturally, a more complex EQ can be configured around the same arrangement. A midfrequency bell curve is easily introduced by any of the means in Fig. 25-68, giving a good hint on how to avoid using a real tuned circuit using inductors.

A variable signal either positive or negative in phase to the source $V_{in}$ can be picked off from a pot straight across the existing high-frequency and low-frequency chains, taken to an active filter arrangement to derive the needed amplitude response shape. The signal is then returned to the loop at either the virtual-earth point (to which the high-frequency and low-frequency chains are tied) or to the noninverting reference input, Fig. 25-68D, depending on whether the absolute phase of the filter is positive or negative. Industry favorites seem to be this approach using either a Wein Bridge bandpass or a state-variable integrator-loop type.

Any number of such active chains may be introduced, provided two great hangups don’t intrude excessively:

---

**Figure 25-68.** Resonant frequency selective elements in the Baxandall equalizer.
• Hangup 1 is the interaction between frequency groups. Hanging on two control chains that operate at the same frequency either adjustably or through overlap can at best be deceiving or at worst self-defeating. In the Baxandall (as with most other arrangements), if maximum gain (say, 15 dB) is attained at a given frequency by one control, a second similarly tuned chain, cranked for maximum, will not give the expected additional 15 dB gain. The overall loop is already operating close to the maximum gain defined by the stopper resistors. A notable measured result is for the maximum boost-and-cut capability of a sweep-mid bell curve to be restricted at the extent of its range where it overlaps across the shelving high-frequency and low-frequency curves.

A rough rule born from hard experience of squeezing the most EQ from the least electronics is to not allow overlap incursion beyond the point where either curve has ±6 dB EQ effect individually. Overlapping is best achieved from the comfort of another EQ stage, although that too invokes other compromises.

• Hangup 2 is noise. The basic Baxandall, using purely passive frequency-determining components, is a fairly quiet arrangement. With controls at flat, it is theoretically only 6 dB noisier than the unity-gain noise of the amplifier plus additional thermal noise due to network resistances—all in the −100 dBu region. The noise character varies with the controls, as would be expected of an amplifier whose gain is directly manipulated at the frequencies in question—high-frequency boost, more high-frequency noise, and so on.

As soon as active filtering is involved, more noise is unavoidably introduced, often highly colored and consequently much more noticeable. What is worse is that it’s present all the time irrespective of control positions. Even with its appropriate control at neutral center, it is quite usual to hear a midsweep swoosh in the noise changing with filter frequency. This is, along with the strange spectral character of the noise emerging from some filters, notably, the integrator-loop variety, a result of unoptimized impedances and dubious stability almost inherent to their design.

25.11.26 Swinging Output Control

The source impedance versus feedback impedance ratiometric approach of the Baxandall is not the only way of achieving symmetrical boost-and-cut, as stunning as its simplicity and elegance may be. A method of enclosing the controls within the feedback leg of a noninverting amplifier is developed in Fig. 25-69. This has the advantage of leaving the noninverting input of the op-amp free, obviating the need for a preceding low-impedance source or buffer amplifier. Roundabout to this swing is the necessity of a buffer amplifier or quite high destination load impedance since the output is variable in impedance and included within the feedback loop of the op-amp. Serious control law modification, potential phase margin erosion with consequent instability, and certain head room loss are among the penalties for careless termination.

Unity gain in Fig. 25-69A is achieved when the attenuation in the feedback chain equals the output attenuation; the feedback attenuator causes the op-amp to have as much voltage gain as the output attenuator losses. Replacing the two bottom legs of the attenuators with a swinging potentiometer, Fig. 25-69B, provides a boost-and-cut facility; when the pot is swung toward min, the feedback leg is effectively lengthened to ground, and the amplifier gain is reduced somewhat. Meanwhile, the output attenuator is shortened considerably, reducing the output accordingly. At max the reverse occurs. The feedback leg is shortened, increasing the loop gain of the op-amp while the output attenuator is lengthened, losing less of the available output. A small stopper resistor defines the overall gain swing about unity, which would otherwise range from zero to earsplitting, respectively.

Introducing reactances and complex impedances into the potentiometer ground leg (or legs as in Fig. 25-69C) results again in boost-and-cut control over the frequency bands in which the reactances are lowest, i.e., high frequency for capacitors, low frequency for inductors (real or fake), and so on. This arrangement, which is in a few professional systems and in some Japanese hi-fi, has only one major drawback other than the previously mentioned output-loading considerations. In order to achieve reasonable control dB-per-rotation linearity, the two attenuators (feedback and output) need to be of about 3 dB loss each with the control at center. This implies that the obtainable output voltage is 3 dB below the output swing capability of the op-amp, landing a head room deficit of that amount in the equalizer stage—probably where it is most needed.

25.11.27 Swinging Input Control

Avoiding the head room headache but utilizing a rather similar technique, the swinging-inputs gain block of Fig. 25-70 is very promising. Here, the feedback attenuator remains unchanged, but the output attenuator is
shifted around to the noninverting input of the op-amp. At minimum, the input attenuation is quite vicious while the feedback leg is long, making the op-amp deliver only a small amount of gain. When the attenuation characteristics are reversed for maximum, the op-amp works at a high loop gain, while the input is only slightly attenuated. Unity is achieved at control center where the input attenuation equals the make-up gain of the amplifier.

There is a fascinating tradeoff between noise mechanisms in this circuit arrangement. Assuming a maximum of three controls (for fairly basic high-frequency, low-frequency, and midsweep curves) before interaction becomes a major hassle, the amplifier can have between 10 dB and 20 dB of fairly frequency-conscious background gain (i.e., with all controls flat) rendering it at first sight significantly noisier than a Baxandall. However, the impedances around the amplifier are around a decade lower. This considerably reduces thermal noise generation due to resistive elements and op-amp internal mechanisms.

In addition, the noise generated by the active frequency-determining filters is, with the controls neutral, injected equally into the inverting and noninverting inputs of the op-amp. Differential amplifiers being what they are, common-mode signals (such as this equally injected filter noise) get canceled out and do not appear at the output.

Interaction can still intrude, and care is required to prevent excessive frequency band overlap. Center-tapped pots (the tap grounded) eliminate many interactive effects but at the cost of increased invariable background gain (noise) and peculiar, almost intractable, boost-and-cut gain variation linearity versus control rotation.
A three-section parametric EQ with additional versatile shelving-type high- and low-frequency controls is detailed in Fig. 25-71. It is designed to be easily shortened to high-frequency, low-frequency, plus a single midband parametric section, for applications that don’t demand the full complement of facilities. Each individual section is switchable in or out to allow preset controls. Simple in-and-out comparisons with tie-down resistors maintain the dc conditions of the unused filters to minimize switch clicks. Even a brief look at the circuit reveals a major benefit. The signal path through the EQ is merely via three op-amps, IC2 is an input differential amplifier, and IC3 does duty as the output line amp. In the shortened version this path is reduced to only two op-amps, IC1 and IC3, which serve also as a swinging-input EQ gain block. IC2 and its associated circuitry are unused in this simplified version.

The unusual components around the differential input stage provide unity differential in unbalanced out levels while providing an identical impedance (with respect to ground) on each of the two input legs. Naturally, the more precise the component values, the better the common-mode rejection is likely to be.

IC2 in Fig. 25-71 is the first swinging-input stage. It has two nonfrequency overlapping filters hanging off it, one section covering 25 Hz to 500 Hz, the other covering 1 Hz to 20 kHz. Each filter network creates a complex impedance form against frequency that looks like a series \( LC \)-tuned circuit to ground. This fake-tuned circuit (formed from two constant-amplitude phase-shift networks in a loop, named the CAPS-variable filter) reach parameters ordinary filters cannot reach.

The center frequency is continuously and smoothly variable over its range using reverse-log potentiometers; \( Q \) remaining consistent over the entire swing. The \( Q \) itself is continuously variable between 0.75 and 5 (very broad to fairly sharp, representing bandwidths of 1.5 to 0.2 octaves, respectively). Positive feedback inside the loop, which defines the \( Q \), is balanced against negative feedback, which controls minimum filter impedance and, correspondingly, amplitude. Interestingly enough, this circuit relies on the input impedance of the swinging-input stage as part of the negative feedback attenuator. Fortunately, this impedance is reasonably constant irrespective of boost-and-cut control positioning.

In the absence of complementary square-law/reverse square-law dual-gang potentiometers ideally required for the purpose, readily available log/antilog dual-gang pots, retarded a bit to a reasonable approximation, control the positive/negative feedback balance. As a result of this compromise, the filter crest amplitude (maximum effect) varies within \( \pm 1 \) dB as the \( Q \) control is swept; in comparison to the dramatic sonic difference from such a \( Q \) variation, this tends to insignificance. The result of all this, at the output of IC2, is a pair of resonant-type curves of continuously variable place, height, depth, and width.

A reasonably hefty pair of transistors is hung on the end of IC3 to provide a respectable line-drive capability, in addition to the use of the amplifier as a swinging-input EQ section. There is enough open-loop gain in the combination of the op-amp and transistors (over a much greater bandwidth than mere audio) to cope with 15 dB of EQ boost and output-stage nonlinearities.

Differing from the last EQ stage, this one only has a single midfrequency bell-curve creator, operating over a range of 300 Hz to 3 kHz, together with high- and low-frequency range impedance generators.

Gyrating inductance to create a conventional low-frequency shelving response (variable in turnover frequency by a 220 kΩ antilog pot) is achieved around IC11. A fairly large (2.2 \( \mu F \)) series capacitor forming a resonance is switchable in and out. The value of the capacitor is carefully calculated to work with the circuit impedances to provide an extreme low-frequency response that falls back to unity gain below the resultant resonant frequency without compromising the higher frequency edge of the curve. The \( Q \) of this arrangement reduces proportionally to increasing frequency. Typical resultant response curves, Fig. 25-72, show just what all this means, demonstrating an extraordinarily useful bottom-end control.

Unusual is one way to describe the high-frequency impedance generator and its EQ effect. It is essentially a supercapacitor, or capacitative capacitor. In other words, it’s a circuit that, when in conjunction with a resistor, causes a second-order response as would normally be
expected of an inductor and capacitor combination—a slope of 12 dB/octave as opposed to a single-order effect of 6 dB/octave. Fig. 25-73 shows what it does as an EQ element.

The response is hinged about 1 kHz. The control varies the frequency (between 5 kHz and 20 kHz) at which the gain reaches maximum (or minimum if the boost-and-cut control is cut). The slope between 1 kHz and the chosen maximum frequency is virtually a straight line representing a nearly constant dB/octave characteristic, with a nearly flat-top shelving characteristic.

In electronic terms, this is achieved by progressively degenerating the super capacitor until it’s no longer super—i.e., it eventually ends up looking like a simple, single capacitor.

25.12 Dynamics

Dynamics processing is becoming as common in today’s signal paths as equalization. Many commercial mixing consoles carry dynamics as standard on a per-channel basis. Formerly, the occasional necessity of hanging in external dynamics processing was the major justification for channel insert (or patch) points. These patch points were typically either before or after (pre- or post-) equalizer in the signal chain as shown in Fig. 25-74.

Preequalization actually amounts to postinput stage; the purpose of an insert point here is to control unruly input signals that may otherwise clip later in the chain—in particular within the EQ section where serious amounts of gain at some frequencies may be instituted. Characteristically this pick-off point is after any high-pass filtering, so that any low frequency rumble that may cause false triggering within the dynamics may be removed. On the other hand, the post-EQ insert point allows control over the entire channel immediately prior to the channel fader and is commonly used for automatic gain controlling.

Dynamics is automatic control of signal level by an amount determined by the characteristics of the signal itself. In a linear 1:1 circuit, what goes in comes out untouched and unhindered. For example, if we have a circuit that automatically senses the input signal and uses that measurement to control the output signal, if the input signal rises in level by 6 dB, the output signal is controlled to rise only 3 dB. The output signal has been compressed by a ratio of 2:1 with respect to the input signal.

There are four basic types of dynamic signal processing:

1. Limiting.
2. Gating.
3. Compression.
4. Expansion.

It is arguable that limiting is a special case of compression and that gating is similarly a special case of expansion, effectively reducing the number of basic groups to two. Although in practice the means of achieving these pairs of effects are indeed similar, true definitive compression is a long way from limiting, as gating is from expansion. The discussion about time constants etc. within the following Limiting section is directly applicable to each of the other sorts of dynamics.

Fig. 25-75 shows a now customary style of input-output signal level plot of a compound (more than one dynamics type active) dynamics section, with typical slopes for each of limiting, compression, and expansion. (Measured plots of actual dynamics sections can be seen also in the discussion of digital dynamics later.) This style of dynamics display is common on programmable consoles; here it can be a handy form of visualization or representation as the various types are discussed. Linear (i.e., no processing) is represented by the dotted line, showing equal output for input. Unusually (!) a section of linear remains in this compound curve, displaced upward by 15 dB; this is a normal occurrence when automatic gain reduction such as compression and/or limiting is used. In order to make up for the gain reduction above the threshold, some gain is applied to compensate and bring the output signal back up to usable levels. This is often called makeup, or buildout gain.

25.12.1 Limiting

This is the conceptually easiest and most commonly applied form of dynamics processing. Nearly any audio heard outside of a recording studio has been passed through a limiter at some point in the chain—TV audio, radio, even (and especially) CDs. This very pervasiveness has had the rather odd unforeseen effect that culturally we have gone beyond acceptance and become dependent on the sound of excessive limiting and heavy compression; even to educated ears a new CD can sound wrong or wimpy in comparison to what had been heard on the radio, where typically murderous additional processing is applied. Record shops actually do get complaints like that. The race to be louder than loud has unfortunately spilled over into the record production arena back from radio where it had previously raged.
Figure 25-71. Five-band equalizer circuit diagram.
Figure 25-71. Five-band equalizer circuit diagram. Continued.
alone sparked by the AM radio loudness wars of the '60s and '70s; the deleterious effect will have future musical historians scratching their heads.

Every recording and transmission medium has definite head room limitations, a maximum level beyond which the signal just plain overloads, distorts, or becomes a serious liability. AM radio overmodulation not only sounds horrid but causes interfering splatter up and down the dial, FM transmitter overdeviation causes adjacent channel interference and runs the risk of distortion in receiver discriminators; disk cutters can produce grooves that run into each other (long after they become unplayable by any normal pickup), PA loudspeakers fry, tape saturates, distorts, and screams, and best of all anything digital just plain runs out of bits and cracks up. The answer? A device that senses when enough is nearly enough and automatically reduces the source level such that a proscribed output level is not transgressed. This is a limiter.

Fig. 25-76A shows the all-time basic limiter—a pair of back-to-back diodes. These clamp the input signal from the source resistor to within their nonconductive range; beyond 700 mV of either polarity one or other of the diodes conducts, sawing off any excessive signal. Brutal, but effective. The downside is gross distortion—serious waveform modification is going on, profuse audible distortion products are generated. Fig. 25-76B shows the same idea with germanium diodes. These tend to have a lower turn-on voltage (200–300 mV) but a gentler knee, with the effect shown. This sounds considerably less harsh—fewer high-order distortion products are being created. In situations where ultimate signal quality is not necessary, but increased signal density (translated: loud) is required, these clipping circuits work like a charm; communication circuits often use this technique to saw the top 10 dB or so peaks off speech and thus gain a nearly corresponding degree of increased apparent loudness. The trick is to filter away or contain and control the resulting distortion products such that they become less agonizing, while retaining the high signal density clipping affords. Such is meat for a whole other saga.

The ideal circuit is one that knows its input is going over the top and can reduce its gain such that the signal is left relatively undistorted but as loud as it can be within the given constraints. Fig. 25-76C is a block diagram of such a device. The side chain circuit is a tripwire in this instance; if the amplifier output exceeds a stipulated level (just below what the destination can handle) the side chain develops a control signal that

Figure 25-72. Frequency response of the low-frequency section of Fig. 25-71 (control at maximum gain).

Figure 25-73. Characteristics of the high-frequency section of Fig. 25-71 (boost-cut control at maximum boost).

Figure 25-74. Typical insert points for dynamic processing.
tells the input attenuator to drop the input signal sufficiently. The whole circuit operates in check—the bigger the input signal, the bigger the potential overload, the bigger the control signal, the more the attenuation. Below the tripwire—the threshold—the whole circuit behaves the same as an ordinary straight amplifier. Fig. 25-76D is about as simple as a decently performing limiter can get and was first noted in the original mid-sixties Philips cassette recorder.

**Figure 25-75. Dynamics Input/Output Plot**

The LM386 is a small power op-amp commonly used to drive headphones or small loudspeakers but works well just as an ordinary amplifier, in this case at some 30 dB gain. It is used here for its power output stage, which is hefty enough it can ignore the diode rectifier and side chain loading effects. This diode conducts when the positive-going output signal exceeds about 700 mV and charges a reservoir capacitor, \(C_r\). This is buffered by an emitter follower (\(TR_f\)) feeding the gain controlling transistor \(TR_g\). When the voltage on the base of \(TR_f\) is sufficient to force conduction through the two base-emitter junctions, \(TR_g\) turns on, causing an increasingly low-impedance path to ground at the input to the amplifier. It forms a potentiometer, with the source resistor \(R_s\) attenuating the input signal to the level at which the rectifier and two transistors are just conducting. In this circuit that amounts to a positive-going output signal of about 2 V (the added voltage drops of the rectifier and the two transistor base-emitter junctions). Simplicity has its drawbacks and in this instance they are noise and distortion. Although the distortion is in a different league from a diode clipper, transistors are not ideal VCAs and are somewhat nonlinear in this application. If, however, the signal

**Figure 25-76. Simple limiters.**
across them is kept low (in this instance, −30 dBu, the lower the better) it can be quite acceptable for a lot of applications. Keeping the signal low necessitates following gain to bring the signal back up again. That means amplifier noise.

There is a wide variety of possible voltage-control elements and Fig. 25-76E shows a smoother version of the transistor limiter using a JFET. The principle is much the same, only the side chain and VCA circuitry has developed somewhat. FETs have such spread characteristics that a preset is necessary to set their bias points. In normal operation the FET needs to be biased just nonconducting; that is, nonattenuating. This necessary adjustment also provides a means of varying the output level at which the limiter starts to bite, and incidentally some control over the ratio of the gain reduction. (The greater the bias, the more control voltage signal is needed to be generated before the FET turns on and starts attenuating, where it does so in a tightly controlled manner. A low bias results in a lower, or indeed no, threshold and a far gentler gain-control ratio. Carefully trading these two—a high threshold for a hard ratio or low and “smushy” threshold and gentle FET turn-on—against overall gain formed the basis of FET-based compressors such as the famed Audio and Design F760 and the UREI 1176LN.)

FETs have very high gate impedances, precluding the need for a follower. The control voltage is summed at the device gate with a sample of the input signal. Automodulation is an effect of FETs where the source-drain resistance (the resistance we’re depending on as part of the input attenuator) varies with signal voltage across it. This is attacked in two ways: first by keeping the signal across the FET low, as in the transistor limiter, and second by supplying the gate with some anti-wobble signal that does a fairly good job of forcing the source-drain path to wobble against and largely cancel the automodulation effect.

But why have time constants at all? If the idea is to provide protection for overloads, why bother with how they’re handled? Well that’s all diode clippers do, Figs. 25-76A and B. They have zero attack time, which means there is no delay or run-up to them when dealing with an overload. Similarly, they have a zero release time, meaning that once the overload is dealt with it’s instantly business as usual. The trouble is, they sound horrible, as would either the transistor or the FET limiter with infinitely short parameters.

25.12.1.1 Side-chain Time Constants

Between the rectifier and the FET in Fig. 25-76E is a simple resistor-capacitor network that determines how the side chain works and its effect on the automatic gain reduction. This is in contrast to the transistor circuit where the reservoir capacitor discharges through the transistors at one end and is charged rapidly through the diode from the other. Here we can adjust the rate at which the capacitor charges and at which it discharges. The implications of these on how the circuit behaves and sounds are crucial.

25.12.1.2 Attack Time

Fig. 25-77 shows the first few cycles of a train of sine waves that are in excess of the limiter threshold and the effect as the limiter tries to reduce the output to the prescribed level. Fig. 25-77A shows a zero attack time and not unexpectedly looks very sawn off. Lengthening the attack time somewhat, Fig. 25-77B, leaves a recognizable but mutilated crest, while longer still is even less bent, Fig. 25-77C. Unfortunately, the character of distortion products generated by this effect are very audible; they are loud (since it is a loud signal that is subject to control) and of high order and unlikely to be masked by the fundamental signal. Even at this stage it is clear that a longer attack time takes less toll of the input signal integrity; the less a waveform is modified, the better it will sound. Expanding the time scale to many cycles shows how lengthening attack time looks.

A long attack time, Fig. 25-77F, gradually reduces the limiter gain until the signal is completely under control while imposing less immediate distortion on it.

The tradeoff is apparent. An attack time long enough to not mangle the program material also permits excess output level for as long as the circuit takes to bring the gain down sufficiently. Balancing this overshoot against leading-edge distortion due to short attack times is a subjective compromise.

Naturally the lower the frequency, the longer the time period between cycle crests and the greater distorting effect of attack times. An adequate attack-time for high frequencies can easily be still way too short for low frequencies, while an adequate attack time for bass is unnecessarily long for highs. That’s life.

It is normal in a high-quality studio dynamics section to use a full-wave rectifier for the side chain (as opposed to the half-wave shown in these two examples). This gives twice as many opportunities per cycle to sense and adjust the gain (one on the positive-going peak, one on the negative) in addition to allowing for the fact that few real-world signals are symmetrical;
either the positive or negative peaks are more, sometimes greatly, pronounced.

Attack times are measured and quoted either in microseconds or milliseconds (i.e., the time constant of the reservoir capacitor versus charging resistor, which also corresponds approximately to the time a transient takes to be controlled) or alternatively in dB/ms which is the rate at which the attenuation changes.

25.12.1.3 Release Time

The purpose of a release time constant is manifold, but in the case of a peak limiter its value is primarily to minimize distortion, much as the attack time. If the incoming sine wave train is above the threshold and the limiter is trying to contain it, and if the release time is short, the gain will tend to recover between each individual crest of the sine wave. In effect, this is the reverse of the attack-time distortion. Although there is the brutality of a fresh set of attack-time-related distortion on each crest, it must not be forgotten that as the attenuation releases there is a less traumatic but nevertheless real change in shape of the rest of the waveform as its amplitude changes within a cycle.

Release times are normally maintained much longer than attack times. With the exception of true transients, which spike up once and then go away for an indeterminate period of time, if not forever, most sounds tend to stay around for a while—at least for a few cycles. It can be reasonably assumed that, once a signal has hit threshold, more of it will follow; given that, there is little point in letting the attenuation drop back just to be reasserted milliseconds later. The release time is a crude memory of the size of the signal the section is having to deal with at a given moment and by keeping the amount of attenuation relatively stable gives less work to and less damage to wreak for the attacking charge ramp-up. A longer release time constant gives the attack circuitry less to do except at the onset of material over the threshold.

There is always the danger with long release times (if chosen to minimize distortion) in that should a large transient come along, the limiter will do its job and promptly reduce the gain to prevent excess output level. Fine, but the long release time keeps the attenuation invoked sitting around for a long time, compressing following program material and a large amount of following information can be lost until the gain claws its way back up to normal level, Fig. 25-78.

The subjective compromise between long release times (for distortion’s sake) and rapid recovery depends largely on the program material. More so with release than with attack; too short a release time can really tear up bass frequencies. Distortions due to attack and release time constants—transient, intermodulation, and harmonic—owe themselves to the fact that gain is

Figure 25-77. Attack time effect on waveshape.

E. Effect of medium attack time.
F. Effect of long attack time.
changing and rapidly. They are independent of the kind of device doing the attenuation, whether it is a humble transistor or an expensive VCA and they are just as obnoxious. By and large these dynamically induced distortions subjectively far outweigh the steady-state distortion characteristics of the devices. These only become important if the circuit is to sit in a signal path with little or no dynamics processing taking place. Once things start moving one is as good or bad as the other and the subjective quality of a unit is determined by how well the various timings tailor around the program material or how well it does so automatically.

Release settings are generally quoted in milliseconds or seconds, and sometimes as a decay rate such as dB/ms or dB/s. In short, a dynamics processor lives or dies by its side chain.

25.12.1.4 Compound Release Time Constants

The hole-punching problem of a big transient hitting a limiter with a long release time constant can be attacked in a couple of ways. If subtlety is none too great a criterion—for instance, in an AM transmitter limiter where There Shall Be No Overmodulation—it is always possible to put a variation of the back-to-back diode limiter on the output of a timed one, Fig. 25-79A. Set to clip immediately above the normal operating output level of the feedback limiter, it not only cast-iron stops excessive output signal swing but also prevents the transient from entering the side chain and digging too big a hole in the following audio.

The circuit in Fig. 25-79C is used extensively. Instead of a single reservoir capacitor in the side chain with one attack defining resistor and one release defining resistor, Fig. 25-79B, a compound circuit can be arranged, Fig. 25-79C. A small value resistor and capacitor form additional, shorter attack and release time constants working in conjunction with a slower set. The extended attack and release times follow the general loudness envelope of the program material while the shorter ones, riding on the top take care of any short-term discrepancies and transients, generally to the tune of the top 5 dB or so of processing. If a general-purpose, hands-off, no-tweaks limiter is needed, this arrangement with carefully chosen values can work very nicely and is the basis of some commercial outboard limiters in the auto mode.

25.12.1.5 Multiband Processing

A complex but very effective side step to the inapt time constant with frequency problem is shown diagrammatically in Fig. 25-80. Here the input signal is split a number of ways by frequency (in this case three, into bass, mids, and highs). Each band passes into a limiter
with side chain time constants optimized for that band of frequencies; this allows the highs to be optimally treated with short time constants without compromising the other sections, and so on. The bands are recombined and passed through an envelope limiter, which only needs to catch a limited dynamic range and so has little effect on the path and the overall sound. Two bands is enough to remove the pumping effect of the usually energy-intensive bass-modulating higher frequencies; three bands allow for better time-constants for the all-important mid range to be established without compromising the high and low frequencies; more bands, say five or six, allow considerable program density (translation: loudness) to be built up while retaining musicality.

This is a very common technique in radio broadcasting airchain processing, and allows for better or worse far deeper processing than possible with broadband units and totally avoids side chain pumping effects, where typically heavy bass modulates the mids and highs content. It is usual for there to be a number of multiband stages, preceded by broadband AGC and succeeded by broadband limiting/clipping. The first multiband section (five bands is common) being compression and perhaps multiband AGC, feeds a second section of multiband limiting (31 bands of limiting is not unknown!). Needless to say, such devices can be quite an entertainment to set up; indeed, a whole subindustry of processor witchcraft has evolved in radio.

Adjusted well, these units can sound startlingly good (and loud). In corollary, they are far easier to make sound truly dire. Unfortunately, the multiband technique, either using discrete units such as air-chain processors or virtually as software plug-ins to audio workstations and digital consoles, has found its way into music production. The results have rarely been beneficial.

25.12.1.6 Active Release Time Constants

Passively discharging the side-chain reservoir capacitor with a resistor is not necessarily the best way of going about things. Looking at Fig. 25-81A shows that the initial discharge rate is considerably faster than that farther along in time. With a gain control element (i.e., a Voltage Controlled Amplifier/Attenuator—VCA) having a linear control voltage to dB attenuation characteristic, the gain reduction on release would die away very quickly initially and steadily bottom out. This is bad news since a longer than necessary release time constant would need to be applied to preserve adequate low-frequency distortion. If the reservoir capacitor is discharged linearly as in Fig. 25-81B by a constant-current source instead of by a straight resistor (example in Fig. 25-81C), a tidy linear dB attenuation release versus time characteristic ensues; less release time need be wound in for similar LF distortion.

This can be taken a step further. Some gain-control elements with logarithmic (transistors) or square-law (FET) control voltage characteristics, for example, can be made to work with a passive release system to give a pretty good approximation of linear dB/time release. Adding constant-current discharge to one of these circuits gives a slow discharge initially (i.e., good low frequency distortion) with a more rapid tailoff, Fig. 25-81C, which removes unnecessary gain reduction quicker than any other arrangement yet. On program material this works very well, also serving to reduce pumping and suck outs from transients.

25.12.1.7 Hold or Hang Time

Given active discharge with a constant current source, it is always possible to turn the discharge path off. This has the effect of freezing the attenuation at the instant
the discharge is removed; if there is no discharge path, the reservoir can’t discharge, the control voltage remains static, as, consequently, does the attenuation. Recent refinements to dynamics include this feature; if the side chain is attacking in response to an increasing signal over the threshold, the constant-current discharge is turned off automatically. It remains turned off for a preset amount of time after the attacking has ceased and when the circuit would ordinarily be releasing. Instead, the attenuation remains static for that preset time after which the discharge is reinstituted and normal release decay occurs, Fig. 25-81D. The advantages are straightforward; there is no release time-constant-related distortion in the period of time the attenuation is frozen and the subsequent release can be independently set to return gain as quickly or as slowly as desired. Tailoring the attack, hold-and-release times around a given program source can render processing virtually transparent in many cases. *Hold or hang* time is quoted usually as a direct time in milliseconds or seconds.

### 25.12.1.8 Limiting and Compression for Effect

The principal creative purpose for limiting or compression (as opposed to the precautionary and damage-control functions outlined earlier) is to make things loud. Suitable parameters can also imbue low-frequency chunkiness or weight on the sound. Given a certain maximum head room level in a transmission or recording medium, it is often desirable to increase the program density or reduce the dynamic range. A case in point (again) is broadcasting. Their legitimate purpose for compression is to render audible portions of program that may otherwise be too quiet and buried in ambient noise, interference, or static at the receiver end. Automobiles have a notoriously small dynamic window between receiver output capability and cabin noise. A compressor (or usually air chain processor) is set to give sufficiently high output for a quiet program and to automatically reduce the gain when it gets louder.

An interesting subjective side effect of this lies in psychoacoustics; if the ear hears something it knows to be quiet ordinarily at a certain volume, then a sound that it knows to be louder still seems louder even though a limiter may be compressing the two signals to the same level. A classic example is with reverberation tails—these are one of many means by which we subconsciously gauge relative loudness; if the original sound spawning the reverb tail is compressed to be closer to the level of the tail, the whole overall sound seems louder.

Normal program material consists of quite high transients and peaks above the mean average level. If these
peaks are removed (brutally by a clipper or more subtly by a timed processor with short time constants), the average transmitted level can be increased correspondingly. The shorter the time constants, the more apparent loudness can be squeezed out. Usually, though, this is at the expense of quality.

Here belies the principal reason broadcasters like dynamics processing—the louder they seem on the air, the more listeners are attracted to the station. To this end excruciating amounts of gain reduction are common on-air in radio. It’s a well-known effect that something that sounds louder—even marginally—is perceived as sounding better, at least in the short term.

It is also a strong reason compression is prevalent in individual recording channels within a console; each sound can be made not only more controlled in level, which helps balancing, but also denser and more solid sounding. The downside is that it’s so easy to squash vitality out of a sound, trading liveliness and depth for something more up front but ultimately less interesting.

25.12.2 Gating

Gating is to a degree the inverse of limiting. It is the removal of an output signal unless it is of a sufficient strength; in other words, if the input signal is above a threshold level it is permitted to pass, but if it falls below the threshold it is attenuated.

Its purpose is usually to remove or reduce in level a signal when it is no longer usefully contributing to a mix, remove noise in between wanted sections of program and to generally act as an automatic mute. A true gate totally removes the undesired signal but in practice—for noise reduction in particular—a lesser amount of attenuation is invoked; this is set by a control and indicator called depth or maybe just attenuation. Gentle amounts of depth make the operation of a gate far less obvious together with the benefit that there is less intermodulation distortion if the gain is asked to change through less of a range.

The gate attack or wake-up time is generally adjustable and determines how quickly the gate opens in response to a signal tripping the threshold. It is usually set very fast, though, such that none of the leading edge of the signal is missed. The hold time (if there is one available, usually) determines how long the gate remains open after the signal drops below the threshold and the release or decay time sets how quickly the attenuation returns. That these are a direct parallel to their behavior in the limiter is no accident; nearly all dynamics processing sections carry these controls. It only needs to be remembered with a gate that the attack time has to do with how quickly attenuation is removed rather than applied as is the case with a limiter.

The ranges of time-constant values are typically similar to those for a limiter, but the threshold range can extend from 0 dBu (or even as high as +20 dBu in some cases) down to about −40 dBu or below. The higher thresholds are mostly for key triggering while the low extremes are for noise reduction. Automuting settings are somewhat critical, needing to be above the general background level yet below the desired signal’s typical level; there is always some tuning to be done, but figures of −10 dBu to −20 dBu are typical. Depth can be adjustable between 0 dB and 40 dB attenuation (some manufacturers optimistically state infinity).

Practical uses include automatic microphone muting (backup singers), spill removal (e.g., a snare drum microphone is usually gated so that when the snare isn’t actually being hit, the microphone isn’t picking up the rest of the kit), and noise reduction (just enough gating applied to tape track returns to subdue tape hiss or air conditioning rumble). In all cases the parameters are set up to be as unobtrusive as possible. These vary from lightning fast attack and decay on a snare drum to fairly leisurely ramps in noise reduction.

In addition to the hold, or hang, time which prevents the gate from chattering on a marginal signal, an additional tool to prevent falsing is hysteresis between the signal level necessary to open the gate (open threshold) and that below which the gate considers the signal to have gone away (close threshold); this hysteresis (a few dB) is generally concealed from the operator.

25.12.2.1 Gating Feed-Forward Side Chain

Naturally, a gate cannot possibly operate with its side chain taken from the amplifier output as is the case with the feedback limiters described earlier—it would never open. It has to sense prior to the attenuator in the signal chain. This arrangement is called feed-forward side-chain sensing and is the prevalent method of generating control voltages in today’s dynamics processors. Fig. 25-82 shows a typical gate circuit using this method; the input signal as well as going to the attenuator hits a variable gain amplifier, which determines the threshold. The more gain in the amplifier, the sooner the detector threshold is reached. Following the threshold detector—which is in this case a comparator type yes/no level sensor—are the various time constants. Depth is controlled by placing a limit on the amount of attenuation possible.
25.12.2.2 Subtractive Feedback Gate or Expander

An alternative gating method cunningly uses a limiter, albeit with a very low threshold, to subtract from or cancel the straight signal, Fig 25-83. The signal gains through both the straight path and the limiter (below its threshold) are arranged to be the same but out of phase; they cancel out. Above the limiter’s threshold the limiter output remains fixed but the straight signal is left unhindered, so the two no longer cancel, leaving the straight signal predominating. Time constants of the effective gate are determined by those of the limiter, threshold by the gain of the amplifier within the limiter loop, and depth by contriving a mismatch between unlimited level and straight path level to produce less than total cancellation and some residual.

25.12.3 Compression

As briefly outlined at the beginning of this section, compression is where the output signal from the processor does not increase as much as the input signal is increasing. If an input signal jumps in level by 10 dB, a compressor with a ratio of 4:1 would only allow the output to rise 2.5 dB. Correspondingly, a drop in input level of 16 dB into the same compressor would result in 4 dB output level change. A compressor reduces the dynamic range of an input signal by the amount of its ratio.

A true compressor acts on all signals, regardless of actual signal level, in the same manner. No matter if the input signal is way down at −60 dBu or up at +20 dBu, a change in input signal level of a given amount will cause a similar, reduced, change in output signal. Practically speaking, there is no such thing as a true compressor; things that come close and work down to very low signal levels are used in noise reduction systems for telephone lines, tape recorders, and wireless microphones, where they are used with a complementary expander (see later) to reinstitute the original dynamic range.

Most compressors have a threshold below which they leave a signal unscathed (a 1:1 ratio) and above which they proceed to compress the dynamic range, much as a limiter does. The family resemblance becomes all the more striking as compressors with high ratios are considered. A 10:1 compressor above its threshold reduces a 10 dB input level jump to just 1 dB. Infinity-to-1 reduces anything above the threshold to the same output level. Looks like a limiter, smells like a limiter. Generally, compressors are used at far gentler ratios (between 1.5:1 and 4:1) to bring up lower level program material in a less take-it-or-leave-it manner than a limiter while leaving some sense—albeit reduced—of light and shade, louder and quieter. They are also used to subtly make sounds chunkier—a degree of compression tends to accentuate lower frequencies.
which are those generally most predominant and are so controlling of the gain reduction.

Major differences between limiting and compression are in the nature of the side chains, the level detectors, and in particular typically applied time constants. Limiters almost invariably have peak detectors, such that the peak of a waveform is detected and, time constants allowing, protected from overload by the limiter; this is fine for the protection mandate of limiters. Compressors, on the other hand, tend to have much more relaxed attack and release times, such that they are less intense sounding than the typically frenetic limiter settings. Similarly, since the concern with compressors is less peak level than loudness to the ear, which tends to gauge by overall signal energy or power rather than peak values, the detectors are typically average or power sensing. The slower time constants go a long way toward this by essentially ignoring peaks and responding more to an average over the time imposed by the attack and release times. Deliberate averaging detection (as opposed to the more or less accidental) sounds much more even and unobtrusive than peak detection; taking it a step further, power detection by means of a root mean square (rms) level detector is better yet. In reality, though, there’s little to choose between average and rms detection, since although they give significantly different answers under test waveform circumstances, dancing around in the heat of audio battle they are quite difficult to tell apart. Occasionally either one or the other will be fooled by a difficult piece of program material.

The threshold tends to extend farther down for a range typically of −30 to +10 dBu, and the ratio adjusts from 1:1 (straight) usually to infinity:1 or close (limit). Some commercial units extend the ratio beyond infinity to negative values; that is, if a signal progressively exceeds the threshold it gets progressively further attenuated! Although on first glance it seems a bit pointless, it does allow fairly nice sounding level control for a compound signal; it permits looser (longer) attack times than would be possible on an ordinary limiter, with the resultant overshoot merely propelling the signal farther downward away from possible overload. It is also good for some pretty silly effects on individual instruments.

As mentioned under compression, true full-range expansion is a rarity and is generally only found as a complement to a compressor in a double-ended noise reduction system. In these circumstances they are nearly always of 1:2 ratio with an axis point (the level at which the input signal is the same as the output signal level) of around 0 dBu.

Practical expanders come with a threshold setting, above which they leave the signal alone and below which gain reduction sets in. Sounds a bit like a gate? A gate can be emulated by an expansion with a ratio of 1:infinity; any signal below the threshold gets attenuated away completely—the one exception is that expanders usually don’t have a depth setting. The purposes of expansion are very similar to those of a gate, only generally it can sometimes do a better, less noticeable, job. A relatively gentle expanding slope (say 1:2 or 1:3) can provide the same degree of noise reduction as a gate with less abrupt changes in gain; since the signal is audible still (but quieter) and doesn’t have to be resurrected with a start to normal level, fairly gentle (slower than a gate) attack times do not have as noticeable a softening effect on the required leading edge.

Expansion side-chain time constants are similar to those for a gate, as is the threshold range. Ratio, as with compressors, is usually 1:1 to 1:infinity, although often “classic” implementations have a fixed ratio of something close to 1:2. Expansion is used as subtle gating in much the same way as compression is a gentler substitution for hard limiting.

### 25.12.5 Feed-Forward VCA-Style Dynamics

The feed-forward class of dynamics owes itself to the development of VCAs and similar log/antilog processing; it is exemplified by the classic dBx160 series. As far as consoles go, the mere existence of a VCA in the channel for fader automation begs for this style of processing to be incorporated. (VCAs are further discussed under Consoles and Computers, later.) Figure 25-84 shows such a processor in block diagrammatic form.

Key to VCA dynamics is the inherent exponential (logarithmic) control, which relies on reasonably simply implemented basic transistor behavior (base voltage versus current). Gain (or gain reduction) of a VCA is as good as linear dB/v, which can lend to a deterministic design approach (meaning one can pretty well predict what the circuit will do within narrow limits, without a servo loop to help). Simple log/antilogging lends itself to another typical feature of VCA dynamics sections.
Chapter 25

25.12.5.1 rms Detection

Hitherto, detection of signal levels in dynamics had been either peak or average. These were actually achieved by broadly similar circuitry with the difference dictated by the attack time applied after signal rectification; short attack times allowed the reservoir capacitor to charge immediately to the highest signal level applied, while longer attack times tended to smooth out the peaks, settling on an average value of the applied rectified waveform. And a sort of mushy continuum existed between the two.

Rms (root mean square) detection has the intent of providing a measure of the energy in an applied waveform, the actual power. The reasoning is that a power measurement could be considered more equivalent to loudness. Rms is achieved by first squaring the applied signal (i.e., multiplying it by itself, not turning it into a square wave), finding an average value of that squared source, and then determining the square root of that average (unsquaring it). Seems like a lot of bother to go to, doesn’t it? Well, no one would have bothered if there was a reasonably straightforward method. This comes from an application of a log anticell.

A precision-rectified (meaning accurate down to very low levels) input signal is logged, and then its output is doubled (added to itself); doubling a log value squares the number it represents. This signal is then integrated with a time constant long enough to allow reasonable averaging of the lowest frequency under consideration; this incidentally defines the minimum attack time of the processor. This log value average is then halved (division of a log value by two is the same as finding the square root), delivers a log-world rms-detected output. (In this circumstance a subsequent antilog conversion is unnecessary. Actually, the square rooting is ignored at this point, too, since it can be achieved in a later scaling exercise.) The good news is that all that can be done with a handful of transistor junctions. Release time can be extended with a following buffered capacitor, but often the imbued time constant of the rms detection serves as symmetrical attack and release. This somewhat leisurely time response (necessary to permit good rms detection at low frequencies, devoid of distortion-creating ripple) in and of itself ensures that the behavior of such a dynamics section can’t get too wild and interesting, but by corollary such processors do afford probably the least intrusive method of automatic volume control, which is a highly prized attribute on occasion.

25.12.5.2 Thresholding

The rms-detected control signal is then masked in a threshold determining circuit; typically this is a precision rectifier with its reference point determined by a threshold control voltage—the purpose of this is to ignore all variation of the detected voltage until it exceeds (in the case of a compressor) the threshold point, beyond which its output follows the rms detector output. Any control signal escaping the thresholder still has a dB/V characteristic, being still logged, following the input signal. Another (linear-think) way of looking at this is that a division takes place; the detected control signal is divided by the threshold, but with any result less than 1 masked out at 1, only greater than unity results being passed.

If the thresholder is designed to pass only changes below the threshold, then the low-level effects of expansion and gating are possible, signals above threshold being ignored. Separate thresholders and following conditioners are necessary for each desired function of the dynamics section.

25.12.5.3 Ratio

If this thresholded control voltage were applied directly to the (level-adjusted) control port on the VCA, something odd would happen: nothing. More precisely, above the threshold the control signal would rise in accord with a rising applied audio signal to the precise extent that the gain reduction resulting from it would be exactly the same as the increase in signal. The VCA output would remain at a fixed level for any applied signal level above the threshold. In other words, it is a compressor with an infinity:1 ratio, meaning that above the threshold, any amount of signal level variation will have no effect on the output. In yet other words, it would be a limiter (albeit with slow dynamic response).

Introducing a variable attenuator in the feed to the VCA control port from the thresholder affords altering the amount of dynamic gain reduction; less control signal variation, less gain reduction. A nice feature of this very simple approach in log world is that this attenuation (equivalent to solving for variable roots in linear) results in precise applied signal level to dB gain reduction ratios; for a given setting, if the input signal were to rise 6 dB, the output would rise only 3 dB; this ratio, 2:1, would obtain linearly for any applied signals above the threshold.

Astute readers may wonder what would happen if the control signal, rather than being attenuated, was
amplified instead. Yes, the degree of attenuation would become bigger than the corresponding changes in applied signal, and the VCA’s output would actually increasingly reduce beyond the threshold. This effect was brought to stardom by the Eventide Omnipressor.

25.12.5.4 Side-Chain Sources

Figs. 25-84 and 25-85, the block diagram and schematic respectively, of a feed-forward style dynamics element, both only consider the side chain as being taken from the same place as the input to the VCA gain controller. This need not be the case at all. In fact, with a standard channel’s signal processing it would be quite a limitation, forcing the dynamics section to be solely post everything, prefader. The side chain input may be separated and instead taken from pretty much anywhere upstream; the overall effect is (with only some odd side effects) the same as physically moving the whole dynamics section to that location. For the most part, the audio doesn’t care that the control voltage from the sidechain has no relation to that being passed through the VCA. The main areas where things might sound awry are if there is a significant (and audible) deliberate time delay between sense and activation or extremely short time constants are invoked. The first disconnect is obvious, and the second is almost irrelevant since it wouldn’t be sounding very nice anyway.

Taking this a step forward again, a prime virtue of a VCA-based system is that many different sources can operate simultaneously on the one relatively expensive VCA gain element. If there are multiple side chains (say, one for keying/gating/expansion, another for compression) these again need not sense from the same pick-off points but places more suited. The gate would likely sense postinput filters, while the compressor would likely be farther downstream, one side or the other of the EQ. This situation would work, but would result in behavior unlike having a discrete gate up front and a discrete compressor downstream. In the literal case—i.e., with two separate dynamics elements—the incoming signal would be gated before it hit the compressor. In this virtualized case, though, the actual audio signal hitting the compressor side chain would not have previously been gated and hence cause the compressor to act differently than if it had. Subtle, maybe, but a definite difference.

25.12.5.5 Makeup Gain

The side chain’s thresholded and ratioed control signal is summed in with a voltage representing the amount of buildout gain (necessary to compensate for the signal level reduced by the effect of compression/limiting) and is also, in the case of a typical console channel, summed in with the voltage from the automation system representing the fader position. This summation is scaled to suit the actual (highly sensitive) VCA control port, to which it is fed.

25.12.6 A Practical Feed-Forward Design

A highly integrated part, the THAT Corporation’s 4301, has both an rms detector and a VCA built in, in addition
to some op-amps for glue. A simple, very low parts count compressor with all the active elements contained within this part is shown in Fig. 25-85. As can be seen, it relates strongly to the block diagram of Fig. 25-84.

25.13 Mixing

25.13.1 Virtual-Earth Mixers

The circuit diagram of Fig. 25-86 in its simplicity belies the hidden design that is in the relationship of the circuitry to its mechanical and electrical environment.

This is where the care and feeding of op-amps (Section 25.7) and grounding paths (Section 25.8) really pay dividends. Mix-amp stages, with large numbers of permanently assigned sources such as in the main mix buses, are as crucial to the overall well-being of a console as any front-end stage could be. In a typical situation, as a unity-gain virtual-earth mixing stage with 33 sources (channels plus access), the amplifier is being asked for about 30 dB of broadband gain, as much as any other stage in the chain including both the microphone preamp and/or secondary input stage.

25.13.2 Noise Sources

All the following about mix devices assumes that system grounding is impeccable. Jolly good. That said: That mix-amp gain is sometimes referred to as noise gain is not accidental. Unless care is taken to balance fader-back channel noise contributions against this self-generated mix-amp noise, the latter could well predominate and arbitrarily determine the noise floor for the entire console. Similarly, channel noise contribution should equal or outstrip mix-amp noise, but not excessively so: ideally they should equally contribute, to the extent that channel-off noise contribution should not necessarily impact the overall bus noise, while bus noise should not significantly impact channel-on noise. Self-noise generation in the mix-amp is predominantly the amplified thermal noise of the paralleled source and feedback resistances, device input current noise, and surface generation and recombination noise. The last two can be minimized by device choice. Thermal noise is physics and is here to stay. Common sense on first glance says to make the mix resistors as low in value as possible but this has the downside that too low a value would cause quite large signal (hence, ground) currents.
to be thundering about. On a less technical and more economic level, it necessitates somewhat beefier and more serious buffer amplifiers on each source to feed the buses.

Ordinarily though, the mix resistors are of such a value that, in the context of a complete mixer, the combined effectively paralleled resistance is well below the optimum source impedance of nearly any mix-amp
device available, so the primary noise modes are those above-mentioned device vices. This certainly isn’t too difficult with FET front-end devices, with their high OSI (optimum source impedance). These devices have a couple of other major benefits in this application though by virtue of their FET inputs. Input current (hence, input current noise) is extremely low, and being FETs they don’t have the many low-frequency junction and surface noises inherent to bipolar devices. It seems a paradoxic absurdity to use an ultrahigh input impedance device for zero impedance mixing, but in many ways and under some circumstances they’re better suited than bipolar. On the other hand, the intrinsically superior noise performance of a 5534-class device can pay dividends in this application. Like so many cases in console design each individual application needs staring at for its own optimum solution. This is all really only a problem for those who have the luxury of designing small mixers or where it is more or less guaranteed that only a small number of sources will be allowed to hit the bus simultaneously and hence where the parallel impedance of the sources remains fairly high. In most midsize and large consoles without these constraints, mix device noise will likely predominate. Device choice will be down to its self-noise (of course), and output current capability if the summing resistor value is low, and ability to cope with a big hairy capacitative bus sitting on its input current node. Integrated mic-amps have been successfully used as differential passive mix-bus amplifiers, which with their very low OSIs stand a chance of getting closer to that low bus impedance and low bus noise nirvana. However, as alluded to earlier, the channel-off noise contribution from all those bus-driving amplifiers in all those channels is more likely to then predominate. It is a balancing act.

If bus noise performance truly is a major concern (as it could possibly be on a tracking console) removal—as in physical disconnection—of all unused sources from the bus at all times is the best way to get the noise gain down and that bus impedance back up to where mix-amp noise can be optimized to it. No way to run a railroad or a mixdown console, though.

Things can get a bit startling if the resistance/OSI relationship is awry. Above the OSI as much as below its OSI, device noise becomes an increasingly important noise contribution. Many years ago in a mixer design with bipolar device mix-amps and quite high mix resistors, the measured bus noise was actually quieter on a 20-channel version than on the 10-channel original. It wasn’t until much later that what was actually happening finally dawned. Increasing the number of source resistors reduced the bus impedance, previously well above the OSI of the amplifier with only 10 sources, to closer to the OSI, where input noise voltage was contributing less.

Theoretical source impedance and device contribution tell less than half the story in a practical design. They may be quantifiable in the isolation of a test bench, but thrown into a system they can all seem a bit meaningless. It’s all largely a matter of grounding and out-of-band considerations.

### 25.13.3 Radio-Frequency Inductors

Inductors are used between the bus and the amplifier input in Figs. 25-86 and 25-87. A simplistic view is that they are there to stop any radio frequency on the mix bus from finding its way into the electronics, but this is only part of their purpose. The ferrite beads and small chokes (about 5 μH) are there to increase the input impedance and hopefully help decouple the bus from the amplifier at very high frequencies. The larger inductance creates a rising reactance to counteract the falling reactance of the bus capacitance. If left completely unchecked, this capacitance would cause the mix-amp extreme high-frequency loop gain to turn it into an RF oscillator. Feedback phase leading around the amplifier stops the gain from rising, but if it were not for some series loss (accidental or deliberate) in the input leg, it would be insufficient to hold the phase margin of the amplifiers within their limits of stability, especially at bandwidth extremes where device propagation delay becomes significant in the loop. A small series resistance can provide this loss while also defining the maximum gain to which the circuit can rise. A parallel inductor-resistor combination improves on this in a few important respects.

The inductor is calculated to present low in-band (<20 kHz) reactance, allowing the mix-amp to operate on the bus in its intended virtual-earth (zero-impedance) configuration. The reactance rises gently at the audio extremes where device propagation delay becomes significant in the loop. A small series resistance can provide this loss while also defining the maximum gain to which the circuit can rise. A parallel inductor-resistor combination improves on this in a few important respects.

At even higher frequencies, the inductive reactance continues to rise until the combined network impedance is limited by the resistor, which is of high enough value to define amplifier out-of-band gain to a reasonably low value. It is low enough, however, to stop the inevitable inductor-bus capacitance resonance from getting completely out of hand. Making a stable inductance-capacitance oscillator is one way of preventing
spurious instability, but is not exactly the desired end here.

While FET inputs are far less prone than bipolar inputs to the intermodulation and direct demodulation effects that cause RF interference to appear out of nowhere, this fairly healthy brace of filtering may be helpful to those living near a source of high-powered very high frequencies, such as a group of television transmitters.

### 25.13.4 Virtues of Grounding

Grounding paths for virtual-earth mixing, especially in long mixers, are always the final arbiter on how far
down the system noise floor will go and how susceptible the mix stage is to extraneous fields and earth currents. In this age of digits, ground paths are especially crucial. Remember from Fig. 25-65 how the ground noise on the noninverting input of an op-amp mix stage gets amplified up by the noise gain of the stage? This implies that a ground noise of $-100$ dBu will end up at about $-70$ dBu for a 32-source mixer, which is hardly adequate.

A simple, but so often ignored, rule with virtual-earth stages is to make sure that the ground reference has got the same dirt on it as the signal and vice versa. Yes, ground follows signal. If both ground and signal have the same noise in the same phase, there is a chance that the noise will get ignored as common mode and not amplified in the mix-amp. So, for each mix bus, there should be a parallel ground bus being fed by the last relevant ground reference from each channel. Avoiding a major bus-length ground loop (otherwise known as a single-turn transformer!) means that all the heavyweight signal current in the channel proper (e.g., fader/mute/mode switchers) has a direct wire to central ground while the mix-amp has a respectable output referenced ground to work against, clean of channel signal currents but representative of the reference of the buffer amplifiers. The mix-amp does not take a direct system central ground of its own.

### 25.13.5 Passive Mixing

There are, of course, alternatives to single-bus virtual-earth mixing. Passive resistor mixing, Fig. 25-88, is quite viable for fixed-assigment systems that are not going to be chopped, changed, or switched in and out. A major advantage is that bus capacitance is merely something to be taken into account in terms of frequency response and phase rather than directly imperiling the stability of the mix-amp. For passive mixing, the mix-amp is just a buffer amplifier to make up the loss in the resistor tree; RF filtering becomes simple with known filter source and load impedances together with the ability to refer against ground. A primary weakness is that the bus is unbalanced and is of some impedance at audio (albeit fairly low due to paralleled sources). As such it lays itself wide open to induced noise and capacitatively coupled crosstalk. Despite this, it is a method used with considerable success for many years in quite a few production mixers.

In all cases but especially in small mixers, say with fewer than eight sources, there is a theoretical noise advantage to passive mixing over virtual earth. As an extreme example, simple summing of two sources of passive mixing calls for $6$ dB of gain to make up for the loss in the summing network. A virtual-earth mixer needs around $10$ dB. Beyond eight sources this advantage tends to the insignificant.

![Figure 25-88. Passive mixing arrangement.](image)

### 25.13.6 Devolved Mixing

Distributed or devolved mixing, Fig. 25-89, uses local mix-amps to sum relatively small blocks of channels; the outputs of these local amplifiers is then taken to a common summing point. This quite neatly obviates having to deal with a long bus but does create a practical problem of locating the distributed summers.

![Figure 25-89. Distributed or devolved mixing.](image)

Both passive and devolved systems have the advan-
tage that large amounts of the bus can be run in shielded cable. The extra capacitance here does not have the awful consequences it does with long virtual-earth summing amplifiers.

For consistency—if this approach is taken—all buses should be run de-voled. This means the submix facilities for the PFL buses, effect sends, foldbacks, the main stereo/monitor mixer, and analog subgroups (if used). Also, provisions must be made to arrange the master mixer for each of those at the grouping end.

25.13.7 Balanced Mixing

The earliest form of signal mixing consisted of directly paralleling the sources, which were generally medium-impedance (nominal 600 Ω) and balanced. This form of passive balanced mixing persisted until semiconductor electronics and its readily achieved zero impedance transpired. The balancing was done entirely by transformers; again, things that have fallen at least partially by the wayside. As a technique it was simple (for the technology at the time) and maintained all the advantages balanced systems have in general—principally a welcome robustness and immunity to interferences, induced noise, or crosstalk.

Balanced or differential mixing has become practical again with falling component costs and the development of simple electronic differential and floating balanced input and output circuits (see Sections 25.9.6.1 to 25.9.6.4). Fig. 25-90 shows how differential sources of the trivial kind (straight and inverted) can be mixed onto a balanced virtual-earth mixing bus, created and sensed by a superbal input stage.

Although requiring a comparatively large number of parts, the performance of such an arrangement in the context of a large multitrack console is truly staggering, especially noise, head room, electromagnetic field rejection, and crosstalk. The noise improves in two respects:

1. No longer is the mix-amp amplifying the noise on its reference ground. It is referenced to itself, effectively.
2. Square law noise summation—twice the signal (coherent) means 6 dB gain, two lots of incoherent noise 3 dB gain, bingo, 3 dB noise advantage.

Head room, by virtue of two signal paths carrying the same information differentially, is 6 dB higher. (Naturally the noise and head room are interrelated; whichever is more pressing in a given circumstance necessarily takes precedence in the level architecture.) The RF field and crosstalk rejection improvements are dramatic, but they really ought to be expected from the naturally self-canceling nature of balanced systems.

All the problems of keeping virtual-earth mixers tidy and stable apply twofold here; of course, bus buffering is strongly recommended, mostly to allow the bandwidth definition around the superbal to be effective.

Passive balanced mix-amps can be arranged around integrated mic-amp devices such as the THAT 1510; being single-ended output doesn’t lend them to dynamically generating differential virtual–zero impedance mix buses, but does allow the choice of mix resistor values versus mix width to optimize the parts mix-noise contribution. It is presently difficult to consider any serious large console design that doesn’t use balanced mix buses.

25.13.8 Pan Pots

As outlined earlier pan pots are a means of positioning a monophonic image somewhere within a stereophonic image plane. About the simplest pan pot is shown in Fig. 25-91A where a pair of linear potentiometer tracks are complementarily wired; one goes up, the other goes down. All well and good and even the sums work out nicely; if the L and R outputs are subsequently remo-aced the summed signal remains at the same amplitude regardless of pan pot position—center, either end, or anywhere in between. Subjectively, though, the image remains too loud at the peripheries (i.e., extreme left and right) and subdued in the middle.

Replacing the linear pots with a ganged log/anti-log pot (the log section wired upside down) performs much the same function but with a different law, Fig. 25-91B. If a signal is panned steadily right, the left hand output is steadily attenuated, leaving the right output fairly steady in level (in practice it shifts about 1 dB). The center position sees both L and R only attenuated slightly (<1 dB) with respect to the starting mono signal. Not surprisingly this has the opposite subjective effect to linear pots: the image seems louder in the middle than at the peripheries. Despite that, often this law is more appropriate, particularly where the pan pot is used as part of multitrack odd/even panning or in use as a correctional offset control. In these cases there is virtue in leaving at least one side fairly unscaathed.

Somewhere between these two extremes (if extremes is the right expression for a 6 dB difference) should lie a happy medium at which the signal keeps an even subjective level panning across the image plane and also tracks well (i.e., has good correlation between control position and image position). Easy? This has been the
subject of raging controversy and opinion for decades. Should it be 2, 3, 3½, 4, or 4½ dB down at center?

As is often the case, those closely involved with the theorizing somewhat lost touch with how a pan pot is ordinarily used. A pan control usually remains rusted at an initially set position for hours, days, weeks, months—however long the mix takes. If a pan pot is used dynamically for effect during a mix, its very drama drowns any question of whether it was “a wee bit quiet in the middle.”

A single pot used as in Fig. 25-91C allows a choice of central down points by adjusting the relative values of the source resistors and pot value, but at the cost of slightly iffy tracking (most pan effect tends to happen at the extremes of the control travel) and ultimate panning. When panned hard one way it is nearly impossible—due to wiper-track resistance—for the diminished side to achieve complete attenuation. If 40-odd dB is good enough then this may be the one. Shown are values for a 3 dB down panpot.

During the 70s the BBC had the understandable problems of multitudinous operators, countless consoles of varying antiquity, and a considerable number of console suppliers. Their aim was consistency and to this end evolved a dazzlingly simple arrangement shown in Fig. 25-91D recommended for inclusion in new supplied equipment; it works.

25.13.9 Surround Panning

Surround has many variants, but for the purposes of discussion here 5.1 will be considered; other formats have basically similar requirements that may be taken as a subset or extrapolated from 5.1.

Well, quad is back (and it hasn’t forgiven). At least in terms of four of the 5.1 signal paths, left front, right front, left rear and right rear. Panning for these is achieved in much the same manner as it was in those chillingly far-off days, a joysick that controls relative proportions of the source signal to the four output, or a
pair of pots that do substantially the same; one pans left/right, the other front/rear. The “1” of the remaining 1.1 is center; it is to where central dialogue or vocal is panned; this is usually achieved with a blend or similarly named control, which cross-fades the source signal between the center channel and the quad pan pot. In this manner, a source can be directed to any one path, all, or a combination for desired effect.

The last 0.1 is a bass sublow channel. The .1 means that it is (but not always) band limited. It usually has its own level control independent of the full-bandwidth panning.

The surround panned outputs form a channel with six dedicated surround mix buses, which are treated as a married set within the console much as the main stereo mix-bus is/was.

25.14 Monitoring

Monitoring is probably the single most important section of a console. Without it the engineer cannot listen to the results of his labor. At its simplest, monitoring consists of a power amplifier and loudspeakers hung across the main output(s) of the console, with the auxiliary functions either unused or preset. In public address (PA) work the PA actually is the monitoring; the only other function necessary is prefade listen (PFL) and then really only during panic mode. At an alternate extreme the monitoring demands for multitrack recording extend to an entire secondary submixer replete with panning, pre/post foldback effect feeds, and stand-alone soloing, together with listen access to all console send and return ports. The in-line console principle makes efficient use of electronics to combine often coincident signal and monitoring path requirements for normal multitracking techniques. If the architecture is well thought out, it is operationally rare to need to listen to anything other than the main stereo bus output; this output serves as both the multitrack monitoring bus and the stereo mixdown bus.

Three distinct types of monitoring activities evolve in multitrack work:

1. Mainline—The stereo bus encompasses the multitrack machine sources/returns and stereo mixdown. This can be read as surround bus if appropriate.
2. Transient—This allows short-term check listening of individual channels for reassurance or adjustment, using PFL or solo functions.
3. Auxiliary—This provides access to the assorted foldback/effect feeds, effect returns, mastering machine, and subsidiary machine returns.

From an operating point of view, the foregoing activities seem to form natural divisions. From a technical stance, it’s a different matter entirely. The solo (in-place monitoring) function is very closely related to the stereo bus. In fact, it uses exactly the same signal path throughout—and can be seen simply as a modified use of it. PFL, though, despite a similar operation (only prefade as opposed to post pan listening), actually requires an entirely separate bus and mixing system. Its output is switched to override the main path into the monitors. (It may seem strange to go through all this for a spot-check function that tells less than the stereo in-place solo, until it is remembered that a solo disrupts the mix while a PFL is nondestructive.) Conversely, an
operator usually has a psychological hook about the main stereo bus monitoring being the gospel unblemished signal path and that all the auxiliary functions are somehow less polished and somehow tainted. In reality, the monitoring chain normally selects directly between all its sources, merely treating the stereo mix as one of the many. No special treatment is desired or given.

25.14.1 Solo, Solo-Free, and Prefade Listen

An assumption is made that the solo function is such that if a console channel is soloed, all other sources contributing to the main stereo bus are muted, leaving the desired channel in isolation at its set level and panned position. An exception and extension to this are for other channels (principally those returning effects to which our soloed channel may be contributing) to remain unmuted in the stereo mix during solo operation; this is done by using the solo-free button on those channels still needed. Solo-free detaches the channel from the consolewide muting/solo activation logic.

Soloing individual channels wet (i.e., with all its attendant effects) is a common need; at a stage in a production where things are dripping in reverb and sundry funny noises, soloing in context only makes sense—by that time it is well known and redundant what something sounds like dry. A channel’s sound has become an amalgam of the source and applied effects, not just that of the source.

The upshot of this is that solo monitoring is inherent to the stereo mix path. If that path isn’t selected for monitoring, then neither is the solo. So, although a solo overrides the main stereo mix (unless disabled altogether by a master function, solo safe), it cannot override anything else, unlike the PFL.

Although PFL could just be brought up as another monitored source, it is made to emulate solo in single-button touch operation, with the added advantageous capability of overriding everything—whatever is selected to monitoring. Hit a PFL button anywhere on the console and, if desired, it will be what you hear in the monitors. Alternatively it can be arranged to just come up on headphones or a “near field loudspeaker” so as not to disturb the main monitors.

25.14.2 Monitoring Controls

Now we’ve worked out how to get what signal and at what priority into the monitoring chain. What other torture do we put it through?

1. Level control, which is used to adjust the volume. Usually a big knob or a fader of its own. The most used control on any console—just ask any console manufacturer’s service department.
2. Mute is used to turn the row off occasionally.
3. Dim is used so that you can hear what people say.
4. Mono is still used in radio and TV.
5. Phase reverse is used to make sure you haven’t already done it inadvertently. (This function together with the mono button makes for one of the quickest ways in history of lining up analog tape machine azimuth.)
6. Split is unashamedly borrowed from broadcast monitoring technology. This routes a mono sum of the main stereo mix bus continually to the left side of the monitor chain and a mono sum of whatever source is selected (including PFL override) to the right side, providing simultaneous monitoring of two different sources—one of which would almost certainly be console output anyway. (Split’s origins lie in network radio, where announcers on the air have to talk up to program junctions and smoothly hand over to another studio or network feed, news, or whatever at a cue. In order to do this, they have to be able to hear both themselves and the network they are opting into to hear the lead-up and handover cue.) Other than its primary design use, the split function is used considerably under other normal programming, affording random source monitoring without losing track of what the main console output is doing. It’s also used extensively in program prerecording and production, enabling, with practice, real-time multisource edits (jump edits) without recourse to razor blades and tape. Split will eventually find a niche in multitrack recording techniques; if nothing else, it can fulfill the requirement for single-loudspeaker mono monitoring, by simply selecting the right side to a dead source.
7. Desktop loudspeakers, or idiot speakers, are used to do transistor-radio and cheap hi-fi impersonations, also affording a respite of sorts from the sometimes wearing grandiosity of normal monitor loudspeakers.
8. Near-field loudspeakers (relatively small speakers, usually perched on the console’s meter bridge) are used as a twofold reality check during mix: they are close enough to the engineer for the room acoustics to be unimportant; they are closer in size/quality to what the majority of listeners will be using. Often, they are used as the prime monitoring with big
monitors and idiots being used briefly to make sure nothing’s gone amiss or become overblown.

25.14.3 Related Crosstalk

In a program sense, two forms of crosstalk are relevant. The first, related crosstalk, is a signal bleeding over into another signal path that is carrying a musically and temporally related signal (e.g., between the left and right of a stereo pair or between adjacent tracks of a multitrack recorder). It happens quite often and is fortunately not often subjectively obvious or embarrassing; usually they’re playing the same song!

Crosstalk within multitrack recording systems is usually little short of horrifying. As a result of the large physical size of the console, ground paths are unavoidably long and ground currents generate (and cross-inject into other paths) crosstalk voltages across the resultant ground impedances. Capacitance between interconnecting cabling, looms, modules, buses, indeed everything, results in a reasonably suspect electrical overall crosstalk performance. Naturally, the better the design and construction, the better a console tends to be in this respect. One typically gets what one pays for.

This was overshadowed and mitigated by analog multitrack tape machine crosstalk between tracks—a safe order of magnitude worse than even a horrid console could be. These tape machines not only had the same electrical problems as consoles but also had many magnetic heads in very close proximity, all dealing with a tape medium not notable for magnetic isolation anyway. It was all tolerable and usable simply because all the crosstalk was related and blended in unnoticeably.

25.14.4 Unrelated Crosstalk

Unrelated crosstalk is the clashing and cross-bleeding of signals that have nothing whatsoever to do with each other and are a mutual embarrassment.

In console monitoring a hostile signal (i.e. a delayed replay B check of a master) can be screaming about in uncomfortable proximity to the main stereo mix paths. Broadcasters face this same problem all the time. All their sources are hostile unless brought up on air.

This is unrelated crosstalk, where the bleeding signal is totally dissimilar and irrelevant to the interfered signal. Basically, if any unrelated crosstalk is audible above system background noise, it will be noticed.

A fairly recent and insidious sort of unrelated crosstalk comes in the forms of assorted chirps, buzzes, and sizzles stemming from the relentless march of digits into console design and operations. The Society of Motion Picture and Television Engineers (SMPTE) time codes and automation codes were bad enough, but trying to get computer clock droning and vdu squeaks out of the mixing buses and audio paths is not one of life’s most enjoyable tasks.

Designing it out in the first place is the only way to deal with computer noise:

1. Make sure all the logic grounds and analog grounds interrelation makes sense or are tailed back separately and never meet.
2. Scrutinize printed circuit layouts to make sure there are no digital signals adjacent to or on the direct opposite side of the board to any analog signal.
3. Intersperse lots of ground traces.
4. Screen high-current high-speed digital signals.
5. Try to allow only static digital control lines onto analog boards—this means decoding digital buses elsewhere than on audio boards.
6. Ground-plane everywhere there is board space.
7. Choose logic families—or at least interface devices—that are low current and devoid of large power-rail gulps. CMOS is just fine.
8. Decouple everything for all signals—decouple digital for AF and analog for RF.
9. Work on your karma.

25.14.5 Quantifying Crosstalk

“If you can hear it or measure it, it’s failed.” Such is the empirical crosstalk test. A more formal test was originally the test for interchannel crosstalk (i.e., between any channels in a console); it’s also used for any dissimilar path crosstalk measurements. In short, it asks for better than 60 dB of isolation of 6 kHz between the paths, measured with a standard peak program meter (PPM) with a CCIR 468 weighting filter in line. Since this CCIR curve has 12 dB of gain at its crest (at 6 kHz), the specification is actually calling for better than 72 dB of isolation at 6 kHz, which is neither easy nor often realistic. Such a figure is occasionally not far above system noise floors. Remember, it’s a peak measurement; an rms measurement would be some 7–10 dB lower. Nobody said it was going to be easy. Crosstalk’s a tough problem.

25.14.6 Meters

Some indication to the operator of the signal levels running through the console and, most importantly, the levels that are being sent to other places is necessary. In Fig. 25-92 a pair of level meter feeds are taken from the
top of the dim switches; thus, they follow monitoring. A further pair permanently hung across the main stereo mix output is optional. It’s customary to provide metering facilities on each channel; in this design the feed is taken following the monitor path source/return switching. This allows level indication of what is going to a tape track during recording and an “all is well” playback display. Gazing at a row of meters hanging off a multitrack playback, it’s surprisingly easy to tell what each is indicating. This is an important cue to a mixing engineer.

There are two basic types of meters, both evolving around the same period on opposing sides of the Atlantic. Each tells the observer entirely different things. Nearly every other sort of audio level indicator (LCD displays, rows of LEDs etc.) nods in style toward one or other of these, (see Chapter 26).

25.14.6.1 VU Meters

Volume unit (VU) meters evolved as a standard in the United States by Bell Telephone Laboratories. A need was shown for a consistent instrument to measure audio levels on lines; it is pictured in Fig. 25-93. The VU meter has a quite tightly defined specification, even down to the buff color of the scale! It is the ubiquitous style of meter that finds itself everywhere, from broadcast consoles to cassette players, but with very few of the interpretations actually bearing much resemblance to the original Bell Laboratories’ intentions. It might only consist of a light termination, a rectifier, and a moving-coil meter, but at least the characteristics of all were well defined; enough to be called a standard. Its inception was in Ma Bell’s self-defense; she needed some sort of consistency to the levels being hurled down her lines.

In essence, it was a meter only valid for hanging across 600 \( \Omega \) transmission lines; the 0 VU marking indicates an actual line power level of +4 dBm. The attack and decay times (the time taken for the meter to indicate a steady input signal of 0 VU accurately and the time taken for the needle to fall back afterwards) are some 300 ms. This time is based predominantly on the physical meter ballistics and happens to correlate quite nicely with the level-sensing integration time of the human ear. The VU is intended to give an approximation of how subjectively loud different pieces of program material are in order to match them evenly. This it does quite well. What it doesn’t do is give any idea of the actual signal level. The relatively leisurely integration time misses most transients altogether with the consequence that a VU meter will underindicate actual signal level; depending on program material this can be by as much as 20 dB (on impulses and transients—snare drums spring to mind), 12–15 dB on piano, and 8–10 dB on spoken voice.

The underread is unimportant in the respect that the VU does allow subjective level matching and is very easy to read and use. On a purely technical level, the rectifier in a neat, unbuffered VU meter hung straight across a 600 \( \Omega \) line imbues a serious amount of distortion (some 0.3%) to the program material. This has become more and more of an embarrassment over the years. It is less of a problem with zero-impedance feeds, but, unbuffered, it is still evident.

25.14.6.2 Peak Program Meter (PPM)

The peak program meter, Fig. 25-94, was the British Broadcasting Corporation’s answer to the same problem—the BS4297 spec. PPM differs from the VU in three very important respects:

1. The PPM is a peak-reading instrument, capable of accurately displaying signal transients. Correspondingly, it has a very short attack time, coupled with a long fallback decay time to give a chance to see the peaks once it has captured them.
2. The PPM is black.
3. The PPM has a logarithmic scale, allowing accurate signal-level measurements to be made over all the scale range.

The scale consists of seven marks, numbered 1 to 7, each division representing 4 dB level change. PPM 4, the middle mark, is set to indicate 0 dBm/0 dBu. The normal operational maximum signal limit is PPM 6, or +8 dBu.

As accurate and as useful as the PPM is, operators have to consult a list of peak levels for different types of program material (e.g., PPM 5 to 5½ for speech and PPM 4 for heavily compressed pop music) in order to perform the same function as a VU meter, which is subjective level matching. A VU meter makes these adjustments automatically since, although it’s worthless for peaks, it follows program density, or loudness, well.

Virtually every other level-indicating device emulates either the VU or the PPM characteristics—or both. There are other European meters—peak reading and log scales over a very wide (40 dB) range and with a longer fallback time than the PPM. Using one of these for the first time is unnerving; audience noise and even studio noise often make the meter dither some way off the bottom stop—a very unusual sight to eyes used to VUs and PPMs.

Proper American broadcasters have taken quite a fancy to a mutant PPM that is similar in dynamic characteristics to BS4297, but with the level for the various marks elevated by 8 dB. The marks give actual level values (up to a maximum of +16 dB whereupon it’s painted red) instead of the familiar 1 to 7. This is, it is given to be believed, so that the signal levels generated from control areas using these meters are similar to those from older areas using (curiously nonstandard) +8 dBm referred VU meters. Such are the levels they are used to sending down interstudio and telephone lines.

The elevated-level PPM is an idea with some merit when most of the material dealt with is prerecorded and fairly predictable in level so it does not require an awful lot of head room.

25.14.6.3 Other Metering

A preponderance of LED or FIP bar-graph-style metering, or imitations thereof on GUI (graphical user interface) screens, has caused nearly any sense of adherence to any sort of accepted standard to be abandoned. Most, and especially those on digital equipment, have a very short—if not zero—attack time, which can give rise to misleading readings, and such a wide range of arbitrary release times that it is very difficult to interpret their indications at all. The most an operator can hope to do is to keep it dancing without pinning it. About the best one can rely on is that the top of the meter represents 0 dBfs—or digital full-scale; nominal levels are either −18 dBfs or −20 dBfs (close enough in fader-pushing terms if a world apart technically) depending on whether the influencing force previously used black or beige meters, respectively.

25.15 A Typical Multitrack Console Described

Elsewhere in this chapter, versions of practically every kind of electronic subsystem that finds its way into today’s mixing consoles has been described, explored, and analyzed. Here is a description of a complete commercial multitrack mixing console, together with the trials and tribulations of dealing with the electronics as part of an overall system having a life and needs of its own.

A system can be defined as a means of reducing the versatility of its component parts. Ideally, there should be no system, but practicality dictates that there must be one. The thought is mortifying: hundreds of elements, the microphone amplifiers, differential input amplifiers, line amplifiers, equalizers, filters, and routing matrices roaming loose and needing to be coupled together for each individual operational requirement.

We need a saving grace, and fortunately there is one. Engineering and balancing habits are pretty well entrenched, giving rise to a few well-defined, commonly used elemental combinations. Rationalizing these combinations and arranging easy selection of them as necessary is a good compromise. We’ve not so much lost versatility as gained a family of operating modes.

25.15.1 Channel System Example

This entire channel subsystem relies on the electronic switching elements used being entirely transparent, noiseless, distortionless, clickless, and other impossibilities. Noise due to the potentiometric CMOS switching
employed here is very largely due to the individual summing amplifiers, scaled by the gain asked of them.

Noise resulting from them is defined to low (−100 dBu or better) floor levels—fairly meaningless under the stampede of typical front-end or machine noise.

Distortion is primarily due to the automodulation of the CMOS transmission gates; that is, the path resistance varies with the instantaneous signal voltage. This, at zero level, is typically a nonsensical value. Both the harmonic and intermodulation products are almost unmeasurably low principally because of the near virtual-ground operation of the active CMOS elements. There is no voltage swing, no automodulation.

25.15.2 Function Modes

Reference should be made to Figs. 25-95 through 25-98 during this discussion of the channel system. These illustrations show the overall channel in block diagram form and the various ways the circuit blocks are configured for the different functions expected of the channel in use. Fig. 25-95 has all the reconfiguration represented by diagrammatically accurate but forbiddingly incomprehensible mechanical switching. Figs. 25-96 and 25-97 replace those in the main signal paths with electronic switching elements, which may seem more or less of a jungle, dependent on whether you were brought up on hard-gold contacts or silicon.

Certainly there are fewer electronic switchpoints than there were mechanical. This rationalization is primarily due to yet another incursion of esoteric (for audio) digital things.

A simplified representation of the four basic channel operating modes is given in Fig. 25-98A for recording, Fig. 25-98B for mixdown/direct to stereo, and Fig. 25-98C for overdubbing. The Xs show the switching points. Briefly, main multitrack operating modes and their implementation in this system are outlined here.

25.15.3 Recording Mode

In the recording mode, the object is to get a live source (e.g., microphone) through the signal modification chain (i.e., limiting, equalization) and on to a track or tracks of the multitrack machine. Level control on this path is by the main fader (or VCA fader if automation is applicable). Before and after monitoring of the tape track dedicated to the channel is routed onto the main stereo monitoring/mix-bus via the secondary level control.

25.15.4 Mixdown Mode

The machine return is brought through the modification chain and mixed onto the main stereo monitoring/mix-bus via the main/VCA fader. The machine monitoring chain is disabled.

Since a major justification for keeping the multitrack routing open during mixdown is to provide additional effects feeds, this is best served if the secondary level control is fed post main fader and post mute/solo switching. To enable this, a crossfeed electronic routing is included in Fig. 25-98B. However, independent control is restored when required if a fader reverse is called.

Another mode, direct to stereo, is a derivative of mixdown. It enables live sources to be mixed straight on to the main stereo bus, obviating the need to use multitrack routing.

25.15.5 Overdub Mode

A halfway house between record and mixdown, the overdub mode is intended for use when most of the console is in mixdown but individual channels are being laid or touched up. The signal flow is the same as in the record mode, only with the main/VCA and secondary level controls interchanged. The main/VCA fader in this mode, therefore, controls the monitor feed into the main stereo mix-bus, which ties in with the operation of this fader on all the other channels that are in mixdown. A handy interlock exists in this mode to facilitate single button drop in. When the channel system function is selected to overdub and the monitoring path is set to A check (machine input), a relay closing pair is made that may be plumbed into the remote control access of the machine. Provided the track is armed ready, hitting A check automatically drops the machine into record simultaneously.

25.15.6 Logic Control

This particular console design was intended to be capable of running with or without control by a microprocessor. Much of the localized logic dealing with switches, control, and indication encompasses the necessity to stand alone and in some instances to provide an optional microprocessor with a means of reading back actual console status. Using conventional switch-matrix sensing and latched control/indicator driving by a microcontroller could make redundant much of this hardware, if permanent processor control were envisaged. Similarly, much of the discrete logic
Figure 25-95. In-line multitrack recording and monitoring channel.
Figure 25-96. Channel system—audio paths.
elements would today be wrapped up in programmable CPLD and FPGA (field-programmable gate array) packages for flexibility and to minimize part count and board space. The discrete logic is left detailed here, however, on the basis that it would be useful to have an idea of what sort of logic would need to be programmed into these parts!

A distinction is made in Figs. 25-96 and 25-97 between the analog signal switches and their digital control electronics not purely because of the differing disciplines but for clarity’s sake; that is, to avoid too many lines running all over the place on the drawing.

Each top-panel switch is a momentary-action touch switch with an associated LED indicator (with the exception of the function mode switch). The toggle push-on and push-off characteristic is provided by the basic debouncer/flip-flop circuit, as shown in Fig. 25-99. This action is not only fun, play-worthy, and therefore, fashionable, it also scores in a couple of other important respects:

**Cost.** The combination of a small, mechanically simple, nonlatching, push-to-make switch and a fairly small number of silicon bits is much less expensive than latching pushbutton switches.

**Versatility.** Using electronic latching rather than mechanical catches makes remote/automatic function presetting and triggering comparatively simple.

### 25.15.7 Switch Debouncing

**Debouncing** is removing the ragged edges from a switching signal. Switch contacts do not simply make contact when pressed and break contact on release. The two bits of metal grind against each other or bounce a few times while moving together or apart, resulting in a series of ragged, spiky “almost contacts” rather than simply touch or not touch.

Ordinarily, this doesn’t matter too much, but, if the switch is feeding a bistable flip-flop (as here), the fun begins. Flip-flops are usually edge triggers; on a positive-going transition, another pulse flops it back and so on. A string of rapid, unpredictable pulses, as provided by nearly any mechanical switch, sends flip-flops frantic.

Retarding the switch with time constants is nearly foolproof, but the arrangement in Fig. 25-99 is practically faultless. The 4098 contains two monostables, which are handy since the 4013 contains two flip-flops. It can sense either positive or negative transitions, posi-
Figure 25-98. Channel system—control logic.
tive in this application, catch the very first input transition, and stuff out a uniform, clean, predictable clock pulse for the flip-flop. Subsequent bounces merely extend the output pulse slightly but don’t generate any spurious output transitions. An alternative would be the interspersing of Schmitt trigger buffers between the switches and the flip-flops. These have a very wide hysteresis, which in conjunction with some R/C retarding can also provide surprise-free toggling.

Flip-flops can have their outputs jammed by stuffing the required state-up set (making the $Q$ output go positive) or reset (negative)—an invitation for remote processor control.

25.15.8 Logic Sense

Some of the logic in this particular design is unconventional, all done in the name of reducing component count, largely obviating level-shifting transistors while maintaining the inviolable ground-for-active law of control interfacing. This is a common-sense rule that simply means that any accessible control line should just need to be taken to some reasonable ground in order to activate whatever it’s supposed to—not to a specific voltage above or below ground. This helps avoid the “should this go to $+5 \text{ V}$ or $-24 \text{ V}$” routine, while greatly simplifying system design—grounds are omnipresent.

The main reason for the unusual logic powering, Fig. 25-97, stems from the use of a bipolar PROM in the assignment logic. This needs a tightly controlled 5 V supply, unlike CMOS ICs, which will run off nearly anything with volts on it.

25.15.9 What Is a PROM?

PROMs (or programmable read-only memories) are digital devices used extensively in computer technology for storing individual items of information or sequences of information that are regularly referred to:

- **Memory** is self-explanatory.
- **Read-only** means that in normal operation it’s only possible to retrieve the information that’s stored. New information cannot be put in or the contents modified.
- **Programmable** means, given the right gear and software, prepared information can be written into the PROM. The type used in this design can’t be restuffed though, since the programming is achieved by literally blowing tiny internal fuses in the shape of the data. This seeming inaccessibility is reasonable with such devices where the device cost is cheap compared with programming costs (human time).

The information stored is, of course, binary in nature—a 0 or a 1, up or down, there or not, and so on. The number of these binary bits contained in each PROM can be in the millions. Four megabit proms are now common. For this channel system control, the PROM used stores 256 bits, which, in fact, is still a bit of overkill, but they don’t really come much smaller.

This baby PROM, a Harris 7602, is much like most adult PROMs in that the bits are organized internally in chunks eight wide, as in a digital word (byte). Eight happens to be the byte width of most popular microcontrollers. In the baby PROM there are 32 such bytes of stored data ($32 \times 8 = 256$), each being accessible with a specific 5-bit-wide address code (given by the binary
Consoles 929

numbers from 0 to 31). For any of up to 32 command states, preprogrammed responses for eight output lines are immediately accessible.

This particular type of baby PROM is usually used at the top end of microprocessor memory maps where a page (256 bytes) is given over to the function of the processor vectors, such as interrupts. As an example, if the processor receives a nonmaskable interrupt (NMI), it usually means “Panic! The power is collapsing!” or some other similar situation. NMI makes the processor look at a certain address in the page of the baby PROM, which tells it where to find in memory a program to save the environment (i.e., hide safely all the crucial operating data, quickly).

In the context of this channel system, the PROM outputs drive the analog switches (organized per Fig. 25-96) to route and control the channel and monitor signal paths through the system elements. This occurs in accordance with and under the command of the PROM address inputs, which are indicators of selected channel function (record/mixdown/overdub), local or remote fader reverse commands, and, importantly, mute and solo status.

Most of the control logic is still done in hardware, largely consisting of jammable debouncer/flip-flops. For the channel function control, a single pushbutton that steps through the four functions is realized by a simple 2 bit counter (IC23 in Fig. 25-97). This generates a 2 bit code that feeds both the PROM control inputs and a 4028 binary to decimal decoder IC25, which drives the relative status indicating front-panel LEDs.

Solo, solo-free, and solo-safe are dealt with in IC16, IC20, and IC24, but the relevant action on the analog circuitry is still executed via the PROM. It can be deduced that the solo command and mute of the PROM do just the same thing, resulting in a fair number of duplicated and redundant program codes within the PROM. At least this gives room for expansion or function modification (if and when required) by simple card link changes and a differently programmed PROM. Here is one of digital’s great strengths—the future capability of “chameleoning” a system simply by software changes, not by hardware: a built-in upgrade path.

25.15.10 Logic Meets Analog

The 7602 PROM hangs between logic ground and −5 V (of the split ±5 V logic supply), thus necessitating all input feeds to be similar in swing—0 to −5 V. All the drive logic flip-flops, debouncer, and master bus logic are similarly powered.

Analog transmission gates, such as the design of Fig. 25-96, are required to pass (and stop) analog signals referred to ground and, therefore, of both polarities, so the gates have to be fed from a split supply (in this instance, the ±5 V logic supply).

Converting between the 0 and −5 V logic and the ±5 V control voltage swing needed by the gates is done by using the open-collector output drives of the PROM, Fig. 25-100. Open-collector is exactly that—there is no positive output pull-up internal to this PROM. The idea is that it may be paralleled with other open-collector devices in a wired-OR bus configuration. When the output transistor is turned off, the collector is at a high-impedance state. The collector is pulled up an extra 5 V above the internal supply of the PROM. When the transistor turns on, the collector dutifully zaps down to the −5 V supply. It doesn’t care what is at the other end of the load pulling resistor provided it isn’t of excessive potential (12 V is safe; the output ports are, in fact, the programming path with these devices and much above that may induce some involuntary reprogramming).

Some of the analog switches are driven directly off the PROM outputs, while others have the necessary inverse-switching feed provided by conventional inverters.

As a note to the unwary, bipolar memories such as the 7602 use a lot of power when being switched. This explains the large amount of decoupling festooned around it and the logic supply generally. Needless to say, the analog transmission gates are referred to audio ground, not the click-infested logic ground, despite the fact that they are powered off the logic supply.

![Figure 25-100. Input/output termination (unipolar to bipolar control swing conversion utilizing PROM open-collector output).](image-url)
25.15.11 Auxiliary Channel Feeds

Two prefade (and so premute) feeds are provided on each channel, each with a level control and pannable across a stereo pair of mix-buses. This provides a versatile facility enabling separate stereo foldbacks or four separate feeds. Each of the pairs is selectable to post-fade should extra effect feeds be needed during a heavy mixdown, whereupon they will also be subject to channel mutes. A few effects such as stereo reverberation plate/black box would benefit enormously in operation if they could be sourced from stereo auxiliary feeds such as these.

Four individual postfade effect feeds are individually mutable (locally or remotely), individually level controlled, and selectable to prefade.

Effect feeds are quite often switched during mixes; consequently, analog transmission gates are used, facilitating automation. Local activation is achieved through the debounce/latch arrangement used extensively in the channel mode switching, Figs. 25-99 and 25-101. The latch output drives a simple, single-element transmission gate. Isolation, crosstalk, and noise criteria are not particularly critical on these feeds, but they still come out quite creditably. The console switch-on master reset bus (MRB) cancels all these feeds, leaving a clean slate rather than the alternative unpredictable hordes of ons, offs, and maybes in the event of a power interruption or control zeroing.

25.15.12 Summing Modules

Much of the actual mixing within the system described so far is self-contained. Multitrack routing, when achieved via a matrix, allows multiple sourcing to any
chosen group or machine track. A stereo mixdown of all the channels is possible with this method by selecting them to an arbitrary pair of tracks across which the mastering machine is hung. This is, in fact, the mixdown technique used in many console systems whether in-line or discrete monitoring. Although entirely feasible, it is not the manner in which this particular system is intended to be used, and is becoming rarer in the commercial world.

Stereo mixdown is achieved in the same buses as the multitrack monitor mix, the solo monitor function making its home here, too.

A master group module contains the mix-amps, fader, and line amps pertaining to the stereo bus together with sundry other related things, like mono summing (required for a monitor feed) and clean auxiliary bus access for extending the monitor mix (for effect returns or temporary extra channels).
25.15.13 Mixes to Outputs

The virtual-earth mixing buses of the console all end up in identical mix-amp, attenuator, and line amp configurations. The exceptions are the mono sources (effect sends) that have individual master level controls rather than ganged stereo attenuators and the PFL (which does not need a level control because it is a purely monitoring function). These back-end stages are homed in two of the very few on-off system blocks in this design: stereo monitor/mix (with the master fader) and the PFL summing occupy the master module, while the remaining auxiliary functions are summed in the auxiliary master module, Figs. 25-86 and 25-87.

The outputs are taken to the jackfield, where they are normalized to their appropriate destinations and directly bridged by the differential inputs of the monitor selector switching matrix (adjacent to the field). It is assumed that output transformers or electronic balanced output line amps will be implemented.

25.15.14 Master Functions

Fig. 25-102 shows a simple console master function circuitry. All the clever switching is done in the channels, allowing this unit to be little more than switch contacts. No debouncing is necessary since the master buses directly actuate the set and reset latch functions of the channel function registers.

Lockouts are arranged on the fader main/reverse selection and master monitor A and B switching to prevent both of the relevant control buses from being switched at the same time; this could otherwise lead to

![Diagram](image-url)

Figure 25-102. Desk master function control circuitry.
some very odd things happening inside the channel signal routing. Similarly, a ground follow-through lockout arrangement is used on the master function mode selection. Otherwise, the consequences of more than one button being pushed simultaneously would be to select a virtually random mode.

Note that all the switching is to ground from the logic –5 V supply. This interfaces with the majority of the channel logic as described. An important feature is the master reset bus and its control. Ordinarily, an array of random logic circuitry dependent on flip-flops and latches (of which this design is an example) would, on power up, tend to settle into whatever state these registers felt like at the time. The result would depend on device symmetry, temperature, and humidity, but worse still, the results are not usually repeatable. An intriguing exception to this is the knack of CMOS flip-flops to come back up in their previous state after a short power disablement, probably a function of small charge storage.

### 25.15.15 Power on Reset

Wisdom and common sense dictate that on power up the console should come on neutral, with all channels muted and with monitoring functions such as PFL and solo disabled. The exception to this is if the console control surface is totally under the control of a computer (all functions), in which case it may be arranged to come up in exactly the state in which it was last turned off, or otherwise lost power. Even in this case, it would be wise to bring the monitoring up muted. As well as providing a frame of reference from which to start reusing the console, it saves all the aggravation of finding the one function that’s killing the monitoring. There are few things scarier or more frustrating than a large console that is mysteriously and totally silent. Console mode and basic monitoring conditions can be set up just by pushing the relevant master controls. Processor control of course would afford the console being reinstated to its last used configuration.

TR₁ in Fig. 25-102 grounds the master reset bus (M.R.B.) for as long as the 22 μF capacitor takes to charge up—around a quarter of a second. This charging takes place when the –5 V logic supply appears. Should the supply collapse, the capacitor is rapidly discharged via D₁ ready to reinitialize the M.R.B. signal as soon as power is reestablished.

Although it would be extremely simple to do, no top-panel master reset control is made available because sooner or later someone would hit that button at exactly the wrong moment. This follows the same philosophy that frowns upon a top-panel ac line switch.

### 25.15.16 Meters and Head room

There are plenty of proprietary meters of the popular standards and types, plus quite a few strange ones, too. It’s all a matter of personal preference and the information hopefully gleaned from the assorted needles, lights, and cathode rays dancing before the eyes.

Without jumping into the argument of average versus peak-reading instruments, it is relevant to state that the choice will directly affect the operational levels, the level architecture, the machine lineups, and the various tweaks, notably the input stage limiter threshold in this design. Out of habit, this console was designed with standard PPMs in mind, where the peak operational level throughout the system is expected to be PPM 6, or +8 Bu. Lineup level (i.e., the system and output level for which the front-end gain stage is calibrated) is 0 dBu, PPM 4. This will suit any current or expected PPMs.

VUs are very good for giving an idea of subjective loudness and not worrying you about transients that can often be anything up to 20 dB above the indicated value.

### 25.15.17 System Level Architecture

Nonunity-level architectures are regrettably necessary under some conditions—detailed here are ways (quite typical fixes within most console designs) that are directly applicable to this described console.

Given standard +4 dBm referred VU meters, under normal operational circumstances, head room in any console is perilously skinny. Various ways of dealing with potentially inadequate head room are in use, Fig. 25-103. A favorite is to run the entire console system at a depressed level, usually –4 dB, the necessary 4 dB makeup at the end being done passively by an output transformer ratio stepup. This is a poor choice for two reasons. The transformer stepup arrangement is overly critical to termination impedance, and the frequency response could suffer with a heavily reactive load such as a long line.

A more modern solution on a similar theme is to adopt a depressed level of –6 dBu and make up the level at the output in a quasi-balanced electronic output stage—in this way head room is not compromised at any point along the way.

Head room is mostly a problem in input channels, before the channel gain-controlling element, the fader. Both ragged unpredictable input sources and equalizer gain gobble up the nonmargin. Hopefully, beyond that point the levels and, hence, the mix are easily and well regulated by the faders. Dropping the channel operating...
level by 6 dB or 10 dB helps matters tremendously, and
the gain is made up either in the mix-amps or the post-
fader buffer amps (the latter being normal). This does
compromise bus noise (quiescent console output noise),
but since the main justification for doing it is the high
level of signals present, the pluses outweigh the
minuses. This depressed channel system is worthwhile
in any circumstance, regardless of metering type, where
there is likely to be a great unknown lurking on the end
of an input line.

Some of the disadvantages are that all the channel
insert points operate at the depressed (10 dBu) level,
which may or may not give problems in some less than
versatile outboard devices. The more immediate
concern is that other internal channel circuits will need
adjusting.

Machine line-in feeds from the A and B input
differential amplifiers will need to be dropped by 10 dB.
This drop is easily accomplished by altering the values
of the resistors around electronic switches to scale down
a factor of 3.16 (10 dB), as shown by Fig. 25-104. The
PFL bus mix-amp gains are required to increase 10 dB
(the extra bus noise here is no great crime), and an extra
10 dB of gain is put into the prefader auxiliary feed

buffer amplifiers. Reestablishing main path gain to
unity is simply achieved by upping the gain of the
post-fader buffer amplifier in Fig. 25-104 and by
changing the feedback bottom leg resistors in Fig. 25-96
from $1.8 \, \text{k}\Omega$ to $430 \, \Omega$. This provides for 10 dB of fader
back-off and the necessary 10 dB reinstatement.

If all that sounds complicated, just bear in mind that
it’s achieved with gain changes—in this case just with
resistor changes. It doesn’t matter that the machine
monitor differential input amplifiers are still operating
at a normal undepressed level. The A’ check is directly
monitoring a console output, which is at normal level
anyway, so there is no head room problem. As for the B’
check, if we have more level coming back from the
machine than we’re putting in (A’ check), then it’s time
for realignment.

It is entirely possible to recalculate the values around
the differential amplifier to drop 10 dB and still maintain
input balance, but that would greatly increase the
number of component changes necessary to alter channel
system level. This is no mean consideration should you
choose to do so on a console of 32 or 48 channels.

Ultimately, it is up to the designer to make the
product—this mixer—as transparent and free for the

![Image](https://example.com/image.png)

**Figure 25-103.** System level architecture.
operators as possible. Messing around with system head rooms does somewhat fall into the category of kludge, but as a means to the end of facilitating the music-making process less painful, who can argue? A console is after all a creative tool, not a museum of technical operating standards.

25.16 Consoles and Computers

Varying levels of logical control, remote control, automation, and data storage and recall were common on analog consoles long before digital consoles came along, on which of course there is no option. The “Why?” of such digital control of analog was a much harder question to answer at the time, but decent solutions to most of the requirements were found.

Automated fader systems led to the quest for storing and recalling all console functions, since the instantaneous storage, recall, and automation of console settings had immediate application in several spheres of activity. But by the time this was all achievable with a comparable level of performance as from a nonautomated console, digital mixers were becoming a reality. Since they were of necessity completely programmable, and the control hardware and software was by its very nature already there and in place to do automation to some degree or other, it was a done deal.

What has emerged out of the growth of digital control is the fascinating question of control-surface ergonomics; far from being shackled to the hardware beneath them, now the surfaces can actually be designed to best suit their purpose. Seconds aside, back to back, ten paces then turn, please.

A further set of considerations comes from the wisdom, necessity, and/or desirability of siting the guts of the console (the signal-processing bit) remote from the control surface. Apart from the need for extensive communication between the two (usually attacked by
networking-think) the effect on the design of the console architecture is actually surprisingly minor, and the impacts such as they are will be dealt with piecemeal as required. No, the control surface is the real battleground.

25.16.1 Fader Automation

The first victims of automation were the faders. Once heavy multitrack (16/24 track) had become commonplace, a severely limiting factor of human physiology—only ten fingers—proved something of an obstacle in a mixdown situation demanding considerably in excess of that number. The hitherto classic solution—reduction mixes of subgroups of tracks to a more manageable quantity—forces another tape generation; this is not a good idea considering one of multitrack’s touted advantages is freedom from bouncing.

To be able to remember, and subsequently modify if need be, fader movements during a mix seemed like a good idea. There were, and still are, two fundamental approaches to this requirement:

1. Remember the physical position of the fader and on recall arrange for it to move physically to its required position.

   This first technique was introduced initially by one major manufacturer (Neve’s NECAM system) and with the availability of reasonably economical motorized faders is now fairly widespread. Most others fall broadly into the second camp. Moving fader systems are dearly loved by their users because of their unequivocal indication at all times—by the actual fader positions—of what the system is actually doing. It has one other major benefit—the involuntary hysterical laughter it spontaneously generates from anyone who for the first time sees a swath of motor-driven faders dancing about on their own.

   With the ready availability of such moving faders at cost points suited to nearly every level of application, moving fader automation systems have become the de facto standard for both automated analog and digital mixers.

2. Drive a voltage-controlled amplifier (VCA) from the fader and on recall reapply the appropriate control voltage to the VCA—the fader itself is not then controlling the VCA, Fig. 25-105.

   VCA systems remain viable in analog consoles, though, since they offer advantages at that crucial fader point that moving faders cannot alone fulfill. Although VCA automation systems were once implemented in a purely analog fashion, the fader position values being stored by a PWM or voltage-to-frequency conversion methodology on an analog tape track, these techniques mercifully gave way to digital manipulation and storage as soon as it was practicable.

   A nulling indicator, as described later, is usually employed to match actual VCA gains to that notionally indicated by the fader.

![Figure 25-105. Simplistic VCA-type fader automation.](image)

25.16.2 VCAs

Several functions in mixing consoles cry out for a perfect and consistent controllable gain block. In addition to automated fader systems, dynamics control and other analog-controlled gain stages could all benefit by something that looks like Fig. 25-106. It is a black box to which audio is applied, from which audio is extracted, and a control port that determines how much audio is passed. Ideally the law of the control signal should be predictable and consistent. No biasing, no tweaks, no singing, no dancing. Should be easy, right?

![Figure 25-106. Ideal gain control](image)

As seen elsewhere, raw active electronic devices can be used as gain-variable stages with varying degrees of success, compromises, and weirdnesses; their limitations are various but notably include limited audio signal handling capability, high distortion, and often nonlinear (or nonsensible) control-voltage laws. In feedback-style automatic gain-reduction circuits such as compressors and limiters, the law of nonlinearity tends to disappear within the servo-loop feedback and have
either negligible or—better yet—an interesting effect on the behavior of the circuit in response to stimulation. Effectively biased—to avoid their turned-off regions—FETs can have a square law response, transistors an exponential (logarithmic) response of collector current with respect to applied base voltage. Logarithmic?—dBs are logarithmic!

25.16.2.1 Transistor Junctions

The departure point for the journey to VCA-dom is Fig. 25-107A, which is for our immediate purpose actually pretty useless but elsewhere is known as a cascode amplifier. The upper transistor’s emitter serves as a nonvoltage varying load to the lower transistor, allowing it to achieve large bandwidth current gain free of Miller effect; the upper transistor (as essentially a common-base amplifier) has no current gain but serves to buffer the load in its collector from the lower transistor, which is busy doing all the work. Varying the base voltage of the upper transistor has little effect on anything other than altering the maximum voltage swing capability on the load, certainly not gain, which is all very much different from the long-tailed pair of Fig. 25-107B. Note that the upper stage is and can be used differentially, as is the output, but it works single-ended too. Here the current through the load is modified by signals applied to either or both upper or lower stage transistor bases. The overall current through the arrangement is set by the lower transistor, which is shared by the upper two; assuming both of the upper two transistor’s bases are held at the same voltage, the currents will be shared equally; if one is raised with respect to the other though, its share of the current will rise, having stolen it from the other and vice versa (the total current stays the same). So, wobbling the lower transistor’s base will change the overall current, an upper’s base that in both upper transistors, complimentarily, the combined effect is multiplicative gain variation. (Conveniently, one of the signals [usually the audio] can be applied to and recovered from the pair of upper transistors differentially, although it is not unusual for them to be driven one-sided, the opposing base grounded.) The one remaining drawback is that the operating points of all the devices are moving around in accord with the control voltage applied to the base of the lower transistor and so the control voltage unavoidably appears as part and parcel of the derived output signal.

25.16.2.2 Gilbert Cell

Fig. 25-107C shows what is the essential heart of a good VCA—two long-tailed pairs back-to-back. Actually it’s a bit more like three; a long-tailed pair with a long-tailed pair in each output leg. So universal is this basic configuration that it has become the Hoover of VCAs—it is what springs to mind when VCA is mentioned; variations and extensions to this theme are used extensively. Called variously the Gilbert cell or, by RF guys, a double-balanced modulator its main attributes are the innate cancellation in the output of both the applied
signal and of the control voltage (CV); all that appears at the output is the product of the applied signal and CV. Product implies it is the result of multiplication, which it indeed is. The circuit is the basis of a good if hardly perfect analog multiplier. Better yet, since it uses good old transistors with their exponential base-voltage to collector-current response, the control law is for the large part linear with respect to decibels of gain and attenuation. Which is why all the bother and complication.

25.16.2.3 Log-Antilog Cell

A different approach, resulting in a different internal topology is what could be called the log-anti-log approach and is schematically described for simplicity (although the actual integrated implementation is nothing like this) in Fig. 25-108.

It again relies on the exponential relationship between the base voltage and collector current of the transistor. The first stage is a log convertor, converting the (positive-going in this example) input signal into a (negative-going) logarithmically representative voltage; summed in with this is the control voltage, which, since we’re in log domain, is linear voltage per dB; the composite is then antilogged back into the real world. The effect of adding or subtracting the control voltage is to increase or decrease the linear end-to-end gain.

25.16.2.4 Commercial VCAs

Commercial IC VCAs typically use one or other of these approaches; VCAs are almost always acquired and used in IC form. One built out of discretes will work, of course, but the inherently much closer matching of active semiconductors on the same substrate reduces much matching of parts and tweaking out of various offsets, and the manufacturers have gone to the bother of thermally compensating and biasing everything up such that it “plays nice” with the real world. Nevertheless, for optimum operation of this arrangement or circuits based on it, preset adjustments are the norm, even for integrated versions. Stabilization of operation against temperature is a further complication, if perhaps less so for consoles that will spend their lives in air-conditioned environments.

Beyond the basic and remarkably well-performing circuit element, there are, of course, other issues that come along with real live electronics. A prime consideration is noise; the best operating points for the transistors vary depending on the parameter that needs to be optimal (see the discussion on microphone amplifiers for collector-current versus noise); what may be right for noise almost certainly isn’t right for adequate large-signal handling. Attempts have been made to provide for both by altering the bias point of the transistors dynamically in accord with applied signals, such that they’re closer to right for both the low-level region (noise) and high-level operation. Another approach has been to parallel up many of the IC VCAs in order to improve the combined devices’ noise-voltage to noise-current ratios to improve noise and better suit operation at ordinary audio signal impedances and levels (this goes hand-in-hand with paralleling or using multiparallel input transistors to optimize OSI in transformerless microphone amplifiers).

Input buffering and conditioning of the control signals makes them easy to use; already quite linear, the linearity can be extended over a greater control range and can be arranged to be changed at so many dB per volt of control signal (say, 20 dB/V) as to be convenient with the A/D and D/A converters in an automation system and the voltage swing off dc-driven faders. Typically, though, the control port sensitivity on integrated VCAs can be much higher than this—a few mV per dB—and needs to be treated with respect.

25.16.2.5 Control Voltage Noise

This discussion highlights a crucial design issue—that of ensuring a very quiet control signal. This might seem an odd concern until one realizes that at typical control sensitivities, mere mV of undesired ripple or noise on that control line will modulate the through audio noticeably. Note modulate. Since the balanced modulator that is the VCA will not permit control voltage itself into the output, a real audio signal has to be passing through the VCA for this modulation to take place. This, more than anything, is the underlying cause of VCAs’ largely undeserved reputation for sounding dirty. Like all these kinds of aspersions, there is a germ of a reality behind them. And this one is CV noise. Any circuitry involved in the CV should be handled with the care one would apply to the “real” signal path; there is a very real temp-
tation to be more casual (and cheaper) with control stuff that should be avoided.

A less-than-obvious concern springs from the fact that the audio path and the control path are not only cross-disciplinary, but are architecturally dissimilar. Audio paths are (assuming mixer channels) following the signal flow, as are their grounds, while the control voltages for a number of, if not all, channels are being handled en masse and distributed star fashion. If ever there was an inadvertent recipe for a ground-induced noise problem, this is it. If the CV is referenced to a ground that is moving in any fashion at all in relation to the audio ground at the VCA, then that difference is effectively added to the CV as far as the VCA is concerned creating noise modulation.

25.16.2.6 VCA Channel Application

Fig. 25-109 shows a typical implementation of a high-end integrated VCA.

The THAT Corporation (“son of dbx”) VCA-type 2180 is a current-in, current-out device for audio, hence, a standard current-to-voltage convertor using a good bipolar op-amp following. Note also a seeming overkill op-amp on the control-voltage summer. The control port is where things get interesting. The control feed to the VCA can be a summed combination of several different sources (a quick point here—since VCA control voltages are logarithmic, adding voltages results in multiplication in the VCA, or in other words, the dBs represented by the voltages add or subtract):

1. The channel fader, only it isn’t, really. It’s actually the output of a D/A convertor that is either reflecting the fader position as sensed by an A/D convertor, or replaying a prior fader position from the automation system. But, for now, we’ll call it the fader.

2. Gain-reduction control from the channel dynamics. It is common to use the high-quality fader VCA as the gain-control element for on-channel dynamics. It presupposes the dynamics have deterministic feed-forward detectors and conditioners. Obviously, a feedback-style compressor could not use this VCA.

3. VCA subgroups. A common feature on sound-reinforcement consoles, these are controlled by a central set of a number of VCA group master faders (usually eight). These generate a control voltage,

Figure 25-109. Simplified channel-style VCA using commercial IC.
each of which is bused up and down the length of the console; each channel has the option of selecting one (or more, if one likes danger in one’s life) of these voltages to be summed into its own VCA. This is a very convenient manner of grouping related channels under a control without having to create real audio subgroups.

4. VCA master. Again, a centralized fader only operating as an overall master over all channels contributing to the main mix bus. Although seeming to be redundant being that there is almost certainly a real audio fader on the mix bus output, a VCA Master has the advantage that all the levels of sources contributing to a mix can be adjusted, rather than the output of the mix stage. Helps avoid headroom problems in the mix stage.

It should be stressed that the 5 V supply for the 0 to 5 V control signals should be oppressively regulated and fabulously quiet, squeaky clean. Borrowing some off the nearest micro and hanging 100 nF across it doesn’t count—sorry.

In console designs with sophisticated computer control, all but the local channel dynamics control signal are manipulated and summed digitally and this composite result is fed to the channel VCA via a D/A convertor; this dramatically simplifies the multiplicity of summed analog control voltages per channel.

### 25.16.3 Digitally Controlled Amplifiers

VCAs are not the solution for all variable control in analog circuitry. In order to be driven from a digital control system a D/A convertor output needs to be used to derive an analog control voltage for each VCA. This can get very expensive, very quickly. A gain controllable stage that can be more directly connected to the controlling microcontroller is desirable.

#### 25.16.3.1 Multiplying DACs

A more direct approach, meaning it can be driven directly off a digital control system, is to use a multiplying digital to analog convertor (MDAC) (don’t you just love that “multiplying” bit?)—In particular, a referenced-input four quadrant multiplier, which implies it can produce an output both positive and negative in potential (or current in this particular case) and which is proportional to a voltage applied to its reference terminal, Fig. 25-110. Now, bear in mind these devices were never intended to be used in this way, but luckily they do so well.

The audio signal is applied to the reference pin; a digital number, in this case 12 bits wide serially fed into the device, is applied to the 12 bit R-2R-style ladder DAC, Fig. 25-127; the audio signal is attenuated in proportion to the applied digital number with respect to the 12 bit maximum (1024 steps). The output current is sensed and converted back to a voltage by the following virtual-earth input amplifier, using the friendly internal feedback resistor around the op-amp. The interface is dead simple, linearity is pretty good, the signal handling is excellent, and the noise isn’t bad—dancing in the streets!—except every time the gain is changed (a new digital word transferred into it) it makes a little tick noise, which is very audible on high-level signals, low-frequency signals, and especially the combination. In fact, as the gain is moved (a la fader), classic zipper noise is very evident. The only good news about all this is that for a large part, program material’s spectral content masks this noise. However, when the device is used as a frequency or Q-determining element in an equalizer, the effect becomes comical; depending on one’s sense of humor. There are two approaches necessary to nail this noise, since it is actually due to two separate causes.

#### 25.16.3.2 Charge Injection

This is a near unavoidable effect in CMOS and other electronic switches, where a tiny amount of differentiated charge impinges itself onto the signal path from transitions of the control port. In a multiplying DAC, any number of bits may be changing as the gain is varied, and so the total charge injection varies correspondingly. It is, however, almost completely independent of the applied audio signal.

Cancellation works well, with reservations. One approach is simply to use a second MDAC with its own inverter that sums into the virtual-earth point of the main MDAC path, with its reference pin undriven. However, with only slightly more complexity the
arrangement as in Fig. 25-111 emerges, which is our old friend the Superbal differential summing arrangement fed by both DACs being driven differentially. Not only does this provide a gain-control stage with full-rail differential signal-handling capability, but also the charge-injection noise is substantially canceled. To get the best noise cancellation, however, the DACs really need to be matched (a DCR test through the ladder is a reasonable guide for matching) or pairs on the same substrate employed.

25.16.3.3 Zero-Crossing

The second impulse noise cause is attempting to switch a high-value signal; any truncated or very rapidly level-shifted high-level signal is going to go “click!” (Run tone through a switch and turn it on and off a few times. The switch click—nicknamed tone-click—will vary in intensity seemingly at random; that’s because the switching is occurring at random points through the sine wave’s cycle. Those at or near the crests of the sine wave will click loudest.) The simple solution is, don’t. If one arranges only to change gain while the applied signal is crossing through zero or is at a low level, this manifestation will all but disappear.

This is a control issue rather than an audio path issue; Fig. 25-111 illustrates differential MDACs with a peripheral circuit that achieves near-zero-crossing. The MDACs in Figs. 25-110 and 25-111 are double-buffered. In other words, it is possible to load a new gain value into them without disturbing the current operational gain and then transfer the new value over when desired by means of the /LD control pin. The arrangement shown allows the controlling micro to do a “hit and run” on the circuit, depositing the new gain data and telling the circuit to take it at the next zero-crossing; the micro doesn’t have to hang around waiting for a
zero-cross to occur. It can be zooming around setting up other MDACs in the meantime or attending to other microlike things. The circuit is addressed, the new gain data serially clocked into the MDACs’ first buffer and then the micro nudges high the ARM line. (The ARM line needs only an instantaneous +5 V pulse; positive feedback around the first comparator keeps it set. Likewise, it can if desired be nudged down to dis-ARM—nice, but useless.) Comparators wait for the applied audio signal to fall into a low near-zero signal window, at which point an instantaneous strobe pulse for the /LDs is generated, which latches the new gain data into the MDAC ladder and simultaneously cancels the ARMing.

This arrangement would not be the avenue best traveled for dynamics, being that it takes a comparatively long time to load in data and wait for zero-crossings, limiting apparent responsiveness—VCAs are a far better course for dynamics—but for anything else it works a treat. With reasonably matched 12 bit MDACs this gain-control circuit is virtually transparent and even works well in high-Q filters and EQs. It’s still not inexpensive though, and the dawning realization of exactly how many of these circuits (or DAC/VCAs) would be necessary to fulfill complete automation of a decent size mixing console, and just how much they’d all cost, has quite a stunning effect.

25.16.4 Discrete Logic and Programmable Gate Arrays

In the next few (as in many earlier) pages, some interface circuitry will be described in seeming excruciating detail; the literal approaches taken will be valid for small or localized circumstances where discrete logic makes sense and the tremendous advantages (cost, board real estate) of integration into large-scale programmable digital parts cannot be realized; where the system is large enough, the detail serves as a road map for what needs to be emulated in the PLD (programmable logic device) or FPGA (field-programmable gate array). The ubiquity of these parts now has led to a hardware design approach that is at once bold yet somewhat alien to those who still remember tape-and-dot layouts; everything on a board, say switches, resolvers, converters, etc., are taken directly to pins on a gate array; the interface to the host microcontroller is brought to the gate array; then how it’s all interconnected, strategized, timed, polled, strobed, etc., becomes a pure (software) programming exercise for the gate array. Errors and changes similarly become just software changes, too, not board re-spins.

25.16.5 Recall and Reset

Remembering the position of controls in a conventional console was the great innovative burst of the late 1970s. The niceties of techniques vary, of course, but Figs. 25-112 to 25-116 are reasonably representative. The great advantage of this sort of method is that it can be applied to an existing design with virtually no modification; all that’s required is a rider pot on the back of variable controls (although this can be a bit difficult with dual-concentric pots) and an extra pair of contacts on switches.

25.16.6 Data Acquisition

The digital data-capture system is fairly straightforward. Switch closures are sensed in batches of 8 (or 16 if a large microcomputer or a minicomputer is in use), while each individual pot position is resolved to the accuracy afforded by an 8 bit analog-to-digital (A/D) converter—256 possible positions. Although very high for resolution and practical resetability of most pots, it is actually harder work reducing the capability than leaving it be! This may be true for pots, but with high-quality faders it may seem too coarse; 12 bit resolution may be necessary.

Two different types of input multiplexers are needed, one for switch closure sensing and an analog switcher for the rider-pot voltages. In computer thinking, each set of eight switches and each rider-pot is regarded as a single memory address; an entire console worth of control settings occupies a chunk of the computer memory map. It’s easy for the processor to run through these addresses and collect a set of data.

In Fig. 25-112 a channel’s worth of multiplexing is shown—32 switch sensings and 16 pots. Inexpensive CMOS switchers are used throughout; speed isn’t a real problem. The switch-sense multiplexers directly hit an 8 bit data bus, which can either be the actual processor data bus (if the processor clock speed isn’t too fast for the CMOS propagation delays) or, ordinarily, a buffered sub-bus with slower timing. Speed freaks wondering why things are almost deliberately slowed down should remember two things:

1. A data acquisition system such as this running at even a leisurely processor clock rate is quick! This is not a real-time variable system, it’s intended mostly for snapshot storage of console status; the acquired data is really trivial by most processor system standards.
2. The A/D conversion time for the pots keeps the processor hanging about in wait states far longer.
Figure 25-112. Rider switch multiplexing.
Figure 25-113. Rider pot multiplexing and address decoding.

Figure 25-114. An A/D converter (as part of the system in Fig. 25-113).
A/D conversion can be done in a number of fashions for this system.

25.16.7 Control A/D Conversion: Central or Distributed?

Central conversion means that there is just one A/D converter in the processor rack frame. All the multiplexed rider-pot voltages hit one bus, which is then A/D converted centrally and the result of the conversion goes directly to the processor data bus. The obvious advantage is low cost—only one converter. Disadvantages are speed (a successive-approximation converter takes several processor clock cycles to perform a conversion; this can be obviated by using a very high-speed comparator-type flash converter) and bus slewing (caused mostly by bus capacitance). Since each rider-pot source is not zero impedance unless it’s at one end of its track or the other and CMOS analog transmission gates have a finite on impedance, there is a definite time constant involved, with the bus capacitance needing a certain amount of time to charge to the correct potential (as determined by the rider pot). The previous bus potential can, of course, be anywhere depending on the previously selected position of the pot. Even if this time constant can be made short with respect to an acquisition cycle, it even then really can make a nonsense of 256 level, 8 bit resolution!

Buffering each rider pot to present a known zero impedance to the multiplexer is a partial solution; buffering the multiplexer output—a seemingly obvious solution—creates more problems. First, the buffer output needs to be gated away from the bus for the times it’s not addressed, so there is a transmission gate impedance there regardless. Second, it has to be a very fast follower if it isn’t to create worse slewing than the bus! Remember that the multiplexers are switching at processor or sub-bus speed. Suitable amplifiers tend to be as expensive as they are fast.

Distributed A/D essentially means having a converter on each subassembly (channel) or for a small number of pots. There are, for example, proprietary converters that continually read and cycle through eight inputs independently of the main processor, yet allow free access to the collected data. Either a batch of these or the equivalent built from individual converters and multiplexers allows the processor to work unhampered by conversion-related hangups, while also keeping all system interconnections digital. Similarly, this method avoids gross bus-slewing (there would no longer be a long analog bus). As always, there are difficulties:

1. Although 8 bit successive approximation A/D chips are now cheap, the number has grown.
2. There are more bits on the channel subassembly.
3. The multiplexers feeding the on-board converter are still switching at high speed—slewing inaccuracies are still possible. Clever priming algorithms can increase conversion accuracies while maintaining a high overall acquisition rate, almost as high as for switch-closure bytes. These set in motion a conversion on one channel, allowing plenty of time for switcher settling and so on before the result is looked for on the bus. During the idle period the computer is dealing with other setups and results from other channels.

Both central and distributed systems are successfully used in circumstances where ultimate speed isn’t that important. Remember that this is not intended as a real-time application and the actual amount of data is small. Accurate enough resolution is reasonably easily achieved.

With the cost of such devices becoming pocket change, it is not unrealistic to throw a microcontroller at each channel simply to perform these tasks; a significant reduction in parts can be afforded.

25.16.8 Recall Display

Figs. 25-114 through 25-116 describe how all the relevant console control positions can be digitized into processor-manageable form. Storage on a mass medium such as hard disk or network is a fairly simple computer file-management exercise, as is recalling it. What to do with the recalled information is now the question.

It is assumed that this particular requirement is informational recall only, not hardware reset (i.e., setting up
the parameters of the channel to their stored values). Eyeball comparison and human tweaking is the resetting mechanism employed. The comparison is between a recalled value displayed on a meter, LED column, bar display, null indicator, or up on a GUI (Graphical User Interface) screen, and the immediate real value read from the control in question and displayed on an adjacent display. As the relevant control is tweaked, its indicated value will be higher or lower than the stored value; when the two are matched, then the control position is the same as it was when the snapshot was taken. Fig. 25-115 shows in simplistic form the basis of the matching process.

GUI displays are presently the easiest way of performing this matching. So much information is visible at once, which is a blessing in this circumstance.

Even with increasingly common totally programmable/recallable consoles, screen-based display of control statuses is a very useful function, if in addition to localized feedback to each individual control. It looks good, too.

25.16.9 Nulling

Null indicators are particularly easy to implement and use. They usually take the form of a pair of LEDs adjacent to the relevant control. If the real value is higher than the recalled value, the upper LED lights; if it is less, the lower one lights. If they both come on, the two values are matched. Even simpler nulling indicators take the form of a single LED that only comes on (or alternatively goes out) when the two values match. A nicer arrangement is a single-cell green/red LED giving an unequivocal “go” or “no go” indication. This device makes it particularly easy to spot anything out of order on a channel.

A fairly elaborate demultiplexing system has to be plumbed onto the channel board, however, to deliver the software-derived nulling indications to the front-panel LEDs; Fig. 25-116 is representative. A further amount of processor memory area needs to be dedicated for this output facility in addition to that already spoken for by the input multiplexing.

Another software consideration when using null indicators is that the chance of actually finding the 1 in 256 position that is correct is pretty slim. Reducing the effective resolutional accuracy to fewer bits can make the operation a lot simpler. The accuracy of the recall system can easily outstrip that which it is monitoring and it is a judgment call between resetting precision and the ease of so doing.

As laborious as these facilities may be operationally, a complete reset of console parameters can be achieved. It is considerably less laborious and inaccurate than writing everything down.

Interestingly enough, any bus-slew inaccuracies engendered on storage tend to be canceled during recall. When all the controls on a channel are reset at or close to their original settings, all the bus errors will be very similar to those present when stored.

25.16.10 Resetting Functions

The next logical step in developing computer assistance is for the machine not only to remember console settings but also to reestablish the console to its previous operational state on command. This means that if the multitrack routing on channel 27 was going to machine track 15 when the console status was stored, then regardless of what has happened or how the routing may have altered or configurations changed, upon recall channel 27 will go to track 15.

Most of the circuitry described in this chapter, especially the multitrack console example, is from a generation of design where active resetting of all major switched functions was a requirement. Variable controls were not even considered as candidates for resettability since it demanded too great a shift in technology. As we will see, the techniques necessary for that become instrumental in a deeper, broader change of console design, structure, operation, and philosophy.

Every switched function that is intended to reset needs to be made electronically controllable; the techniques are detailed in earlier sections. This replacement, by and large, has already been implemented with other ends in mind, such as simplifying PC layouts, avoiding large physical switches, and, not the least, facilitating some of the tortuous signal rerouting required in a modern production console.

In addition to the data acquisition system as just described (i.e., switches to computer), a second digital distribution system—computer to switches—is required. Techniques similar to those described for nulling indication work well.

25.16.11 Motorized Pots and Faders

Motorized pots and faders look and feel like conventional ones, only a clutched motor drive controlled by a servo allows the mechanics to be reset to any point on their travel. A rider track, either a normal resistive track encoded by an A/D converter or a digital track direct input allows a microcontroller to keep track of the posi-
Comparing its present position with one previously stored drives the servo to equalize the two—i.e., return the control to its prior position.

These are increasingly used in newer consoles, particularly automated or soft consoles, where one physical control can be responsible for many channels or functions.

### 25.16.12 Resolvers

Resolvers are continuously rotating (no end stop) controls that otherwise look like a conventional potentiometer. Indication for these is commonly arranged to be a circularly disposed set of LEDs around or within the resolver knob rather than linear, adjacent. Such arrangements of varying degrees of cleverness are a staple of control surfaces nowadays. A resolver, when rotated, sends out two streams of pulses, half overlapping as in Fig. 25-117; in other words, they are 90° out-of-phase or in quadrature. This is enough information to determine not only how fast it is rotating (by counting the number of pulses from one of the trains) but also in which direction. These two, rate and direction sense, are enough for a controlling processor to analyze and appropriately perform control.

The simple circuit of Fig. 25-118 sorts it out; it's a 4013 D-type latch. The data port is fed by one train, while the edge-triggered clock input is fed by the other.
If the clock is triggered by the rising edge of the A train and the B train is active, then the latch output goes high, indicating one direction of rotation (left to right in Fig. 25-117). In the other direction, the rising clock edge from A corresponds to B being inactive, so the latch output goes low.

It is rather a simplistic circuit that assumes that the making contacts of the resolver are perfect and no false triggering will occur. With more swanky optical resolvers this may be true, but with mechanical ones a little debounce clean up prior to the D-latch gates may be advisable.

25.16.13 Control Surfaces

A large problem with recording and live consoles has been precisely that—they’ve gotten large. Console channels have grown into long, thin strips for purely historical reasons, and the manufacturing technique of hanging all the signal-path electronics on acres of dense PC card has just tagged along with little evolution. Removing the audio electronics (analog or digital) from the control surface into a remotely controlled equipment rack seemed quite an obvious development, although until recently it was a technically unwieldy one. Many types of analog circuits lend themselves to direct remoting. For example, VCAs for level control need, in essence, a single dc control line. Others, such as equalizers and microphone preamplifiers, don’t. Noise and difficulties in extending nonzero-impedance configurations are both significant problems. As with everything else, these areas of difficulty look quite different given a dose of digits. As has been seen, with only minor compromises, digitally controlled remotoable audio circuits of all sorts are realizable at some cost and complexity; it is entirely possible for the control surface to become now just that, no audio need go anywhere near it.

The question of whether the control surface and signal processing electronics should be divorced and live in environments possibly better suited to them is a more vital one with digital mixers than with analog; although possible, it was (is) actually very expensive to do remote, fully digitally controlled analog (DCA) circuitry that sounded decent and wasn’t riddled with clicks, burps, and fizzies. It is more expensive now, amusingly, than having a fully digital signal path, which has really sorted that argument out once and for all.

25.16.13.1 The Single Channel Concept

There is an immediately apparent redundancy with large consoles—rows and rows of identical channel modules. The first intuitive step would be to reduce all those to just one set of channel controls that is selectable or assignable to any channel that needs tweaking. The first modification to this rather simplistic single-channel console concept is that the main level faders need to be kept continuously available in front of the operator; a button adjacent to each of the individual faders (the “ME!” button) calls the set of assignable channel controls to the channel to which that fader is related.

The second modification concerns the assigned controls. Like the knobless fader, they have to be separately acting for indicating. On being called, the indicating part of the control adopts the settings pertinent to that channel; the control, whether it be knob, switch, or fader style, can then act on the selected channel with the indicators following their action on the remote circuitry.
A wide and glittering variety of controls have evolved to suit this requirement, but they all basically have a row or concentric ring of indicating lights, fluorescent indicators, or LCD panels disposed around the digital resolver control knob. Alternatives to knobs, switches, and indicators such as interactive GUI screens suffer from an ergonomic disconnect between the physical operation of the control and from where the relevant feedback is displayed, unless the control becomes a mouse-driven widget on the screen. GUIs do, however, pose a very attractive supplemental display method, if not primary.

A third modification to the initial rationalization concerns the many auxiliary mixes found in a console, whether they be for effect feeds, foldback, or, perhaps most importantly, multitrack monitoring. Although the controls for these are traditionally regarded as channel controls, intuitively they are thought of and operated on horizontally across the console; if someone’s setting up a foldback mix they’d most likely be working along the row of controls for that mix bus (to which they’d also almost certainly be listening via monitoring) and have very little interest in any other channel controls at all. Making the operator select each channel at a time to do such a routine mix setup is a very retrograde move—it imposes an unwelcome multi step process that diverts concentration from the task at hand to the means of achieving it. Quite sensibly then, any same-function bus-oriented controls should become accessible together. This is precisely the rationale behind the channel faders all being accessible simultaneously. Ideally, a row of interactive knobs, one per channel across the console, the function of which follows the feature of interest (like that foldback mix) is appealing. Such have been variously called smart bus or virtual controls. A neat bit of further rationalization comes into play here; the consolewide set of controls implied in having parallel access to auxiliary buses (meaning that in addition to a fader for each channel there would be an auxiliary bus control also) can be avoided if really necessary by using the already existent faders. After all, if we’re busy setting up an auxiliary mix, we won’t be overly concerned about other mixes, including the main one. Even if something does need instant attention, reassigning the faders to main mix is only a button away.

So here is the essence of control surface rationalization. There would be a row of moving faders and possibly a smart knob, one for each channel, with an adjacent control select button (ME!) that renders a singular set of channel controls (whether glass or physical) operative on that particular channel. We would also have a row of buttons (with again possibly GUI supple-

mentation) that selects on which mix-bus(es) the fader row is acting.

Early practical experience with this showed, even with operators who came to grips with the single-channel concept readily, that there should be ideally more than one set of channel controls—it is a common requirement to play two or more channels against each other in a mix. Secondarily it was felt that having a set of controls always set up on the one critical channel in a mix (the money mic) and having one or more floating surfaces perhaps represented a better compromise. This represents the fourth major modification to the single-channel concept, although most rationalized designs still lean to just supplying the one set of channel controls.

The great beauty of making all controls transient (i.e., not totally dedicated to any one channel’s function) is that all console functions are implicitly digitally stored, recallable, manipulatable, and automatable.

### 25.16.13.2 Commercial Console Control Surfaces

There are, however, very strong reasons for retaining the single control per function and module strip layout familiar from big analog consoles of yore over to digital consoles, regardless of the undoubted temptation to rationalize.

By way of prime example, Figs. 25-119 and 25-120 show a world-class analog production console, the SSL Duality, and the corresponding world-class digital production console, the SSL C200—if you can tell them apart—which is the whole point. The very sensible argument is that there is a very large user base familiar with the ergonomics and accomplished in the use of the analog console, so why on earth force a learning curve on them? Both of these consoles are intended to work in a highly integrated fashion with/as digital audio workstations, explored below.

At the other end of the rationalization spectrum is the Innova-Son Compact, shown in Fig. 25-121. This is as close to the single-channel concept as it is possible to get; other than the faders all controls are centralized, following the ME! button’s activation on the desired channel. There are some very clever features not obvious from the photograph: all the faders are moving faders; if a channel ME! button is pressed, all the group faders move to represent that channel’s feeds to each of those groups. If a group ME! is pressed, all the channel faders move to represent each of the channels’ contributions to that group. A very impressive surface and fun to drive.

It is not a surprising leap to see that a rationalized surface such as that can have the input (and output for
that matter) channels paged; this means that a switch can instantly throw a whole second (or more) batch of controlled channels up onto the surface. Superficially a great idea, since a modest-sized surface can drive a much larger console, this seemingly facile addition is far harder to come to grips with operationally than rationalizing the channels themselves was. It is quite unnerving to have half a console disappear! It takes considerable effort to design and engineer a surface with enough clues as to the background channels’ existence and well-being to make paging a comfortable operation.

Fig. 25-122 shows a highly considered control surface design somewhere between the two extremes of knob-per-function and completely rationalized. The Wheatstone D-12 television audio console has centralized EQ, dynamics, routing, surround panning, auxiliary and mix-minus feeds, which are brought into play by, guess what, a ME! button on each relevant channel. Additionally, though, it is to be noted that there remains a considerable amount of localized control on each channel; these controls are what an operator needs to get his or her hands on immediately (and which of course can differ between setup and when on-air contexts), with no intervening selection step involved. (Remember, broadcast is a high-stakes no-second-take environment). Input metering is adjacent to each fader, and two sets of channel ID indication above each fader help assuage paging concerns; full console status and metering are spread across the numerous GUI displays in the penthouse.

There are circumstances where the use of a room might be quite diverse over the course of a workday or likewise the technical adeptness of the users; in mind is that of a radio broadcast studio. One could have the problem of there being a perceived baffling sea of knobs for a disk jockey, yet insufficient control for a commercial producer. A convenient solution, falling out of the soft control surface concept, is shown in Figure 25-123; the hardware surface is very basic—just what an on-air presenter needs—but the (removable if need be) screen can be ME’d and mouse driven to have a full set of EQ, dynamics, and effects per channel: happy advertising.
producer. It would even be possible to run the console entirely from the screen, with no regard or need for the hardware surface.

And so in a few short paragraphs, we’ve moved from a knob per function to no knobs at all. Already in the fairly young game of control surface design sans frontiers manufacturers are rightly taking the measure of their cliental and producing surfaces much closer to their actual requirements than ever before, liberated by digital control. It is very encouraging. There is no universal perfect control surface solution; seemingly polar protagonists of the knob-per-function and fader-and-a-button approaches are equally exactly correct.

25.16.13.3 Control Surface Intelligence

Even if there is no signal processing going on in the same box, the control surface still has an awful lot going on inside it, Fig. 25-124. Typically there will be a large embedded controller, or even a PC-style microcomputer to administer things such as control surface host; it will likely be of the x86 persuasion, or a capable

**Figure 25-123.** Wheatstone Evolution 6 Console. Courtesy Wheatstone Corp.

**Figure 25-124.** Control surface control architecture
embedded processor such as an ARM. Being short of the tyranny of thin module strips allows the garnering of a reasonable number of controls’ data and the driving of a reasonable number of indicators without the indirection and bottle-necking encumbrance of a console long data busing scheme. Even a large console’s worth of controls and indicators is easy pickings for a large processor treating them as medium-speed peripherals through industry standard buffers or FPGAs. Should a devolved scheme be necessary from a semimodular or macromodular approach to the surface each submodule may be looked after by a smaller embedded micro or even an FPGA, with communication from each back to the host by fast serial link.

Chances are, this host will also be feeding data to a subsidiary LCD screen driver processor (or two, or three), talking down Ethernet to the signal-processing host sending it fresh parameters (or even coefficient sets if they’re being calculated at the surface end), receiving back from the processing host packets of metering information to be divvied out to the appropriate displays, and last but certainly not least attending to the level of automation (static snapshots or real time) in which the console is operating. To this end, it almost certainly has mass storage, such as loads of flash ram, and/or a hard drive.

25.16.13.4 Multiuser, Multifunction

User arguments can run something like, “But we might want to change several things at once, and Fred the producer likes to look after the monitor mix while I do the rest.” The control software would naturally allow simultaneous control actions on a pair or across a group of channels to be ganged, which is fairly trivial and not the point being addressed. The main engineer console can be regarded and would be regarded by the host computer in console systems as simply a terminal, albeit the main one. There is nothing to stop other terminals of greater, equal but probably lesser or deliberately limited facilities having access to the main body of electronics, sharing the network and its resources, in other words. In practice they would have access to and be able to manipulate a preprogrammed subset of the total capability (e.g., our producer friend’s monitor mix) concurrent to the main terminal or control surface. Another obvious secondary terminal would be a second or even third set of assignable channel controls for multi-op situations, although we can’t help wondering how often they would be redundant except in the all-hands on-deck film mix-down world. As a capability it would go a long way to soothing the frustration of engineers new to the concept who are wary of losing so many controls at once in sacrifice to the new false god rationalization!

Simultaneous access to the same set of information is what the term multiusers is all about. Multiple control surfaces pose no real issues—control systems and networking operate so quickly in relation to the rate of changes a mixing engineer can make that several concurrent operators sense no interaction at all.

In computer terms the system described bears more than a passing resemblance to a hardware-related database, remotely controlled by a terminal or terminals down a network. Again, in computer terms, it’s a pretty small database, and at least on the control side a pretty lightly loaded network, too.

25.16.14 Goodbye Jackfields, Hello Routing

Considering that one of the easiest audio subsystems to organize using digital technology is signal switching, it’s astonishing jackfields still exist. Analog switching matrices are now at such a level of development that they can be considered transparent to the system. Digital routers of course have no impact on signal quality whatsoever. Neither in any way, even when many are cascaded, create performance limitations. They are dense (many thousand source/destination crosspoints will fit in the same rack space as 144 jack holes) and decreasingly expensive—much less expensive per crosspoint than a comparable jack circuit. Control is soft and the operation can thus be anything from a humble computer terminal, PC application, to effectively complete seamless integration as part of the console’s control surface. Of course, within assignable systems, the matrix is controlled by an interactive control surface by the operator, all routings and parameters being storable, recallable, and resettable as are the rest of the parameters of the console, in real time if desired. Try that with 50 patch cords!

Inputs and outputs of everything internal to the console (equalizers, dynamics sections, front-end amplifiers, line-output amplifiers, and so on) and everything external to the console (effects, machine input and outputs, and so on) all appear as sources or destinations on the matrix. The concept of insert point has disappeared; anything can go in anywhere. After decades of things getting more complex suddenly things have become simple again—there is no system and no prewired interconnections. A system to fit a given circumstance is built up from scratch using all the circuitry building blocks interconnected as required via
the matrix. A repertoire of usual starting points—preassembled patches—is stored and recalled as needed.

In pure digital signal-processing systems, this is taken a step further, where processing elements can be arranged in order at will or dropped into place in the form of plug-ins. No arbitrary system: full circle.

25.16.15 Integrated Control of Outboard Gear

A great many bits and pieces of outboard signal-processing gear (known vernacularly as toys) are involved in the successful production of present-day program material. Already the term outboard is flimsy since via the system matrix, or via plug-ins, their signal paths are already firmly internalized. The old music-industry serial communications link MIDI, despite its limitations, still bears integration into any studio interactive system. The centralized control point for these is the interactive main control surface for the operator, and a MIDI-controller application is required unless the console as a whole (strangely but sometimes quite sensibly) merely becomes a MIDI slave to an external controller.

It is no coincidence that major players in the DAW world, and hence with influence tendril-like into the rest of pro-audio, were initially strongly into the instrument, machine-control, musical synthesis, and arrangement world of MIDI control (e.g., Steinberg, with CuBase); it helps explain, too, why there is such a tight integration of MIDI music-making capability with audio processing in these DAWs, and their look and feel is unmistakably MI (musical instrument) in flavor.

At last the impossible studio system of a mere few years ago, integrated, completely automated, and resettable in real time in conjunction with effects, storage machinery, and other systems such as video, is here.

25.16.16 Digital Audio Workstations (DAWs)

Control by GUI only, where all audio functions are controlled by mouse activation of on-screen widgets in the form of pseudo-knobs, buttons, and sliders, has been a natural progression, if for no other reason than it is cheap—there’s no physical surface to build or buy! A GUI, though, presupposes that the actual signal processing is already in digitally controlled form, usually pure digital. Although a GUI can be part of an embedded system controlling a traditional digital console as described later, often it is part and parcel, along with the control code and signal processing code, wrapped up within a PC. This does not make it a nonconsole, all the parts and processes that make up a console are in place, just in the one place.

DAWs rapidly transcended being the dinky two-track editing tools they started out as and have become the de facto console experience in many spheres of audio. Characterized at heart by being (or having at least the appearance of being) software applications that run on the familiar PC or Mac; by absorbing the recording into the PC’s hard drive, by providing access to just enough audio signal processing, by rationalizing control extensively so that it fits adequately on a screen, DAWs rule the nonlive and production audio arenas. While many DAWs totally run within and skirt the processing limitations of the host PC (which are becoming less limited as PCs become more capable daily) in some cases extensive additional DSP farms are employed to do the heavy lifting, leaving the PC mostly to do the user interface. In either case, the PC-based DAW is a perfectly valid multitrack production environment. Paradoxically, that which was the DAW’s initial strength—the convenience, familiarity, and low cost of the PC environment and GUI—is now the major (there are others) drawback. Screen-based DAWs using point-and-click are highly rationalized in operation, and do not lend themselves well to other than single-operation-at-a-time usage.

This is the predominant reason DAWs and their underlying technology are still eschewed in any live audio activity, with more traditional (including rationalized!) console surfaces maintaining favor. That said, there are burgeoning after-market and own-brand control surfaces expressly to augment and improve operation of DAWs, and many traditional console manufacturers have embraced the underlying technologies and merged the two approaches quite seamlessly; these range from a small surface of little faders all the way up to major surfaces such as the SSLs above.

25.17 Digital Consoles

It is an impossibility given the nature of this book and the space available to give a thorough treatise on digital mixers and their techniques. It gets pretty mathematical, pretty scary, pretty quickly. What is intended here is an outline of typical audio digital signal-processing considerations, methods, and limitations from an intuitive and practical standpoint and ultimately in the context of a practical digital console design.

An analog versus digital divide still exists simply because as with any pair of such disparate technologies, what is easy in one can be hard in the other and vice versa; digital can do some things that are practically
impossible for analog—time-related machinations, for example, which are typically gruesome in analog. Tritely, it used to be said that real-deal EQ and dynamics were the province of analog, being that it has hitherto been easier and cheaper to achieve nice-sounding, complex, and flexible phase and frequency response shaping with a handful of analog components; this has become less of a black-and-white proposition though as the size, speed, and power of digital signal processors have increased and relevant expertise and ears were applied. Very fine digital EQ, dynamics, and effects are indeed possible. Suggestion otherwise “is fightin’ words” and many would suggest that digital audio processing has now surpassed analog in all important respects.

Particularly in mixing, switching, and routing there has been a dramatic bipolar switch over to digital purely on ease and inexpensiveness of implementation as appropriate parts became readily available; Fig. 25-124, a photograph of a couple of LSI ICs and a handful of support parts, illuminates this blindingly; of course it could be argued that the same could simply be achieved in analog with a mere 144 op-amps and 2304 VCAs, but by whom or why is uncertain.

Digital recording and transmission—including the most far-reaching domestic example, CD’s are covered extensively in other sections of this book. That these are where digits first made their mark on pro audio is hardly surprising; once the speed of the associated processing speed and bandwidths were high enough, well-proven techniques from the communications and computer world were applied to the problems of storing and moving the fairly prodigious number of bits digital audio demands. After all, the major telephone companies worldwide have been using high-speed digital streams for decades. Early successes for audio include the conversion of the BBC’s nationwide radio network program distribution system to digital in 1971. The turn of the 80s saw the first few serious digital tape machines, heralded by the 3M/BBC design; then a little thing called the PC happened. Hard disk recording moved from the high-end esoteric to the bedroom studio and is now both ubiquitous and universal. And very good. The pro-audio digital revolution is almost complete. Resistance is futile.

25.17.1 Digital Audio Systems

Fig. 25-126 shows about the simplest example of a DSP (digital signal processing) system possible. The processor itself, in old days racks of discrete logic and latterly specifically tailored microprocessors, is sandwiched between means of coupling it to an analog world outside. We’ll first look at the converters and then the DSP bit.

25.18 converters

25.18.1 A/D Conversion

25.18.1.1 Resolution

A DSP processor needs a stream of digital words of sufficient resolution to adequately portray the actual input signal level at a given moment. This resolution is determined by the number of binary bits in each word; each bit corresponds to a doubling of the resolution, or roughly 6 dB of dynamic range capability. Phone systems typically use 8 bits (approximately 48 dB dynamic range linear, although effectively more when companded), the BBC’s original distribution system was a 13 bit system (78 dB), CDs 16 bit (9 dB) and most production and recording systems a nominal 24 bit.

The A/D conversion process is fraught, particularly with high-resolution converters, and the actual dynamic range is often much less than theoretically possible from the number of bits. System noises, either from the analog paths or crosstalk from various digital signals, are the predominant limitation; gross errors used to come from nonmonotonicity. Strictly speaking, a converter should, if the input signal is increased by one unit of the resolution, reflect this by increasing the value of the output digital word by one bit. Often, particularly at transitions of the major bits, this goes awry and an
untoward jump in output level occurs. (As an example, the transition from 01111111 to 10000000 in an 8 bit word is a likely point of nonmonotonicity. Although this only reflects one increment of resolution change, a lot of converter bits are changing simultaneously; the more that have to change—especially the wider the word—the more chance for error. Trust is being laid in the converter’s manufacturer that each successive bit carries exactly twice the weight of the previous one; with very wide converters the increments of resolution are tiny and the odds are increasingly slim. In a 16 bit converter the most significant bit has to be accurate to within at least a bit of resolution for the device to be monotonic; this corresponds to an accuracy of better than 0.0015%. Enough said. The more bits change in a transition, each of the individual bit’s tolerances come into play and errors are far more likely.

The almost wholesale shift to sigma-delta–type A/D converters, which are inherently monotonic, has all but buried this problem now in most practical circumstances. Integrated IC sigma-delta converters are available very inexpensively with what used to be considered science-fiction performance. As mentioned, the primary limitation is noise, either induced digital mush or from the necessary analog parts in the mixed-signal format of these devices; such is not an ideal environment for low-level analog. The low supply rail voltages (5 V is considered big these days) mean that the additional dynamic range available from conventional high rails (such as typically ±15 V or more) is simply not available.

Although it is actually quite difficult now to find a converter that is rated at any less than 24 bits (and to be fair, their internal structure, in particular the word width of the FIRs, is 24 bit), the actual performance depends on how many of those bits represent useful data and how many are marketing bits.

25.18.1.2 Sampling Rate

In addition to the required resolution, speed of conversion plays a great part. In order to give an accurate portrayal over time of an input signals waveshape, there need to be enough conversions for the digitized signal to be reconstructed to an exact analog of the original signal. The lowest theoretical (Nyquist) sampling rate is twice the highest frequency intended to be processed. This implies at least two digital word conversions taking place for each cycle of (typically in audio) 20 kHz. In practice the sampling rate is made even higher, and figures of 44.1 kHz (domestic) and 48 kHz in professional audio are the most common, 96 kHz and higher yet looming and in search of a mainstream application.

25.18.1.3 Convertor Limitations and Requirements

Currently the figures of 24 bit linear conversion at a 48 kHz rate are de facto standard values in pro audio. Although these parameters are capable of very respectable sonic performance, certainly comparable or in excess of the analog recording and transmission methods digital has supplanted, their practical implementations fall somewhat short of the performance of analog electronics. This is not a snipe at digital; it is clear to anyone who chooses to investigate that the practical differences are small.

The first question is of how much resolution is actually required. A good quiet balanced-bus multitrack console’s typical input-output path can be expected to have some 26 dB head room above an operating level of 0 dBu and a noise floor some 90 dB below that for a 116 dB dynamic range. A similar quality mixer summing a fair number of sources can still be reasonably expected to have a noise floor of –80 dBu corresponding to 106 dB dynamic range. These values imply digital word widths of some 20 bits and 18 bits, respectively. Converters of these capabilities are readily available commercially, if implemented well. A further related question is what is the highest dynamic range signal source? A very good condenser microphone with a very quiet FET in it in a very quiet room is probably the best candidate; it might be able to cope with a 130 dB SPL gunshot at the high end of the range while still hearing breathing noises in the room at the other.

Why one might want, other than as a science experi-
25.18.1.4 AntiAliasing Filters

Early converters used brutal brick-wall filters at the Nyquist frequency to prevent ultrasonic frequencies from being mirrored down (aliased) into the audio and prevent further ultrasonic signals from heterodyning with the sampling frequency.

For example, a 40 kHz signal passing into a 48 kHz rate sampler will produce an 8 kHz by-product that will definitely become audible upon signal reconstruction. There is no way these filters could ever be described as anything other than a bad thing. Their temporal response was appalling, their effect reaching far, far down into the desired audio passband. More than anything else, it was these filters that gave digital audio a bad name in its early days.

Sigma-delta converters come to the rescue. Oversampling, a technique of taking and reconstructing samples at a multiple of the sampling rate (4, 8, 16, or so), allowing the nasty filters to be both relaxed in brutility and moved correspondingly higher in frequency, dramatically improved this situation—the filters had far less in-band effect. Sigma-delta converters typically initially sample 64, 128, or even 256 times above the nominal sample rate with the consequence that the antialiasing can be reduced to as little as a gentle single or double-pole filter; the band limitation is done inside the converters by a phase-linear FIR filter, with considerably reduced sonic impact.

Nevertheless, there have been experiments that indicate that even such benign internal filters at 20 kHz are with some program material and under some conditions audible, in comparison to the same class of filter set twice as high in frequency. Since the only way to properly engineer such a filter at 40 kHz is to double the sample rate, it seems that the predominant improvement (and ever-so-slight at that) of a 96+ kHz system is not the increased bandwidth available—arguments will continue to rage about our ability to hear/sense stuff up there, and even the desirability of its existence—but that doubling the rate is the only means of pushing the last vestiges of filter effects from audibility. Since this means doubling the amount of processing hardware in a system, it is not a light decision.

25.18.1.5 Types of A/D converters

There are three types of converters with possible application to digital audio. Although without question the sigma-delta type rules the roost in pro audio, enough applications use flash and successive approximation for them to be considered here.

Flash Conversion. Flash conversion involves a long train of comparators, such that a given signal amplitude will trip a given number of comparators and fairly simple conversion logic can turn their outputs into a binary word. It is the fastest conversion method as far as logic propagation times; a change in input level is instantly reflected in output code. The down side is the sheer number of comparators needed for a sensible size word width, one for each possible level of resolution; also the offset inaccuracies of the comparators tend to dwarf the required resolution! This said, they are little used, except in some hybrid converters where a 4-bit flash converter will provide the major resolution of a wider word, leaving the remainder to a more accurate type.

Successive-Approximation Encoder. The successive-approximation encoder is a very common form of encoder, especially where high speed at high accuracy and with low latency (processing delay time) are
required. There is but one comparator unlike in flash, easing accuracy. Conversion takes at least as many cycles as there are bits of resolution. Operation consists of comparing internal voltages, weighted in accordance with the bit value, against a frozen (by a sample and hold circuit) sample of the input signal. It needs to be frozen since the conversion is not instantaneous and the input signal level could change in the time it does take. The most significant bit’s value is half the permissible input range, the second a quarter, the third an eighth, the fourth a sixteenth, and so on in binary weighting. They are applied in turn to the comparator, MSB first. If the sample is larger than the MSB, then the MSB is left asserted; if not, it is dropped. The next weight is applied; if the input sample is still larger than the combination of MSB and No. 2, then No. 2 is left asserted, and so on. Eventually all the bits are tried against the input sample with the bits remaining asserted, forming the 1s of the digital word, the remainder the 0s.

Both of the above converters generate an absolute digital value of the input signal at each sample period.

**Sigma-Delta Conversion.** Sigma-delta, or also called delta-sigma, conversion starts off in essence by measuring relatively how far the input signal moves, up or down, rather than stating exactly where it is. Conversion occurs much more often than the required output sampling rate (e.g., 48 kHz) often 128 or 256 times higher. The conversion itself is much simpler though. Simplistically, at each conversion it only has to make the decision whether the input signal has moved up or down from where it was last sampled. Its output is a very fast stream of up and down signals; the sampling is fast enough that it can keep pace with the input signal’s probable changes, sensing automatically whether large level shifts or tiny ones are taking place. Subsequent intelligence (filtering) keeps track of this torrent of single-bit state changes and renders down a conventional digital word for an absolute output value.

As a method it has many advantages, not the least of which being the enormous internal sampling rate; the antialiasing filter can be relaxed considerably, both in order and cutoff frequency (often it just consists of a single- or double-order filter set much higher in frequency than with other encoders—and sometimes left out completely!). Filtering is left to within the digital domain.

They are also monotonic, having none of the problems of the other types of comparator level or ladder accuracy. What they do have, and which can be a concern in some applications, is a comparatively very long latency (signal processing delay time) before a relevant sample pops out for digital digestion; at normal sample rates and depending on the length of the FIR decimation filters within, this latency can be around a millisecond or so. Sigma-delta A/Ds predominate in pro-audio.

### 25.18.2 Digital-to-Analog Conversion (DAC)

#### 25.18.2.1 Conventional Ladder DACs

A means of turning the processed output signal from the DSP back into analog is necessary. These are described in Chapters 31, 38, and 39, but for completeness are outlined here. A DAC adds together voltages (or currents) of weightings corresponding to the importance of the binary bits. Fig. 25-127 shows a simplistic DAC. The required output digital word is applied and the most significant bit, if set high, sources a current of 1 mA. The next most significant bit sources half that or 0.5 mA, the next half that (0.25 mA), and so on down to 7.8 μA increment for the least significant bit. In the 8 bit converter shown, the maximum output current is just short of 2 mA (1.996 mA) with all the bits set (one extreme) and none if all are low (the other extreme). Any current between those two, in 255 steps, which is the resolution of an 8 bit word, can be achieved by setting up a permutation of the input bits. This output current can be converted to an output voltage by a summing amplifier.

![Figure 25-127. Simplistic digital to analog converter.](image)

There are other kinds of D/A techniques, probably the most common being the R/2R ladder, Fig. 25-128.
Much as the simple DAC, asserting a bit causes a correspondingly binary weighted current to be output.

25.18.2.2 Reconstruction Filters

All the earlier comments about antialiasing filters apply here, too. As well as the required audio—up to 20 kHz in bandwidth—coming out of the DAC there are a host of other products, the most unappealing and closest in spectral terms being a mirror image of the audio centered on the sampling frequency and descending in frequency; a 20 kHz audio signal sampled at 48 kHz will be output from the DAC along with an image at 28 kHz (sample frequency minus audio). Heterodyning strikes again; there will also be an image at 68 kHz (sample frequency plus audio), and in all likelihood more sets of images centered on harmonics of the sampling frequency. The most dangerous sonically though is that first inverse image.

25.18.2.3 Oversampling

Enter a filter every bit as precipitous as the one needed at the front end. Every bit as nasty, too. Solutions other than good, well-designed filters come from the digital domain; oversampling, for one. One approach is to intersperse an interpolation filter between the processor and DAC. This digital filter reconstructs the audio but at a higher sample rate; the smoothing of the filter effectively creates more sample points between the few actually being issued by the digital source (DSP). If a guessed digital word is inserted between each of the real ones, the effective sampling rate becomes doubled and, in practice, the DAC is working twice as hard and fast outputting analog.

Here is the good part. If the sampling rate is doubled, the heterodyning images start that much higher up in frequency; following the earlier example through, a 20 kHz signal’s first inverse image is now going to be at 76 kHz (96 kHz minus 20 kHz) instead of 28 kHz as before. The immediate benefit is in the relaxation of the reconstruction filter—it can be much less steep and pushed up in frequency somewhat away from the audio band.

The oversampling process can be carried on even further; four times, eight times, even sixteen times and more with greater oversampling rates commonly used, pushing the undesired products correspondingly higher in frequency and so dramatically relaxing reconstruction filter requirements. The fact that fifteen out of sixteen samples may be filter guesses belies the fact that it isn’t those that improve the audible performance—it is the absence of brutal analog filtering that makes all the difference. Exactly the same conditions apply here to the application of higher (96+ kHz) sample rates, simply with the intent of pushing antialiasing filter effects out of audibility, as in A/D converters.

25.18.2.4 Sigma-Delta DACs

Sigma-delta DACs oversample to the same degree (64, 256, or beyond) as their previously described A/D brothers and the corresponding increase in frequency of the reconstruction filter dramatically simplifies their implementation. Most D/As in proaudio are now sigma-deltas, although conventional laddertypes are still in wide use, and especially where higher than normal audio speed is required (such as in a broadcast stereo encoder). Again, latency is the only major drawback to this type; the processing delay again depends on sample rate and the particular device and its filter length, but is generally around a millisecond. This, of course, means that a system using sigma-deltas at both ends (ADC and DAC) can potentially have a latency of a couple of milliseconds or so; this can be a bust in some applications.

25.18.3 Sample-Rate converters (SRCs)

A big problem facing digital audio system designers in the early days was combining sources from different machinery that, unless heroics were performed and all the system’s machinery was phase and word-clock synchronized, almost certainly were all running at

![Figure 25-128. An R/2R digital to analog conversion ladder.](image-url)
ever-so-slightly-exactly-not-quite on the same frequencies, from their own independent clocks. Mixing such is a disaster.

SRCs allow sources with a wide range of sample rates to be reclocked to the console’s master clock, allowing them to be processed normally. Being that they use internally very long FIR filters and of varying length depending on the ratio of input-to-output rate conversion, they not only have latency, but it changes too. Another slight shortcoming is the tendency to affect the ultimate dynamic range by leaving artifacts way down in level, but most current parts are excellent in this regard. All in all, they are a near miracle-cure for what was an intractable problem.

25.19 Digital Signal Processors

There are a number of features that distinguish devices specifically designed for DSP from the admittedly bigger and faster but generally dumber and seriously more expensive behemoths powering PCs and the like.

25.19.1 Multiplier/Accumulator (MAC)

The heart of a DSP device is the hardware multiplier in its arithmetic logic unit. This takes two full data-width numbers, multiplies them, and leaves the result in an accumulator, quickly. Further products of multiplications can be arranged by a software instruction called a MAC, Multiply/ACcumulate, to be added to results previously stored in the accumulator. The MAC is central to DSP. Nearly every manipulation of a signal in the digital domain is ultimately achieved by multiplying a sample by another value, called the coefficient. The simplest example is that of level control—in audio terms, gain control. If an incoming sample is multiplied by a value of 1, the result lodged in the accumulator is the same as the input sample. If the gain-defining coefficient is greater or less than 1, the accumulated result is correspondingly greater or smaller than the input sample.

The accumulator necessarily needs to be of a wider word width than the input byte width capability since a multiplication can end up with a much bigger or smaller number than the input sample; in the case of the very popular fixed-point Freescale (see Motorola) 56300 series DSP chips, the bus width (input-output word width) is 24 bits while the accumulator widths are 56 bits. It’s a worthwhile rule of thumb—a multiplication results in double the bit width.

In this volume-control example, the input analog signal is sampled at the front end of the encoder, an A/D conversion is performed, and this value is deposited on the DSP chip bus at its command. The input word is multiplied by a coefficient, similarly picked up off the data bus, and the result left in the accumulator. Rounding off fits the possibly too long result to the width of the DAC (e.g., down to 16 bits from a possible maximum result of 32 bits from one 16 bit multiply). The answer is put on the bus to be picked off at command by the D/A convertor. The D/A performs a near-instantaneous conversion back to analog, ready for consumption by the real world. This whole routine is repeated 48,000 times a second; each operation has less than about 20 μs to take place. Congratulations! This is the digital replacement for a $5 potentiometer.

To get a sense of the great strength of the digital solution, Fig. 25-129A shows many A/D and D/A converters hanging on the DSP input-output bus. Each of these is independently addressable by the DSP chip; it can systematically pick an input signal word from any A/D, work on it, then deposit the result into any D/A convertor. Further, it can take input samples from any or all of the A/Ds, multiply them in differing degrees according to differing coefficients, and add the results progressively within the accumulator. This accumulated result is then scaled and passed to a D/A. In effect, this is the digital equivalent of mixing a number of sources, all the sources at different gain settings, to one output.

The comparatively simple digital arrangement can be made to equate to an analog soft matrix, as drawn in Fig. 25-129B. It’s starting to look more like a viable cost and space saving replacement; this small example of six-in and six-out is already equivalent to 36 VCAs.

More inputs and more outputs to and from the mix stage are of course possible. The principal limitations are accumulator width, which is taken care of by building in adequate head room just as one does in analog, but more importantly processor time; after all, it still has to do all the input-to-output multiplies within a 20.8 μs window.

25.19.2 Instruction Cycles

A processor instruction cycle is simplistically the time it takes to perform one single simple operation, such as a bus access (to acquire or dispose of data), an arithmetic function or a move of data from a register to elsewhere. Multiplies can take a bit longer, depending on the chip, but DSP chip architectures with hardware multipliers are very slick and time efficient. They need to be. The processor speed determines how many of these clock cycles are available for processing in a given time
window and so directly limits how much work the processor can do. For example, a 200 Meg device has a processor cycle rate of 200,000,000 Hz. Given a 48 kHz sampling rate, this gives a maximum of just over 4000 cycles per sample period. Some operations can take more than just one clock cycle, so this is an outside ideal figure. In practice, it works out at somewhat fewer. Although it looks like a big number, it seems vanishingly small as soon as anything clever is attempted with the DSP. This, above all else, is the primary reason why upping the sample rate above the bare possible minimum is a very unpopular notion in DSP circles. Cycle budgets rule.

25.19.3 Processor Types

Specific DSP devices are chosen for a wide variety of reasons, both real and perceived. Device flexibility, per-unit cost, and ease of implementation (in the forms of support from the manufacturer and quality of the design tools) all factor in. In very large run products such as consumer items, part cost will probably override everything else while ease and speed of implementation tend to be more important in lower-volume, high-tweak-factor arenas such as pro-audio. Rarely is there one overweaning performance feature that makes or breaks a choice. However, since in order to squeeze the most processing from each device a considerable amount of their programming is still at the machine-code level, the designer’s familiarity with a particular assembler language can have a strong influence—this definitely falls into the ease and speed of implantation department.

Perhaps the minimum for processing audio data is a 24 bit word width and correspondingly wider accumulators and registers. As such the Freescale devices just about fit the bill. They are fixed point processors, which directly limits their dynamic range to the number of bits (144 dB for 24 bits, 336 dB for the accumulators); fortunately, this is plenty for most real-world audio processing. Some applications, like some filters, demand wider immediate dynamic ranges in their calculation and intermediate-value data storage, and for those instances long or double-precision arithmetic is used. The downside is that such filters can take up to twice as long (twice as many cycles) to calculate as single precision.

25.19.4 Floating Point

Floating point processors (floaters) as exemplified by Analog Device’s “Sharc” series avoid this problem by representing numbers internally in exponent/mantissa format, having far more involved internal processing to handle the complexity of dealing with these numbers. The Sharcs can be operated as either 32 bit fixed point or 32 bit floating point. Since the dynamic range of a floater is as good as infinite regardless, none of the dancing around one sometimes has to do with a fixed
point applies. On the other hand, the capacity to dig a big hole is as good as infinite, too.

25.19.5 Parallelism

DSPs differ from conventional microprocessors in that their architecture is contrived to make certain common processes as slick as possible and to be able to perform as much real data manipulation and housekeeping within each clock cycle as possible. This latter is called parallelism, and the degree of parallelism is what sets devices apart in capability. For instance, performing an FIR filter (or a mixer routine, for that matter) within one clock cycle, a DSP can.

• Do a multiply and accumulate (MAC).
• Fetch in the next data word ready for the next MAC, update data pointer.
• Fetch in the next coefficient ready for the next MAC, update coefficient pointer.
• Update the program counter.

In short, everything that needs to happen to ensure a filter point can be calculated within one cycle is done, ready for the next.

25.19.6 Multiple Memory Spaces

Memory allocation is nearly always somewhat different from ordinary processors, which usually have just one memory space shared between all functions; DSPs have at least two separate memory spaces; the Freescales have three, for example: one for the program information (program memory), one typically for coefficients, and one typically for the inevitable intermediate filter values etc. necessarily stored between per-sample calculations and for internally stacked-up audio data, if brought in enbloc from outside.

25.19.7 Real-Time Specific Peripherals

Additionally, most DSPs have convenient peripherals built into them to allow ready, seamless, and fast transfer of data in and out of the chip, either into memory-mapped data space and/or through a variety of serial communication formats. It is usually possible to seamlessly connect a DSP to a number of conventionally serially formatted A/D or D/A converters and to other DSPs. Definitely not least, a ready and fast means of importing fresh programs/coefficients with which to modify the data is always available via a host port.

A related major tool is DMA, or direct memory access. This allows the moving of considerable amounts of data into and out of the DSPs memories with little impact on the main cycle budget other than that required to set up the necessary pointers and to fire off the DMA activity at the required times. On very busy processors conflicts can arise (DMA does borrow some real processor resources while it’s not looking, and under normal circumstances usually gets away with it) so it’s not entirely free, but it is more than handy.

25.20 Time Processing in DSP

25.20.1 Time Manipulation

Something what is very readily achieved in digital is storing information, either long term onto disks or flash memory, medium term in RAM, or short term within processor registers and internal RAM. Nearly all manipulations of data of any complexity greater than the soft matrix example above demand storage.

25.20.2 Delay

A stream of input data is written into RAM memory and subsequently, some time later, read out again. The length of time recordable (sample length) depends on the size of memory and the sampling rate—the faster the rate, the quicker the memory will be eaten. This memorized sample may be stored elsewhere then—say, on a hard drive.

Say a relatively short time delay is required for an echo. The input data stream would be written into RAM and read out at a fixed time (a certain number of samples) later. Sooner rather than later the memory would run out and the delay stop, so the memory is usually arranged as a circular buffer; when the buffer end is reached, the memory register leaps back to the start of the buffer and overwrites what was previously there, and so on. The buffer is read in the same manner, at a time after it has been written determined by the required delay. As long as the buffer is long enough to contain enough samples for the required delay, a continuous delayed output version of the input is available. The main advantage to the seeming complexity of the circular buffer is that only pointers, or indexes, are being changed and updated; the only audio samples being changed are the writing of the newest sample over the oldest one. What is important is what is not happening; huge amounts of data are not being read and
rewritten somewhere else. The complexity is merely keeping track of those read and write pointers, which is in reality simple arithmetic and indeed an automated function in many processors.

### 25.20.3 Echo, Echo, Echo

Reentrant, or recursive, delay (spin echo) where a delayed signal repeats continuously until fading away is achieved by attenuating the delayed words (in the multiplier) and adding them in the accumulator with the concurrent new input words.

If the delay is made very short, and the delay is summed in the accumulator with the new, direct sample, something interesting happens—a direct parallel with the analog world. The direct and delayed signals sum and interfere. A 1 ms delay corresponds to a half wavelength of 500 Hz; in other words at 500 Hz with 1 ms delay, the delayed signal will be out of phase by 180° from the input signal. They will cancel and a notch at 500 Hz (and every 500 Hz interval up the spectrum) will occur. Altering the delay time alters the frequencies at which cancellation occurs; studio people call it *flanging*; we’ll call it a comb filter, our very first digital filter.

### 25.20.4 Reverberation

In real acoustic environments, reverberation is the summation of countless random time-delayed reflections and rereflections from floors, walls, ceilings, and obstacles. Complications set in with differing reflections having differing frequency aberrations due to varying surface absorption coefficients, but in essence it is an accumulation of time-delayed signals of various and decreasing levels. As such it can be reasonably well emulated in DSP by more or less complex variations on time delay; relatively long time delay loops are established to emulate major room reflective modes. Many short loops and all-pass configurations are used to emulate the decorrelation that occurs in an acoustic space by multiple short reflections and diffraction. The output-to-input feedback—terms for each of these elements is *adjustable* and *equalization*, typically in the form of simple roll-offs—are applied either after a loop or within its feedback path to mimic the typically higher absorption at higher frequencies in an acoustic environment. There are a lot of small and large elements, all with a lot of handles, or things that need to be fed parameters.

Basically, the number of elements and the skill in determining their convoluted interaction and parameters decide how convincing the reverberant effect is and its characteristics. Some astonishingly good results have been had from DSPs with quite small (64 k word) external memories.

As DSPs become more powerful and much cheaper, becoming increasingly practical is a class of reverberation units that in effect perform a very, very long convolution of an applied audio signal with a digital recording of the reverberation tail of a real venue (see Section 25.21.1, Transversal Filters, for the basic technique). This can involve hundreds of thousands of DSP multiplies (meaning *lots and lots* of DSPs) but is as one would expect highly impressive and flexible. Proprietary convolution algorithms can reduce the computational burden, but it is still nevertheless a big proposition.

### 25.20.5 Averaging

An average of a number of input samples is achieved by adding all the input word values for the period of time over which the average is required; this is normally figured out by numbers of samples—20 ms worth of samples at a 48 kHz rate equates to 960 samples. (This would be a l-o-n-g train of samples.) These samples are all added in the accumulator and then divided by the number of samples—the result is an average value for that 20 ms. If each sample is stored elsewhere, then a rolling average becomes possible; for each new input sample added in, the first sample of the 960 is subtracted, and a new average for that instant is calculated.

Division, as such, is something undertaken only under extreme duress in DSP; it is very thirsty and inefficient. A division in such a case as creating an average as here could be achieved by first arranging, if possible, that the average length is a binary interval (2, 4, 8, 16, etc.). Then the end result of all the additions could be bit-shifted right the corresponding number of times. An arithmetic shift right (moving a digital word one step to the right, filling in the now missing top bit with a zero) is the same as dividing by two; an average of 64 samples would thus need six right shifts. Alternatively, a single multiply by 0.015625 (1/64) (or the reciprocal of whatever the arbitrary number of samples may be) does the job. Either is an awful sight quicker to do in a DSP than a 24 bit division. *Anything* rather than divide.
25.21 DSP Filtering and Equalization

25.21.1 Transversal, Blumlein, or FIR Filters

Yes, Alan Blumlein invented these, too. The train of samples concept becomes very valuable in DSP. This type of filter can produce a wide variety of time effects and frequency response shapes, particularly bandpass and cutoffs. While the determination of coefficients for the various filter types is beyond the scope and intent of this section, the underlying principle is shown in Fig. 25-130. For each sample period (i.e., every 20 μs) a fresh input sample is inserted at the head of the train; all the samples move along the train and the oldest one falls out of the other end and is lost. Each sample is multiplied by a coefficient specific to that position and summed in the accumulator with other results from the other multiplied samples. Each pickoff is subject to a different coefficient and sum sense (normal or inverse). The accumulator value is the new output word for that particular sample time; 20 μs later the whole routine starts over again.

![Figure 25-130. Transversal or finite impulse response filter (FIR).](image)

This passing of one set of data (in this case audio) through another set of data (coefficients) is also called convolution.

25.21.1.1 Impulse Response

As familiar as we are with using the tool of frequency response measurement to analyze or describe the transfer function of a device or circuit, there is an equally powerful descriptor: the impulse response. Embracing the impulse response concept aids gaining a mental picture of how digital filters work. Fig. 25-131A is what the waveform of a large bell excited by an impulse could look like: a damped sine wave at the tone of the bell. (Hardly dissimilar to that from a damped oscillator, or bandpass filter. Hold that thought in mind. Actually, looking at the response, it would probably sound more like the dung of a lamp post, but please suspend disbelief for now.)

Each of the vertical lines represents the instantaneous amplitude of the signal at each sampling period; this, if you like, is a sample-by-sample digital recording of the bell’s sound. If we were to play back the samples at the rate they were recorded, we would hear the bell thunk again. We now use the bell’s samples’ numeric values as coefficients in a transversal filter, Fig. 25-131B, and send an impulse (one sample of full positive amplitude, the rest zero) into the filter; the effect is exactly the same. As the impulse passes each coefficient, the bell sound will be reconstructed once more.

There is nothing to stop us from putting real audio samples into the front of the transversal filter—the effect will be as if the audio is being played through a damped bandpass filter at the frequency of the bell. The bell’s impulse response is impinging itself directly on the audio passing through the transversal stages. It will sound as though you’re listening to the audio with your head stuck up inside that bell. Yes, it’s a filter! In short, if we can describe a desired filter’s impulse response and use its samples as coefficients in a transversal filter, any signal passing through the transversal stages will be filtered accordingly.

This kind of processing is commonly called FIR (finite impulse response) filtering. If a transient (impulse) were encoded and applied to such a filter, the samples describing it would enter the train of stages. Output summation contributions occur until they reach the end. When the last relevant sample has fallen out the end of the train, no further output samples that have anything to do with the originally applied transient are possible. The duration of the transient within the filter is limited to the lifetime of its samples in the train; they eventually all leave. The impulse’s existence is finite. The filter’s length is finite—hence, finite impulse response.

Intuitively, FIRs are very appealing through their very simplicity. Unfortunately, this genre of filtering is rather taxing in current DSP terms since it demands a lot of processor time for any useful audio filters. As a rough rule of thumb, to do anything meaningful at a given frequency the filter must be able to contain a full cycle of that frequency; to operate at 50 Hz an FIR would need to be at least 20 ms long, which (assuming a 48 kHz sampling rate) would be about 1000 filter points long. As mentioned earlier, a 200 MHz part only has about 4000 cycles of processing available per sample—this one filter has just eaten about a quarter of
a whole DSP! Suddenly, except for a few rather special and esoteric circumstances, such as phase-linear EQ and auto adaptivity, it becomes obvious why FIRs are not particularly popular in mainstream audio DSP processing. They are rather hardware and time thirsty.

Impulse response coefficient sets suitable for plugging into transversal filters may be either calculated (long-handed for the rigorously inclined, or within any of the many excellent filter design programs available) or, as in the only half-joking bell example above, recorded by issuing an impulse into a pet filter and using the resulting sampled output as coefficients—audio played through an FIR with those coefficients will sound just as if it was passing through the original filter. As earlier mentioned, there are reverberation units working exactly on that principle.

25.2.1.2 Windowing

Any attempt to generate a set of coefficients for FIRs will run into the problem that an ideal filter simply will not fit into the length of any practical filter. Obviously, the filter has to be long enough to realistically encompass the meat of the desired processing (a 99 point filter won’t do 50 Hz, remember?) but this still leaves the problem that the filter is finite in length. A series of FIR filter designs showing the impulse responses and corresponding frequency responses of a 33 point (33 step long) nominally 12 kHz high-pass filter highlight the quart/pint-pot tradeoffs. Truncation—i.e., lopping the end(s) off to make it fit—leads to Gibb’s phenomenon, in which the desired output frequency response of the filter is seriously compromised by large lobes, Fig. 25-132.

Mr. Hanning, Mr. Hamming, and Mr. Harris (among others) come to the rescue here, with a technique called windowing. These apply weighting to the values of the coefficient set, basically leaving the most significant elements (usually in the middle of the set) alone and
tapering off the values toward the ends of the set. The taper that is applied varies according to the type of window, and the differing types are best suited to differing interests of compromise. Say a brick-wall filter had been described as in the figures; one window may optimize for stop-band rejection, Fig. 25-134, another may trade that against sharpness of the filter cutoff rate, Fig. 25-133, etc. Many thanks to Momentum Data Systems’ software for the curves.

Figure 25-133. The same 33 point filter Hanning windowed.

25.21.1.3 Symmetrical FIRs

There is an FIR implementation that has some quite interesting properties and as such is probably the most used, so much so that the majority of commercial design packages assumes as a default that one wishes to design symmetrical FIRs and that FIR has become almost synonymous with the symmetrical filters they afford.

These allow the imposition of a frequency response (in the case of a conventional-style EQ) *without* altering the phase response, unlike ordinary EQ (and nature) in which any frequency response change comes with a corresponding shift in phase response for free. Although this characteristic might at first blush seem ideal and a major leap forward for audio technology, in practice they are only rarely used; yes, Virginia, they do sound different to conventional EQ with equivalent frequency responses, but not necessarily better. (An odd effect is that one seems to need more phaseless EQ cranked in than conventional EQ for a similar subjective effect.) Certainly, it’s not better enough to displace conventional EQ, which can be readily and far more efficiently created in either digital or analog form. The difference alone, however, is sufficient reason for existence in music production, and special-effects units and audio workstation plug-in software specifically to do symmetrical FIRs are available.

Symmetry refers to the fact that the coefficient set is arranged to be symmetrical about the center—the midpoint—of the filter; identical coefficient set-lets tail off toward the end of the set as tail back toward the front. The midpoint of the filter is regarded as the time center—in other words, a symmetrical FIR has an intrinsic time delay of a passed signal of half the length of time the filter takes to calculate; in our now-famous 50 Hz capable, 960 point filter, the effective time delay is 10 ms, or half of the time it takes for any one data sample to transit the entire filter, being 20 ms. This time delay is another major downside to symmetrical FIRs; in order to keep everything in a multisource console time aligned, all other sources would have to be delayed by the effective time delay of just one FIR’ed source.

Note that not only is half of the filtering done after to the time center, but, and this is the head hurter, half of it is done before the time center, leading up to it. The filter only remains causal because of the intrinsic time delay. That the ear can deal with filtering effects before something has happened and integrate it all into an acceptable sound is a true amazement.

25.21.2 Recursive Processing

This concept was approached in achieving spin echo and reverberation; feeding an already manipulated input sample back around in a loop to be reprocessed along
with new, and/or yet other samples. Fig. 25-135A shows this diagrammatically. A time delay (a number of samples’ delay) is included in a loop and fed back at a level determined by the controlling coefficient. Picking off different samples and treating them with differing coefficients allows great control over the nature of the feedback and the dynamic nature of the loop. The most important thing to note is that once a signal has entered the loop, it just carries on going around and around, being summed with fresh input samples each time. The time taken for a signal to die away is determined by the coefficients in the feedback loop—this can very loosely be paralleled to the analog concept of $Q$: the more positive feedback in a filter the tighter its response, with the drawback that ill attention to its control can result in oscillation. Such is exactly the case with digital recursive stages. Even if controlled, the signal never actually dies away completely; in DSP this can result in leftover bits rattling around, manifesting as repetitive cyclical errors. Sufficient accumulator width needs to be available to round or noise-shape results off nicely.

The first big advantage of recursive processing is that significantly less memory accesses are needed than with FIR—history (equating to length of the filter and its temporal resolution) is built up within the loop rather than being necessary individually and sequentially. The second advantage is that far fewer coefficients and operations are needed.

### 25.21.2.1 IIR Filters

A filter built up around recursive techniques is known as an *infinite impulse response filter* or IIR, Fig. 25-135B, so called because once in the loop, an impulse just keeps trundling around indefinitely, infinitely. In practice it gets rounded off sooner or later, but it makes the distinction from the FIR.

Additionally, an output appears from an IIR at the same time as input samples are applied and the filter starts behaving as a filter immediately; the only delay is the group delay of the filter, exactly as in analog; there’s no waiting for sufficient data to be affected by sufficient coefficients for the nature of the filter to become formed, as occurs in symmetrical FIRs.

IIRs are presently easier, quicker, and carry less time and memory overhead than FIR filters; consequently, they tend to be much more popular for audio DSP.

### 25.21.2.2 The Biquad

There are many different ways of implementing IIRs; the one in Fig. 25-135B is known to its chums as *direct form 1 biquad* and serves to illustrate the process well. (Others may use less memory space, or run a bit quicker, but they come up with the same results.) It’s known as a biquad since it essentially calculates a biquadratic equation. There is no real limit to the number of input and output delays, multiplies, and summations; it’s just that those longer than a classic biquad tend to be rather high-strung creatures that are far less easy to calculate coefficients for and to keep tame (read stable).

There are two halves to the filter: the input stage consists of a short, 3 tap, FIR. The applied input signal is multiplied by a coefficient ($b_0$) and the result put in the accumulator; the two delay line outputs are multiplied by their coefficients ($b_1$ and $b_2$) and added to the accumulator. The output stage is a two-delay recursive section; each of the two delay-line outputs are multiplied by their respective coefficients ($a_1$ and $a_2$), the results adding to the accumulator, the total contents of which now represent the output. Once used in a sample time’s calcula-
tion, the contents of the input and output delay lines move down one, such that the value in input delay 2 is displaced by the former contents of input delay 1, which is in turn filled by the last used input data sample; similar actions occur in the output delay, only the last calculated output sample enters the delay line.

In short, the biquad takes all of five coefficients, five MACs (multiply and accumulates) and a bit of concurrent shuffling of data to happily create a second-order high-pass, low-pass, or bandpass filter. They are very quick and easy to implement in DSP. That it is the basic building block of most digital EQ is hardly, therefore, a surprise.

25.21.2.3 Coefficient Analysis

A look at the coefficients for the input 3-point FIR can give a clue as to what class of filter the biquad is running. (Actually, complicated only by the higher number of coefficients, the same sort of analysis can be done to longer FIR coefficient sets, too.) Fig. 25-136 shows three biquad coefficient sets. Set A shows equal and opposite coefficients for b0 and b2, and none for b1. A very low applied audio frequency (dc, or practically so) will present substantially the same input signal level over the three samples in the FIR; this means that what is contributed to the MAC by the input sample by the b0 multiplication is going to be substantially canceled by a similar size signal from b2 (b1 not contributing at all, being zero). So low frequencies are not being passed. By a similar token, a signal of half the sample frequency (Fs/2) would have near identical values in the first and third positions, i.e., being administered by b0 and b2; since these coefficients are inverted this frequency gets nulled too. The highest valid audio frequency (Fs/2) is not being passed, and neither are very low frequencies. With a bit of luck something in the middle will be, so this is in all likelihood a bandpass filter.

On the second coefficient set, Fig. 25-136B, the effect of multiplies by b0 and b2 are entirely canceled by the effect of b1 at dc, yet by virtue of b0 and b2 not being inverted with respect to each other, Fs/2 is not nulled. The conclusion would be, if one didn’t already know, that this was likely a high-pass filter.

The only apparently slightly misleading case is that of the lowpass filter, Fig. 25-136C, which one would expect to bung in a null at Fs/2, but doesn’t at first glance seem to, being that the b0 and b2 coefficients are the same. Aha! though. If one imagines the positive peaks of an Fs/2 signal being coincident with b0 and b2, then the b1 coefficient is coincident with the negative-going peak—the b1 coefficient, being the sum of b0 and b2, neatly cancels their effect by creating a negative signal equal to their positive contributions at Fs/2.

Fig. 25-137 graphically shows these analysis results. In short the input FIR is a dumb little filter of the same class of the overall filter—and actually is what determines its class—the output feedback IIR structure in effect determining the frequency and Q.

25.21.2.4 Filter Quantization Distortion

The output (recursive) stages of a biquad can cause some pretty wild signal levels to be achieved in the accumulator—they are, after all, little more than a slightly complex feedback circuit; the output signal is fed back in part through both delays in accord with their a1 and a2 multiplies and grows until it (hopefully) stabilizes. (This can be likened to operating a PA right on the edge of feedback at microscopically varying degrees; this is standard operating procedure with IIRs). Filters that are either high in Q and/or more importantly very low in frequency with respect to the sample rate (and that, unfortunately, means most EQ-type frequencies) exacerbate this effect. The cure is to only excite the filter to the degree that the desired output is unity with respect to the source; this is usually achieved by proportionally scaling back the coefficients in the FIR input chain. Looking at the coefficients in Fig. 25-136C, this can be...
seen clearly; the $b_0$ and $b_2$ coefficients are really quite small; the reciprocal of this value is the amount of gain being generated in the IIR output chain. Thankfully, commercial design packages and most cookbook coefficient calculation routines take this scaling into account. But the underlying issue is quite serious. Using, say, 0.0001 as a $b_0$ coefficient (not unrealistic) and assuming a maximum input signal of 1 (the maximum signal range using the fractional arithmetic scheme in some fixed-point DSPs is 1 to $2^{-16}$), then a value of 0.0001 will end up in the accumulator, and despite the huge feedback-derived gain in the IIR output chain, the contribution to the output from the input signal is still only 0.0001; this corresponds to 80 dB. If the output were to be truncated to 24 bits (144 dB) the bottom 13 or so bits worth of the input signal would effectively, be sawn off and thrown away, leaving us with an 11-bit system. In numbers, this leaves a maximum signal to floor ratio of only 64 dB; if the normal operating level of the system is −20 dBFS (decibels below Full Scale) (0.1), that is only −44 dB signal to floor. Practically, with rounding, noise shaping, or dithering, things are worse.

The good news is that such quantization noise in filters can sometimes be masked somewhat by the very signals the filter is passing; the bad news is that when it is audible, it is Audible. And even when not overtly audible, it lends itself to a disquieting roughness to the sound that is difficult to pin down. The accumulator has all the width needed for valid data; standard practice on any filter on which this is even likely to be an issue is to make the IIR chain delay storage wide enough to fully encompass the attenuated input signals. In the specific example of a 24 bit fixed-point processor, the IIR output delay chain is made long, or double width at 48 bits. It also means that nearly always the $a_1$ and a 2 IIR multiplies need to be long too—i.e. the lower 24 bits need to be MAC’ed in with the upper 24, which increases execution time of the filter.

SHARC and other floater programmers are permitted to smile at this point. It is a happy day to doff the shackles of fixed point.

25.21.2.5 Cascaded Biquads

Having previously noted that IIR filters with more than a biquad’s worth of delays and multiplies are not attractive, there are approaches to coupling more than one biquad with the intention of making more complex or effective filters or simply those of a higher order. Better than just running one after another. Fig. 25-138 shows such an arrangement; the second biquad uses the output delays of the first as its input delays, and so on.

25.21.3 Parametric EQ

Raw biquads can take care of most traditional filtering. One approach to doing a console-style parametric EQ section, with independent control over center frequency and $Q$ of the employed filter and of the amount of lift or cut introduced, is shown in Fig. 25-139. A standard biquad is fed directly from the source audio, which is also attenuated by (in this case) 12 dB by the expedient of arithmetically shifting the data two bits to the right (down), or by multiplying by 0.25, in the DSP. The filter’s output, fed through an attenuator, is summed with the attenuated direct signal, and the result arithmetically shifted (ASL) two bits to the left (up 12 dB). This shifting up and down allows a correspondingly higher amount of the filter to be present in the output, which is required if high levels of boost are required. This example’s 12 dB allows a maximum boost of 13.8 dB to be achieved, which happily encompasses the ±12 dB control range often found in EQs; more boost capability would require greater shifting down and back up. One can in a floater (floating-point DSP) leave the straight signal alone and simply multiply the filter...
output up as much as is necessary (the attenuator becomes a gain stage) and avoid the shifts entirely.

EQ boost is achieved by adding in filter; cut is done by subtracting it away—a negative coefficient is thrown at the post filter attenuator instead of a positive one. There is a non obvious criterion for cut coefficients—as one cuts, the effective $Q$ of the EQ responder tends to sharpen; the frequency response of this arrangement at, say, 12 dB of cut is not complementary to that at 12 dB of boost; one needs to relate and modify the filter $Q$ with cut level in order to take this into account and retain customary lift/cut symmetry.

Multiple sections of parametric EQ can be and usually are simply cascaded, although emulation of many classic analog designs has been better served by running the multiple filters in parallel and then adding their gained results all together with the straight signal. The band interactions are entirely different, offensive to a tidy mind, but far closer to the truth!

Given that most parametric EQs use bandpass filters only (at a push even shelving filters can be faked reasonably well using such) and that, as we’ve seen, bandpass filters have their $b1$ coefficient always at zero, it can make sense not to perform that multiply at all, thus saving data fetches and a multiply. Additionally, since the $b0$ and $b2$ coefficients are simply inverse of each other, only one need be sent from the host processor to the DSP, the inversion being simply achieved internally. This is welcome streamlining of the processing.

### 25.21.4 Shelving EQ

Real shelving can be achieved by using a full biquad in the EQ (as opposed to the simplified bandpass-only variety shown) with low-order high-pass or low-pass filter coefficient sets, or an even simpler structure as in Fig. 25-140. Much greater than a single-order response in the filter tends toward a frequency response with a “phase-bounce” in it near the turnover frequency, generally considered undesirable (except perhaps when one is being very picky emulating a Baxandall). The arrangement shown is a shelving EQ using very short filters. Advantage is taken of the fact that with single-order filters one can very easily create a high-pass filter merely by subtracting away a low-pass from a straight signal.
25.21.5 EQ High-Frequency Response Anomalies

Odd phenomena occur when filters are attempted too close to half the sample rate, 24 kHz in a 48 kHz system for discussion here: partly as a result of the inevitable zero in response at half the sample rate with bandpass filters, as we saw, and partly an effect of the prewarping in the transform calculations used to create the filter coefficients. The effective $Q$ of a filter as used in a parametric such as this appears to increase (become sharper) and become asymmetric (high side gets steeper) as its curve approaches $F_s/2$. Although this effect can be considered unimportant, occurring at the audible extreme as it does, this behavior can be improved by the expedient of applying a subsidiary correction to the desired $Q$ value prior to warping, or by the more fundamental approach of oversampling. This basically means running the EQ (or at least the HF bits of the EQ) at twice the sample rate; upsampling to 96 kHz and downsampling (to get back to 48 kHz) are quite straightforward. This has the effect of pushing the squiffy zone up toward the new $F_s/2$ of 48 kHz, where it simply won’t matter, keeping the normal audio-frequency range of EQ linear and tame. Under some conditions with some program material, upsampled EQ (even though subsequently brought back down again) can sound better. One has to be very careful with the nature of the reconstruction filters in the upsampling in order not to imbue even worse funnies in EQ frequency response than one is trying to fix.

Fig. 25-141A shows the squiffy effect on a 16 kHz $Q$ of 2 parametric EQ section; a similar $Q$ of 2 filter at 200 Hz is shown for comparison. Correction (not oversampling in this case) results in the improved lower-frequency slope of the 16 kHz filter; this is now comparable to the skirts of the 200 Hz filter (Fig. 25-141B). Unfortunately, there’s not a whole lot one can do about that zero at 24 kHz without oversampling, so EQ close up to the band limit will always be a bit suspect.

![Figure 25-140. Shelving EQ using single-order filters.](image1)

![Figure 25-141. High-frequency anomaly](image2)

25.22 Digital Dynamics

There are many approaches to dynamics processing in digital, but most fall under one of two categories: mapping and literal. Briefly, Mapping involves creating a plot, a table, or a map describing what the desired output level for any particular input level needs to be; an input sample comes along and based on its value, a gain-control value is picked out of the look-up table map that is to be applied to that particular value of input...
in order to create the desired output level. The map can contain the transfer values for many different sorts of dynamics processing simultaneously—say, compression and gate, limiter and expander, etc. Fig. 25-75 in the earlier discussion of dynamics gives a clue as to the structure of such a map.

*Literal* is building a digital processing equivalent of how one would literally achieve the processing in good old analog.

For all the fuss that is made about how DSP makes doing audio design harder, it’s nice to come across aspects that make life so much easier and nicer. Here are two:

- A machine language mnemonic for ABSolute value. The effect is to look at a number and if it’s negative, make it positive. It’s the DSP equivalent of a precision rectifier, never the most trivial of analog design exercises.
- MPY (Multiply)—This is the most perfect, distortion-free, vice-free gain-control element. One will never, ever, want to play with VCAs or FETs again.

### 25.22.1 Mapping Dynamics

Look-up table dynamics have the strong property of being very fast in terms of processing cycles at the expense of the memory for an adequate map or set of maps. The precalculation has already been done, so all that needs to occur is the indexing of the look-up table from the value of the input signal—returned is the gain-control value—very short and to the point. Depending on the dynamic range over which the dynamics is to behave, the depth to which (how low in level) the dynamic behavior is to be adequately described (important for gates, expanders) and importantly the degree of resolution of the table (so that signal levels don’t noticeably lurch from one value to the next), the size of the tables can get quite healthy. In addition, it is often convenient to actually run more than one table. Required memory usage may or may not be a problem—some DSPs have huge rafts of memory, while others, designed for less memory-intensive streaming audio applications, may have only just enough for the basics.

The map only describes the instantaneous gain value. Direct application of recovered gain values would result in awful distortion. Obviously some temporal constraints need to be added. Typically these are the classic dynamics values of attack and release and such. Where these time constants are applied is an interesting question. In order to use the usually relatively slow release time constant to smooth out the inevitable steps from the table quantization, this usually follows the look-up. If one were to be emulating a peak limiter, then one might well let the input signal directly pick its value from the table and then apply the usual short attack time constant to that. In other words, for a limiter, both attack and release would follow the look-up stage.

Compressors generally have a far more relaxed attack time, with the intention of deriving a signal more corresponding to the audio energy than its instantaneous peak. In this case the attack processing would take the form of short(ish)-term averaging or even rms-like detection; the result of this averaging would be used as the pointer into the look-up table. The release would be left on the output of the look-up, mostly for its role as janitor, tidying up the potentially ragged steps.

Assuming a compressor, a likely threshold range would be from −40 dB below nominal operating level up to, say, 10 dB above. Since nominal operating level is usually at or around −20 dBFS, this implies that the look-up table has to encompass an input signal range of −10 dBFS down to −60 dBFS. It has to do this with sufficient resolution that no gain lurches are obvious. (Although most musical program material can withstand even comically large gain lurches under these circumstances, some—solo flute or a slowly decaying tremolo bass-guitar note spring to mind—will highlight painfully small ones.) Since the gain steps should almost certainly be dB linear or close to it, and the applied signal is linear, it is wise to perform a logarithmic conversion to the input signal to closer approach dB-to-dB mapping in the table. These tend to be computationally expensive or involve look-up tables themselves (!), but the penalties for not prelogging are either a look-up table to achieve adequate resolution at the lower levels (and −60 dBFS is a long way down, to 1/1000 in fact) or reduced accuracy at the lower levels for a smaller map. A linear map for this compressor might need to be 2048 or 4096 steps deep to have nonembarrassing behavior near the bottom.

Big tables, actually big anythings, are bad news in the sense that if the parameters are changed (say the compression ratio is altered a notch) a whole whacking great new table has to be fed from the host microcontroller up to the DSP. The alternative, if the memory in the processor supports it, is to permanently have a suite of maps encompassing the range of parameters required. A different map is pointed to when a parameter changes. *LOTS* of memory!

A nice lateral thought solution to the really deep map problem affords itself with the use of floater (floating-point) processors. (Actually, it can be and is applied in literal approaches, too.) This is to create a
good and concise map, or set of maps for various changes in parameters, and then to move the threshold around by scaling up and down the actual audio samples accordingly. In particular, expansion curves can be created economically of memory; instead of moving the curves around, the audio is scaled instead to create the desired response.

A peak limiter, operating over a comparatively much reduced dynamic range, may possibly eschew a log convertor and just look up directly. On the other hand, an expander may have to adequately describe down to –90 dBFS (or whatever the “don’t care” level might be). Which brings to the fore another point, which is that if different time constants are required for different functions, as they certainly would be between a compressor and a gate, say, it could make sense to use a different look-up table for each.

### 25.22.2 Literal Dynamics

This is the technique of emulating (as close as one can) how an analog circuit achieves the required dynamic behavior. There is a bit more art in this approach, and although the algorithms tend to be longer and certainly more intensive than mapping, there is very little memory usage, and changing parameters just involves sending a handful of coefficients to the DSP from the host, rather than potentially thousands.

It is possible to emulate the rough-and-tumble free-for-all uncontrolled servo-loop behavior of a feedback-style compressor/limiter, or alternatively plod through the tidy-mind deterministic feed-forward VCA approach, which involves division and/or much logging, antilog’ing, and untold processor time (transcendental functions are very long-winded in DSP), for ultimately a well-behaved but, frankly, bland result. (Guess which the author finds more fun?) Filling a whole DSP with such a VCA-like processor isn’t difficult.

There is just as much latitude for approach with literal dynamics as there necessarily has been with analog design; indeed, if one’s goal is to emulate classic analog dynamics this is really the only way to go.

#### 25.22.2.1 A Simple Digital Limiter

Fig. 25-142 highlights how dynamics signal processing in DSP—in this case a simple peak limiter—can almost slavishly follow an analog architecture.

The key to the limiter’s operation is the gain-reduction value—sorry, the author still thinks of this as a control voltage. Remember that multiplying a signal-coefficients by 1 doesn’t change the signal; multiplying by a fraction less than 1 reduces the output signal—i.e. affects gain reduction, which is what we need when a limiter is biting.

First, the immediate present (new) sample is multiplied (MPY) by the stored GR-generated last sample. This is necessary to judge whether and which way this last GR value needs to be adjusted for the present sample. The absolute value (ABS) of this modified input sample is then compared (CMP) to the threshold coefficient. If it is greater than the threshold the GR value needs to be reduced, and the program branches into attack, where the old GR value is multiplied by a coefficient usually just slightly less than 1. Likewise, if the threshold isn’t breached the GR value can be relaxed, so it branches off to release, where it is in effect multiplied by a coefficient just ever so slightly greater than 1. This is shown in the diagram as switching between using the attack coefficients, or the release coefficients. Naturally, the modified GR value has to be clamped such that it can’t rise higher than 1 (and so no longer be GR!) and that is also the normal unity “resting” case.

The coefficients for attack and release are in this simplistic case (it can get considerably more complex!) multiplicative—the GR value is changed by the same proportion or, in other words, the same number of fractional dB per sample. Running at, say, a 48 k sample rate, in order to have a 1 dB/s release rate the coefficient would have to represent 1/48,000 dB increase in GR.
value, or about 1.00005. “Slightly” says it all. This dB-per-time gain trajectory works quite well in audio, emulating the dynamic response of many good analog systems.

The last things that happen are that the newly modified GR value is saved for use next sample and also used to multiply with the present input sample to create the gain-reduced output sample.

All in all, it is almost an exact parallel to a simple analog feedback-style limiter; complexity concessions exist for operating in a sampled-time system (such as the initial input/last GR premultiply), as opposed to relying on the always existent signals in the continuum of analog. On the other hand, one effortlessly achieves true dB/time gain rates for attack and release, usually a feature of posher analog designs and only ever approximated in simple systems.

25.22.2.2 Feedback-Style Limiting and Compression

Unlike most analog GR elements, the “MPY” in a DSP is directly linear in operation—i.e., a gain-reduction value of say 0.3 will cause the signal through the multiplier to be reduced some 10 dB. It is not linear-by-dB, like a VCA, or a mangled exponential/logarithmic like thing such as from using a raw semiconductor element such as a transistor or FET. Yet, as has been shown above, linear-by-dB results can be achieved fairly simply. Emulating other laws can get rather interesting, but are certainly attainable, in pursuit of a sound. Similarly, the determination of the amount of instantaneous feedback in a feedback limiter depends on many things, not least the attack and release time constants necessarily applied to it. Another is whether the control signal is being generated all the time and only applied when the threshold is exceeded or alternatively if the control-signal determination is only woken up when the threshold is exceeded. Both can work well, and both sound utterly different.

Feedback-style compressors can use basic limiters as above as a starting point. The limiter (using the required attack characteristics of the compressor as its attack/release time constants) creates an overage signal implicit in its own control signal, representing the amount the input signal is exceeding the limiter threshold at a given moment. By manipulating this overage so as to create a control signal more in accord with a chosen compression ratio rather than the hard limiting, a suitable release time constant applied, the doctored control signal is used in a second multiply on the untrammed input signal, outside of the feedback loop. As an approach, this combines the edge and sound of a feedback-style dynamics unit with a sane deterministic compression ratio. Fig. 25-143 shows a family of deceptively analog-looking input output curves from a digital soft-knee compressor using the described technique.

Figure 25-143. A family of compression curves from a digital dynamics section.

25.22.2.3 Gating

The purpose of a gate is to attenuate completely or partly a signal that falls below a given threshold. Typically they should wake up (open) quickly, hang open for a while if the signal goes away just in case it really hasn’t, and then close at a gentler rate. Also, to prevent “falsing,” there are two thresholds, one for opening and the other, slightly lower in level to determine closure. Written as described above, it is about as “digital,” yes/no, a set of conditions as one can ever hope to meet in audio and is a complete natural for the literal approach.

The absolute value of the input signal is compared to the open threshold; if tripped, a target control signal of 1 (unattenuated) is applied to a short low-pass filter bearing the attack (open) time constants feeding the attenuator multiplier (this will quickly ramp up the gate to open); at the same time a counter is initialized. The counter is the hang-time counter. It is reinitialized at every sample that the close threshold is exceeded such that it doesn’t get a chance to start counting down unless the signal really has gone away. If that occurs, and the counter does count down to zero, a control signal value of zero (for off) or some other value representing an amount of off attenuation (depth) is applied to a longer release time constant low-pass filter, the output of which is applied to the attenuator multiplier.

Fig. 25-144 shows the dynamic transfer characteristics of a microphone input using a combination gate/soft limiter; this combination is used extensively, in this case for a stage backup vocalist. If the singer is making
enough noise, the gate opens (actually it relieves 14 dB of attenuation, which is enough to make stage spill go away enough), and the limiter almost immediately takes over, keeping the voice at a manageable, consistent level for the mix. Note the 3 dB of makeup gain. Lest one is concerned that this combination is far too unsubtle for quieter songs, remember that this is a digital process and in the context of a programmable console can be (and is) reprogrammed to suit on a song-by-song or even section-by-section within a song.

25.22.3 Inadequate Samples for Limiters

By and large, Mr. Shannon and Mr. Nyquist did great jobs. Digital audio works really well and it is indeed possible to reconstruct an indistinguishable result from a source through a system sampling barely twice as high as audio bandwidth. But there are a couple of places where a limited number of samples trips up—In particular, attempting to sense the peak of a signal, as one attempts to do with limiters and gates, both of which need to respond accurately to them.

Unfairly and unreasonably (since it isn’t terribly relevant to most real audio) we’ll consider first the example of Fs/2—half the sample rate. With only two samples per cycle of sampled signal it is entirely possible for the two samples to miss the signal altogether, if they happen to occur at zero-crossing points of the applied audio signal. But, then again, they might hit the jackpot at the crests.

More realistically, look at the two extreme cases of Fs/4, or 12 kHz for a 48 kHz sample rate, in Fig. 25-145. Nobody is arguing that 12 kHz isn’t audible, yet here is a case where there can be as much as 3 dB error in sensing a level. There are similar, if far less serious points of error dotted throughout the audio spectrum (e.g., Fs/8, 6 kHz etc., or anywhere else where Fs is divided by an even number). Now, to be completely fair, under any reasonable circumstance this effect would not be excited and certainly not be audible, since an exactly 12 kHz tone in isolation is not by and large terribly common or useful—And would be a far-reaching argument in support of a blanket increase in sampling rates for digital audio. However, in the specific case of attempting to peak-sense audio levels, one comes across these spot frequencies with too little effort. This is a reconstruction error, or more precisely, an error due to the samples not explicitly describing the signal but relying on a later reconstruction filter to fill in the gaps. Back to analog, the signal reconstructs just fine! This is just a hint of the occasional disconnect between the two domains.

A second—and actually practically more worrisome—reconstruction error effect is if through clipping or heavy dynamics processing a pair of adjacent-in-time samples are made full-scale, a downstream reconstruction filter will cause a significant overshoot beyond full scale in the recovered analog signal. This can cause clipping in the following analog stages if insufficient head room is allowed, and a nasty surprise to anyone who thinks full scale is the most one can see out of a digital system!

By way of a slightly different practical example of sampling oddities, it was noticed that digital limiters seemed to respond differently each time to a snare-drum impulse; sometimes they’d catch it hard, sometimes they wouldn’t. In comparison an analog limiter just, well, caught it. Now, snare drum is pretty evil, a nasty big initial short spike. On analysis, sometimes the spike was adequately described by the limited number of samples, sometimes it blew through the gaps. There wasn’t much difference, between 3 and 6 dB in captured peak level, but that is plenty enough a difference to be audible and, more to the point here, plenty enough to invalidate the devices as peak limiters!

Oversampling—i.e. making the sample rate twice or even more times higher—has the effect of pushing the worst of the reconstruction-error potholes out of the relevant audio band. Even though one is operating on
Consoles

exactly the same audio data originally sampled at the lower inadequate sample rate, peaks are captured accurately enough for all practical purposes. The missing peaks of Fig. 25-145 are actually being filled in by the reconstruction effect of the low-pass filter employed by the upsampler, in exactly the same way as a D/A’s reconstruction filter would.

As such, there is a very strong argument for oversampling in peak-limiter and other fast dynamics processing. Since it has one tightly defined purpose, the impact of doing the sample-rate conversions does not have too great an impact on DSP processing cycle budgets.

Unfortunately, for the live circumstance of that example snare drum, actually initially converting at the higher sample rate is unavoidable if a more analog behavior is required; the greater number of samples affords fewer gaps for those nasty transients to escape through.

25.22.4 PreDelays, or Look-Ahead

Applied only in rare cases in analog because of the difficulties in providing for good audio delay, predelaying is eminently achievable in digital dynamics sections. Predelay is the technique where the main signal path through the dynamics is delayed for a short period (1 ms, 2 ms or so) to allow the side-chain processing to determine the right amount of gain reduction to be applied; this value is then applied to the main signal path in a gain-control element discrete from that used in the side-chain, Fig. 25-146. The prime use is in peak limiters (which are nearly always feedback style, even where the other sections may be feed forward), where overshoot, which can occur during this onset settling period, can be completely avoided. An improvement in sound results, too, since very hard and brutally short attack times can be mellowed out knowing that overshoot is not going to increase as a result. A relatively soft attack time (for a peak limiter) of 1 ms combined with a comparable predelay captures the peaks without the need for subsidiary clipping and yet is sufficiently aggressive that it retains its loud characteristic but without the usual tell-tale ripping hard edge."

Look-ahead limiting is extensively used in broadcast air-chain processing, and especially on feeds to streaming compression codecs (AAC, MP3, or HD radio, for example), which generally do not react well to the artifacts generated by more conventional clipping or unavoidable transient escapee overloads from ordinary limiters.

![Figure 25-146. Dynamics section pre-delay system.](image)

Only occasionally would such processing be done in a console channel, but when it is, it should be remembered to apply equal delay (whether limiting or not) to other contributory channels in the mix.

25.23 Digital Mixer Architectures

Two distinct approaches seem to be taken to the signal-processing architecture in mixing consoles, probably stemming from how deeply steeped in traditional computer science the designer is.

25.23.1 The Sea of DSPs approach (sometimes known as a Sharc Tank).

In this, a large enough array of DSPs for all envisaged processing is closely coupled to enable the rapid transfer and sharing of data between them. The “tank” is fed with all sources, and all destinations are taken from it. In a telephone-exchange kind of approach, signals requiring processing are farmed out to other processors in the tank and the results returned; it could be regarded from the outside as one big processor. The main advantages of this approach are that not being physically constrained to a particular organization, reconfiguration is straightforward; any signal can go anywhere at any time for any purpose. If more processing is needed it is merely attached to the busing system, growing as required. The major downside is that all the flexibility makes programming such a beast very difficult (the word nightmare has been bandied around).

The “one big processor,” is of course a reality for many modest-sized applications, in the form of the humble PC. These have increasingly faster and more capable processing cores, and multiples of those, too. Although they have their own issues as far as processing audio (e.g., they generally don’t do DSP terribly efficiently), brute force, speed, and might make
up for those. A major positive is having everything under one roof, dispelling the problems of multiple-part interconnectivity.

The second approach very much follows the signal-flow approach of a conventional analog mixing console, using multiple DSPs as required, processing being applied in-line as and where it is needed. On very large consoles the mixing processing itself can take on the look and feel of a tank-style array, but other than that the layout of the signal paths has remarkable parallels to analog.

### 25.23.2 A Practical Digital Mixer

As with the discussion of analog consoles, which revolved around the description of a particular design, so this section uses as its basis the architecture of a real digital mixing console. It is shown in its basic form. As the reader is well aware, pin-by-pin details of implementation, bells, whistles etc. can rapidly mushroom and the weight of resulting detail tend to obscure; as it’s not too difficult to figure out how most of this is done, they have been omitted for clarity. It is important to remember that in terms of lines carrying audio signals, it is accurate, due to the use of the serial audio format outlined below. Shown here in a mid-size 64-by-24 format, this particular design’s premises were simplicity and scalability (it can be readily made bigger or smaller) and has proven to be robust and reliable, using no scary technology and with nothing running on the edge. Over the years this basic architecture has grown and evolved through generations of increasingly powerful DSP and support devices with the odd effect in this blighted world that it has actually become progressively simpler to build with time. Also the steady and welcome improvement in integrated converters has resulted in the overall performance blossoming to the extent that this, along with other digital mixer designs using comparable technology, owe nothing to analog in performance whatsoever.

It is assumed, of course, that the control surface has been undertaken as the separate design exercise that it largely is; this discussion concerns the signal-processing side of things.

#### 25.23.2.1 Serial Audio Format

Nearly all converters and like peripherals such as AES/EBU format transmitters and receivers use in common a serial digital interface; this is usually set up as to be two sets (left and right) of 32 data bits per sample frame (64 total), meaning a data rate of 3.072 MHz (for a 48 kHz sample rate). This is a very tame and robust rate and can be run around quite happily without fear of corruption, and as such is used as the nearly sole means moving audio data around in this console. Adopting this serial format also minimizes the amount of data format changes required.

#### 25.23.2.2 Inputs

Input signals are applied to whatever form of convertor or interface is required: microphone amplifiers or line-level inputs into A/D converters, AES/EBU into AES receivers, and subsequent sample rate converters. Sample-rate converters (SRCs) are necessary since it is unlikely (unless a whole amount of trouble has been gone through to synchronize the whole system of which the console is a part) that other digital sources will be and remain in word/data-rate synchronization with the console. The recorder may well be, but typical AES/EBU devices, such as outboard effects, or remote sources, rarely will be. If it is considered necessary (on the basis that anything that messes with data unnecessarily is a bad thing), the SRCs may be bypassed for sync’ed sources, but frankly SRC’s today have artifact levels so low as to be considered quite blameless.

At this point, all the data is in native format (the convertor serial standard), travelling in pairs—mono signals (microphones, say) in pairs and stereo sources as left/right pairs per data line. For a 64 input console, this means 32 data lines.

The channel signal processing is done four channels (two pairs) per input DSP, Fig. 25-147. The DSPs used here very conveniently have native format inputs and outputs (being designed to work with normal converters), making interfacing really simple. They are also easily powerful enough to do four well-featured channels worth of signal processing. Typically, this would be high- and low-pass filters, a four-band parametric EQ and limiter/compressor/gate dynamics, and delay (memory is attached to the external memory interface of the device to support this if required). The channel DSP has spare input and output capability, which can be implemented if required as selectable direct channel outputs, keying inputs to dynamics, etc.

#### 25.23.2.3 Mix Stage

The 64 channel outputs are taken from the 16 channel processing DSPs as 32 output lines and applied to the mixer stage(s), Fig. 25-148.

The ominously large device labeled FPGA (field-programmable gate array) into which all those lines
Consoles

disappear is programmed to be merely a (large) collection of serial-to-parallel data converters—no voodoo. A slightly simplified version of it’s contents is shown in Fig. 25-149. The FPGA takes each data line and puts it into its own 24 bit long shift-register; when it has counted that the necessary 24 bits have arrived, it seizes the data and tells the mix DSP with which it is associated that the data is ready for harvesting. (A long-ago prototype of this design actually used discrete logic shift registers. Lots of them. It was huge. FPGAs are much better.) To the DSP, the 32 shift register outputs are arrayed and addressed to look exactly like memory, and indeed, the FPGA sits on the 24 bit wide external memory bus of the DSP, with enough address lines to uniquely address each shift register location. Once informed the data is ready, the DSP copies the data values down into its own internal memory, from which the mix code accesses it. Although this can be done in real DSP software, it is usual to invoke a DMA routine (direct memory access) that, depending on the sophistication of the chip, can transfer data quietly in the background of normal processing from one area or peripheral into/out of internal memory with minimal impact on normal operation. In practice, it always seems to slow things up a bit (background is a relative term, it seems), but overall, DMA is slicker. The FPGA/DSP DMA combination does this transfer operation twice per sample, once for left data, the other for right. These two sets of data are held in buffers in DSP memory so as to be in time alignment ready for the next pass of the mix code.

As earlier mentioned, DSPs are designed to do some functions really well and one of those is the FIR filter. This involves multiplying a piece of data by a unique coefficient, adding the product into an accumulator and then rapidly moving on to do the whole thing all over again (next data point, next coefficient), and again, for as long as the filter may be. Well, from a mixing point of view, a group output multiplies an input channel sample by a unique coefficient, adds the product into an accumulator, and then rapidly moves on to do the whole thing all over again (next input sample, next coefficient), and again, until it’s done all the input channel samples. Got it? A mixer and an FIR are as far as the
DSP is concerned chemically indistinguishable. For each mix group in turn the DSP addressing runs through all the input data in turn, multiplying each by its appropriate gain coefficient. Automated addressing in the DSP keeps track of which coefficient goes with what sample. It is about as efficient a processing operation as it can possibly be.

There are of course limits as to how many channels and how many groups a single DSP can mix:

**Crosspoints.** Each channel-to-group calculation is a crosspoint (from the concept of the mixer being a big soft matrix). A 150 MHz DSP has a little over 3000 processing cycles at 48 kHz, but necessary programming overhead precludes the use of all of these for mixing. Around 2000 crosspoints is perhaps more realistic. So for 64 inputs, 32 output mixes per DSP is theoretically possible; 32 sources, 64 outputs; 128 sources, 16 outputs, and so forth. This elasticity has limits, however, as follows:

**Input Bounding.** This is the limit on how many sets of input data one can realistically capture and shovel down into the DSP and still leave it with processing time to do any mixing. Even DMAs have some time impact—in general, DMA notwithstanding, the more time taken dragging data around, the less time available for processing. External memory fetches take time (access to such memory is much slower than to internal memory—hence the need to bring the data down from the FPGA rather than access it directly for the mix). Even though it is theoretically possible to spend an entire sample period wheeling in new data in the background for calculation in the next, data management can get pretty hairy. In comparison the actual mixing is a doddle.

**Output Bounding.** This is less of a problem, since by and large there are fewer of them. But expecting a large number can lead to an issue of how to get all those mixes back out into the world.

Since simplicity was a major aim of this particular design, the outputs of the mixer stage are taken as six pairs (twelve groups) from the DSPs in-built serial interface; these group outputs are applied in the same mix’n’match fashion as the inputs, directly to whatever class of output device is necessary—D/As for analog outputs, AES transmitters for digital, etc. Deriving more outputs from the DSP involves getting those mixes back up into the FPGA—again by DMA—and doing a parallel-to-serial conversion of each there, in reverse fashion to that done on the inputs to the mixer stage. By such means, the modest processing power in this mixer core can easily handle a 64-by-32 console. Here, the twelve buses not coming directly serially out of the DSP are done in this manner.

Increasing the number of mix buses yet further would be achieved by using another FPGA/DSP core, allowing a further thirty two mix buses. The second mix stage’s FPGA is simply parallel-fed from exactly the same thirty two data lines from the input channel processing DSPs as the first mix stage.

The fact that the mix outputs are in serial native format dramatically facilitates the dropping in of a further DSP for post mix processing if required for some applications—graphic EQs and group dynamics sections, for example.

As can be seen from the diagrams and the description, the signal flow of this console is in such striking accord with an analog implementation, one can rightly wonder what all the fuss is about.

FPGA’s are becoming increasingly faster, more capacious, and capable with the addition of on-chip RAM and dedicated multipliers and such. A mixer of modest proportions, such as this design, is implementable directly into an FPGA alone with no need for the DSP. Currently, it is a cost-benefit design exercise, deciding whether a capable enough (and more expensive) FPGA is worth it over the low-cost DSP and cheaper FPGA. But the trend is clear.

**25.23.2.5 Universal Mix Buses**

The described design provides a large number of raw mixes, with no mix-specific hardware or code. It may be noticed that apparently an otherwise vital subsystem to the mixer appears to be missing—monitoring. Well, actually it isn’t, and the fact that it is implicit in the design as it stands points out an approach and attitude to mix buses that would be hard to maintain in analog where every bus is a significant expense: in digital, buses come cheap.

Monitoring in this case commandeers a pair of mix buses (assuming stereo); think PFL bus for now. Any input to the mixer can be monitored on this bus by applying an on coefficient to the appropriate crosspoints to bring the source(s) onto the bus. So far so good. But for monitoring output buses (stereo group, auxes, any of them actually) rather than apply the analog solution of a selector to switch between those existing groups, what one can do is exactly recreate the mix to which one wishes to listen; if one were to apply the same coefficient set that is making, say, auxiliary bus 5 to the monitoring bus, too, then one will exactly recreate what is happening on aux bus 5 in the monitoring.
Where this approach really shines is main mix bus monitoring—one can mess about with the monitoring bus as much as one likes without affecting the main mix at all—nondestructive soloing becomes a reality, simply implemented at that.

Talkback is simply treated as one of the sources to the mixer; it can get routed into any of the mix outputs with no necessity of creating a separate subsystem, with IFB (Interruptible Foldback) talkover ducking or muting deriving from modified coefficients.

Note there is no distinction made between the group outputs as to what their ultimate purpose will be, group, aux, cleanfeed, etc. All that distinction is done at the control surface and the interpretation of its requirements by the host microcontroller—in other words the differences are all in the controlling software and not in the hardware that implements the mixes.

25.23.2.6 Coefficient Compounding

This is a rather fearsome title for a rather nice concept. This is how master fadering and group fadering are achieved. Rather than have a separate downstream gain stage after a mix has been achieved to effect overall level control, a convenient approach with a soft matrix mixer such as has been described here is to take the sensed level of the real, physical, group fader and then multiply each of the coefficients feeding that particular bus by its value. This is a direct analogy of VCA grouping, where one fader actually modifies the level contribution of each source to the mix bus, rather than gain changing the mix after the fact. Since all of these numbers (source contribution coefficients and group fader) exist in the host microcontroller, the arithmetic manipulation is quite straightforward. The database management aspect of this on a large console can get quite interesting, but this pseudo-VCA grouping approach is widespread and very powerful.

25.23.2.7 Coefficient Slewing

Rapidly altering coefficient data in a DSP runs into exactly the same tone click problem as do MDACs in analog; even small transitions made when the audio data sample is nonzero stand a very good chance of being heard as a click. A fader swipe can generate the all-famous zipper noise, and just as with MDACs, without care and attention the effect in EQs is little short of comical.

Sensing zero-crosses in digital is practically impossible, since particularly at high levels of high frequencies there may well not be any samples anywhere near zero—remember this is not a continuum like analog, the samples are just a regular set of stabs in the dark. A wide enough window to capture enough zero-crossings would probably be wide enough to still allow some transitions to be audible. Never mind the fact that the processing overhead for doing a window compare and decision on each and every coefficient would be overwhelming; it would probably cut the potential number of crosspoints in a mix stage down by an order.

A good solution is to allow the DSP to ramp relatively slowly between its present value and the new desired value, creating its own interpolating steps on a sample-by-sample basis small enough that each is inaudible. (This, by the way, is one of the necessary processing elements that eats up a chunk of mix-DSP cycles, limiting the maximum number of crosspoints available to significantly less than the raw cycles availability of the device would suggest.) A slightly different approach is to “pre-slew” the coefficients in an intermediate processor (often also a DSP) to offload the effort from both the host and the target DSPs. The inter-DSP communications can start to get a bit fierce, however.

It is a nerve-wracking moment when first trying on-DSP slewing. After all, the coefficients for IIR filters such as in EQs can be very, very touchy and have little tolerance for error before doing very odd things most unlike the filters they were intended to be. Amazingly though, it seems as though provided the filter set is stable where it starts, and stable where it ends up, it stays stable in between as the coefficients are slewed; it might get just a little wonky, but not enough to cause any serious sonic issues and certainly not enough to explode into what has been charmingly called “screeching cats from hell” (DSP audio guys and gals hear lots of them).

25.23.2.8 Clocking

A major subsystem within a digital mixer is clocking—making sure that each of the various circuit elements get the necessary hard, clean clocks required to operate properly. In this design alone there are six clocks for processing: 12.288 MHz master clock (actually divided down from 24.596 MHz to ensure symmetry), 6.144 MHz used as a master clock by AES/EBU transmitters, 3.072 MHz as the main serial bit clock for the standardized native serial data format, an inverse of that used by some A/D or D/A converters of less serial format flexibility than others, then 48 kHz, which of course is the data sample rate and houses left/right clock.
Although there is from a component-count standpoint a tendency to want to include the clocking generation in with an existing FPGA, say one from a mix stage, it can be beneficial to have it stand alone in a smaller FPGA or CPLD package. Generally, each clock feed to each device should be individually buffered and be as close to its target as possible. Needless to say, this takes a lot of FPGA/CPLD pins, and a single-purpose device starts looking like a good idea. The major benefit is that one can physically locate it where it can do the most good; this is as close as one can get it to the A/D, D/A and sample-rate converters. Ideally (but rarely is it possible) these should all be clustered in a “convertor ghetto” to keep the clock lines really short and tight from the clock generator, which minimizes noise and slewing on the various clocks, which can directly affect convertor jitter noise performance.

### 25.23.3 Signal-Processing Control

Fig. 25-150 outlines a typical control architecture for signal processing, or the *processing end*. It should be considered along with Fig. 25-124, which shows the *control-surface end*. The separation reflects that often the processing and the control are, indeed, in separate places interconnected by a network.

#### 25.23.3.1 Controlling the DSPs

Each of the DSPs has an SPI (serial peripheral interface) port, an industry-standard means of device intercommunication. This consists on each device of a serial clock line, which synchronously clocks data in or out, and a serial data in line; these may be paralleled around all the DSPs. A serial data outline needs to be selected in a multiplexer for feeding data (such as metering information) back into the host processor. There is also a chip select line, which needs to be run individually back to the host; when yanked, a particular DSP knows that the data being clocked out on the serial data line is for it.

It is down this SPI interface bus that the DSPs receive their boot code at turn-on (the program code which it will run), a set of working coefficients (usually those that were current when the console was last turned off), and any changes to those coefficients as the console is being operated and parameters changed.

#### 25.23.3.2 Metering

The indication to the user of the various channels’ and groups’ signal levels, dynamics gain reduction values, etc. is performed by the control-surface host, driving the appropriate indicators. How the data gets to that micro from the DSPs that are doing all the work can vary widely in implementation depending mostly on the physical configuration of the console. If it is a single box, with the signal processing under the hood of the control surface, then metering data can best be taken simply and directly from GPIO (general-purpose input and output) pins on the actual DSPs. Alternatively, but it is giving up a major advantage of the one box, the host micro could recover all the metering data from the DSPs and distribute it all accordingly. If, though, the

![Figure 25-150. Signal-processing control architecture.](image-url)
console is split, then a means of harvesting all the metering data from the DSPs, squirting it all up to the control surface, then disseminating it appropriately definitely has to be devised. This one sentence describes something that has many, many times been hopelessly underestimated, and at least in one case required a whole separate Ethernet run back to the control surface purely to handle metering.

In this design’s case, the host micro polls each of the DSPs in turn, clocking back the metering information from each through the return path of its SPI; a packet is created of each complete console wide set, which is then delivered back to the control surface.

The good news is that metering data is not needed at anything like audio data sample rates. The feeds have been prefiltered in the DSPs with appropriate time constants and updating the relatively small data (8 bits is plenty) relatively slowly (better than every 25 ms or so) is adequate. Nevertheless, unless the polling by the host is under rigorous and deterministic control and the total bandwidth of even this fairly slow, small data set is carefully considered, the metering can start to be a major burden.

25.23.3.3 Host Microcontroller

This is usually a fairly fast and meaty micro, often of the x86 persuasion or large 68000 family. In the case of a self-contained console (control surface and signal processing all being in the same box) this will in all likelihood administer the control surface and displays in addition to the relevant function here, which is riding herd on the DSPs.

The host’s job is to turn control parameters (as generated by the control surface) into coefficient sets that the DSPs can understand to perform the effect of those parameter changes. This would be by the coe-gen, or coefficient generation, software (typically written in C) and is equal in importance—a fact little appreciated—to the actual DSP code the DSPs are running. It is the coe-gen code that just as much determines how a console runs, feels, and sounds—after all, the DSPs are just doing what they’re told and running code sent to them, by this host. By ways of example, the coe-gen code looks up what mix DSP crosspoints need to be modified to what coefficient values in response to a given fader being moved to a certain level and to take into account any mastering overlays, pseudo-VCA subgroups, etc.: what coefficient values to create for a parametric EQ section changed to differing parameters of frequency, level, and Q. In addition to being a fraught exercise in database management, there’s some pretty good math in there too. (In DSP software design, one strives to keep the actual DSP algorithms as straightforward [fast] as possible, leaving as much squirrely and calculation-extensive stuff as possible to the coe-gen code in the host.)

Since a major part of the thrust toward digital consoles has been their promise of storage and recall, statically (snapshot) or dynamically (as in real-time automation), it is beholden to the host to manage the data transfers involved. Everything that may need to be stored is already in the host, but the software routines and hardware to facilitate storage/recall need to be present. A console can be quite self-contained in this regard if the data set is relatively small; on-board flash memory may suffice. Otherwise, whirling and whining hard drives may well be necessary. In the event the console is integrated reasonably closely with an audio recorder, hard disk, or otherwise, the automation data may get squirited onto that as a sideband.

In a split console (control surface is separate from the guts), the host also has to manage intercommunication with the control surface; typically this is done with an Ethernet variant, which demands the existence of a TCP/IP stack for the communication protocol and hardware to terminate the Ethernet.

25.24 Digital Audio Workstations (DAWs)

Fig. 25-151 shows the major (usually indivisible) elements within a digital console system and their relation to each other.

User Surface. This has indication of control positions, metering, and means of controlling the audio processing and can range all the way from the sea-of-knobs large-format console-style surface to graphics on a PC screen with a mouse.

Surface Host. A micro to look at, make sense of the controls, and drive the metering. This can vary from being a small embedded micro to a large PC-like processor, depending on the size of the surface and if it is expected to do high-speed communication, should the control surface be remote. It can also not exist, its nonetheless necessary functions being subsumed by a PC’s CPU processor.

Processing Host. Takes care of looking at the data being passed to it from the surface host, creating the necessary coefficients for the audio processor, and also looks at the various and many metering returns from the audio processor, rendering them down into a form
useful for the control surface to display. This is usually a sizable and capable processor, unless its functions are being done by a PC’s CPU.

**Audio Processing.** This uses the coefficients from the processing host to modify the audio path(s) as desired, usually within a raft of DSPs, either aided by or supplanted by FPGA’s, unless, of course, the audio processing is within a PC’s CPU.

**Routing Assignment.** Decides what audio path is going to get routed through what path within the audio processing and so what controls apply to it. Also decides on what output ports processed audio appears. Often an additional soft matrix done in a DSP mixer (particularly when integrated with Audio Processing), or a hard switch in FPGA, and often a stand-alone product but entirely within the capabilities of a PC’s CPU.

**Audio Input Output.** This is the termination of audio sources and destinations and their conversion into a form of digital information the Audio Processing can assimilate. Examples are A/D and D/A converters, usually many, and SRCS (Sample Rate converters) to seamlessly integrate external digital audio sources. Often stand-alone, in cages dedicated to their purpose, locally or separated from the rest of the system. Often integrated with the Routing/Assignment, and sometimes along with audio processing. And sometimes just plugged straight into a PC. (Bet you can’t guess where this is going…)

The paths between any of these blocks may be broken and subject to transport if need be, but it is far more likely by way of practicality at labeled junctures B, E, and F; for instance, it is generally easier to transport the rendered, lower data concentrations of control parameters and meter data between the Surface and processing hosts at (B) than it would be to try to move the raw preprocessed metering data and coefficient sets, as would be the case if a split were made at juncture (D).

Nearly any audio console with digital control fits into this loose model and contains all these elements in some form or other; even a DCA (digital control of analog) console, with a control surface separated from the processing electronics at interface B, is similar to case (1), a normal console. So it can be seen that the lineage from analog consoles, through DCA, pure digital consoles (which at least initially mirrored analog consoles almost totally), through to DAWs is quite plain.

The subdivisions of these processing blocks for different classes of console, and with likely transport means, are shown in Fig. 25-151:
1. A normal control-surface/mixing router arrangement is shown with a single major transport requirement at juncture (B).
2. A distributed mixing-on-the-network style console is shown with network links inserted at (B) and (E).
3. An all-in-one box arrangement (emulating stand-alone analog consoles and simpler digital consoles) is shown with no transport insertions.
4. A DAW with an external input output unit has a connection at E.
5. A similar DAW but with an add-on physical control surface has links at B as well as E.
6. A simple DAW with limited I/O output having no need of external interconnection.

This latter uses the host PC’s GUI for control and display, the PC’s CPU to do all the hosting and audio processing, and internal converters to get the audio in and out. A surprise may be the extensive use of semi-pro or domestic communications schemes in the DAW contexts—for instance, MIDI (musical instrument digital interface) for the control surface interconnection, and USB as the audio transport to the audio I/O interface box.

The major underlying message from all this is that DAWs are consoles, too! In broad-brush architecture as shown in Fig. 25-151 they are—since they have to perform all the same functions—indistinguishable from “real” consoles, which is actually an understatement, since in many respects DAWs are more versatile and powerful.

25.24.1 The PC

A decently fast and capable central processor(s); a reasonably easily crafted and programmed graphical and user interface; fast, inexpensive, and capacious memory; and omnipresence all afford the PC an enviable basis for audio production. It is and nearly always has been a more cost-effective platform than any purpose-built digital audio system of comparable facility. All the technical advantages made it a natural basis for initially fairly elementary audio functions such as a hard disk recorder/stereo editor, up to today where entire multitrack recording/editing/processing systems readily fit on a laptop—the like, of which would have been the envy of major studios just a couple of decades ago. Despite the best efforts of operating system manufacturers to make real-time audio streaming into and out of PCs problematic, the PC is a formidable tool.

25.24.2 MIDI Sequencing—Where It Began

An early PC application was in the recording, storage, manipulation, and automation of MIDI-encoded musical parts, to facilitate the assemblage of songs. This did not involve any audio, per se, merely the management of streams of MIDI commands against time. These were then issued in sequence down a MIDI path to attached music synthesizers that played the music itself.

The desired ability to compose, rearrange, copy, and time-slip parts in relation to others in synchronization gave birth to extensive and powerful automation, which largely outshone concurrent traditional console automation schemes.

Recording and manipulating audio on a PC occurred when processor speed and disk drive size and access speed allowed (two-track editing became commonplace, resulting in stereo tape recorders plummeting from hallowed possessions to doorstops virtually overnight). Although the means of getting multiple simultaneous live audio streams into the systems lagged, it was certainly possible for multiple tracks to be recorded sequentially so building up a true multitrack recording, and this was exactly the mode of operation prevalent in basement studios anyway.

And so it was not the least bit surprising that the major exponents of MIDI sequencing software became the major exponents of PC-as-studio, and their approaches from MIDI world translated over into audio world reasonably well, despite significant differences in philosophy. This does explain why those previously steeped in traditional recording find the assumptions, methods of control, and even terminology of sequencer-studio tools quite alien, while those who have grown up with it regard traditional techniques (and terminology and assumptions) to be, well, odd and quaint. MIDI sequencers have cast a long shadow over today’s audio processing.

Many of the strengths of the sequencer applied to audio readily in ways unthinkable before—time-slipping or copying individual tracks or segments, unlimited takes of tracks or segments being treated as related parts rather than completely separate tracks, as examples. As the recording hardware (PC) became more powerful and the number of instantaneously available tracks increased, a deliciously ironic approach has come to the fore: originally, the sequencer shuffled MIDI elements around, in the hybrid audio-plus-MIDI the two were treated in parallel yet separately, but now it is common for all the MIDI tracks to be rendered as audio onto audio tracks just like live sources, and the audio control and automation methods rule.
25.24.3 DAW Audio Ins and Outs

Means of moving audio around are covered in more detail in Section 25.25. DAWs just like any other console need to get audio in and out, and from the lesser to the greater this can include:

- PC’s built-in sound card. (It had to be mentioned, and besides, who honestly has never used one in a pinch?) Typically analog-in, analog-out (sometimes S/Pdif), at very low domestic signal levels, and of generally indifferent to awful quality. But convenient.
- USB/Firewire. Links to external sound card convertor boxes from stereo in/out up to as many as 16 in/out, see Fig.25-152.
- ADAT. 8-in or 8-out via fiber-optic cable.
- MADI. Up to 64 ins or outs via coax.
- Ethernet. Either true TCP/IP Ethernet or audio-specific UDP variants using the same hardware typically 64 I/O for UDP.

Specific drivers—and in the case of ethernet and variants whole suites of interface code—need to be installed on the PC to deal with the audio on these various schemes. The DAW software has both input and output routers that can pick which incoming sample within a stream goes to what input, thus track, and which DAW output gets sent out what slot.

So far, the PC-based, sequencer-modeled audio control approach looks like a multitrack recorder (of virtually unlimited scope) with wicked automation and editing. But what of console-style audio processing?

25.24.4 DAW Internal Audio Paths

The audio routing within a DAW tends by design to be quite basic: Fig. 25-152 shows this as being essentially a route from input to a recorder track, thence from either before or after the track to a mix bus (or buses), thence to an output(s). Recognizable console like features such as a fader and panning are included just to show a typical starting environment.

What all the Xs mean is that it is possible to “drop in a plug-in” (translated: apply an instance of a signal-processing software module) or apply the signal at that point to anywhere else there’s an X. An output bus, for example, can and frequently does get routed back to be a recording track source (bouncing in oldskool); many modules may be inserted concatenated-edly at each X. There is considerable flexibility. This approach—nearly everywhere being an insert point and only providing access for processing—as opposed to the “everything’s in there in case” traditional console model allows what processing power there may be to be applied as and where it is needed while leaving all other paths unfettered.

25.24.5 Plug-Ins

A plug In is a collection, library, of disparate software programs that variously (a) actually process (or generate) the audio in some form or other—e.g. EQ, dynamics, delay, reverb, etc., or a MIDI musical instrument; (b) provide a graphical module for display on the system’s GUI, replete with knobs, buttons, dials, gauges, meters, and blinky-lights, (c) calculate the conversion of the parameters from those controls into coefficients that the actual signal processing can understand; and a render metering data in the reverse direction, from audio to GUI. All the “handles” typically become available to the system’s automation system, either directly or by being MIDI addressable—in other words, the module can look to the system as just yet another MIDI slave device, which can automate it accordingly.

Standards have evolved (in the form of requirements by major DAW players) for plug-ins; VST (virtual studio

Figure 25-152. Simplistic DAW audio path.
Consoles

technology) and DirectX stand out as the more popular nonproprietary schemes affording wide interchangeability between different flavors of DAW.

As mentioned, many plug-ins are MIDI musical instruments or devices in their own right, but the widest variety is in audio processing. Most DAWs come with a decent suite of generic modules that allow all the traditional functions, plus some others that had hitherto been rack-box fare, such as reverberation units, flangers, etc.

There is a huge variety of modules available, some being specialized, and many that emulate, with greater or lesser degrees of success, existing real-world boxes, either contemporary or classic. These vary wildly, from being merely a pretty face (GUI) controlling a set of disappointingly cookbook algorithms and being passed off as something special, to exceptionally and painstakingly crafted emulations of existing products, accurate even down to little-known quirks. Emulations aside, DAWs have reached such a level of acceptance and usage that there are module manufacturers for whom plug-ins are their sole business.

25.24.6 DAW Limitations

Any description of DAW limitations is doomed to become laughable as their underlying power inexorably increases. A solution to the lack of signal-processing horsepower in the earlier days was to offload the audio signal processing onto DSP farms, either on slot-in cards that fit within the PC’s box itself or in an external frame. This afforded far superior overall performance than was then possible from the PCs CPU alone and is still an approach taken by DAWs aimed at the professional area. The downside is that it can lend itself to creating a proprietary technological island, exacerbated by the use of nonstandard file formats, making interchange between other types of systems difficult.

Clever approaches to make the best use of limited processor steam revolve around using otherwise dead time and the almost limitless ability to store recorded tracks. As an example, if an EQ is applied to a track, rather than run that EQ in real time each time, it’s played (along with possibly dozens of others, which may very well drown the system), it is run very quickly and quietly, once, across the length of the track, which is then saved as another track. That way the system just plays back a pre-EQed track rather than having to run an EQ—a huge saving in resources. If a change is made to the EQ halfway through a playback, the EQ runs in realtime from the change but at the end of the playback the resultant overall EQed track is saved as yet another track. The system keeps track of which track is the most current: this is also key to how DAWs can seem to have boundless ability to roll back or Undo changes—in addition to the automation remembering all the changes, all the older tracks are still available for instant application. Effects tracks, reverb passes, etc. need only be striped once, and never need to eat PC power again.

Reference to Fig. 25-152 shows that it is, theoretically, possible to avoid the use of the recorder altogether and simply use the DAW as a straightforward mixer. However, one has to remember two things:

1. Every instance of every plug-in will use juice, and one will sooner rather than later find out how many is too many—the resource mitigation dodge of prestripping effects on tracks doesn’t work mixing in real-time, where everything has to be happening at once. Large-scale live recordings can be done on such a DAW—the sources will all go straight to track with little on-the-fly processing being necessary, and it can all get fixed in the mix.

2. There may be excessive latency (input-output delay), mostly from the acts of getting the audio into and out of the box; this may well be audible or annoying in some circumstances.

25.25 Moving Digital Audio Around

As is plain from the earlier discussion of digital audio mixing and processing systems, and in particular that there are few constraints on where the constituent bits are physically in relation to each other, there can be an awful lot of audio to shuffle around between them. The term intra-console is used to distinguish this interconnection between bits of a console system, as opposed to moving lumps of audio around in a facility. Often, though, this gets blurry!

Sometimes all that is required is the movement of some audio from one place to the other, but increasingly there is a requirement to have all—or some—sources available at all—or some—destinations in a free-grouping arrangement. This takes on a life of its own as a network. Most end-to-end signaling types as described here can be made to become part of a such a network if they are arranged to have one of their ends terminated in a hub, in star configuration with other end-to-end links; the hub—router—has the intelligence to route the signals telephone-exchange-like accordingly. Some described transport mechanisms are designed to be networks, or network like, in their own right—the 800 lb. gorilla in this world being Ethernet.
25.25.1 Moving Audio—small-scale

25.25.1.1 AES-3

Stereo pairs (or pairs of monos) have been catered for by the venerable AES-3 standard; this is a Manchester encoded stream of two (up to) 32 bit audio words, some informational tags for link status and format, and a number of user bits that may be used for anything from turning stuff on and off remotely to serially carrying metadata (program-specific information) or more complex real-time control data. It was designed to be robust, simple, and as usable as possible in the predominantly analog world into which it was born, even down to using the familiar 3 pin XLR connectors in its usual implementation. With minor updates, mostly concerning connection variants and data rate (it now handles the once-unthinkable 96 kHz with ease), it still serves well. It is a very close cousin (indeed the underpinnings are chemically indistinguishable, and use the same chip sets) to the domestic S/Pdif (Sony/Philips Digital Interface). The audio is treated identically, but the format and informational tags differ. It is common for AES-3/-S/PDIF receivers to be set up to strip these off so as to allow universal connection, but obviously this is at the expense of any metadata that may accompany the audio stream, and, if this is of the least concern, any digital rights mismanagement flags.

A performance downside to AES-3, particularly with early implementations, was recovered clock jitter. Best performance is achieved by relocking at the receive end, either by SRC (Sample Rate Conversion) or the use of very good flywheel phase-lock loops to reestablish solid, quiet clocking. If the facility is homogenous with everything running off a master clock this is less important; “bits is bits” and as long as they arrive within the same framing period (e.g., 20.8 μs at 48 kHz) and sample clock period, and any D/A is done with the same pristine clocks as any A/D, transmission jitter is irrelevant.

25.25.1.2 AES-42

As will been seen in the later mention of USB microphones, there is a drive to push digital as close to the source as possible, in that case for simplicity’s sake, in proaudio for performance. The concept of putting mic preamplifier, A/D converter, and processing inside the microphone itself is at one and the same time seductive and puzzling. The idea of simply taking a digital stream (possibly in AES-3 format) straight from a microphone into a digital system holds strong sway; reflection shows that this—in any meaningful system—means either the addition of a plethora of hitherto unknown knobs and switches on the microphone itself or the means of remote-controlling all those functions and takes the shine off the idea somewhat, particularly to those to whom a microphone is something one simply plugs in and uses.

As has been made clear, there is little that binds a particular function to a particular physical location or piece of system hardware or software. Given that, some mouse-and-screen GUI widgets to control the microphone parameters, or indeed a physical set of hardware knobs and switches to do the same, don’t care whether the target is in the same box, another processor, or even on the same continent. That, in this instance, the target is on the top of a shiny microphone stand in the studio is irrelevant. So, not only is a means of getting digital audio from the microphone necessary, but means of getting the control parameters or coefficients up to the microphone, as well as a synchronizing reference clock so that the microphone’s pristine audio doesn’t have to suffer the immediate indignity of a sample-rate conversion to match the rest of the system. And, of course, a means of powering all this.

And so was born AES-42, in an effort to standardize all this before multiple incompatible approaches dissipated the concept’s appeal. Fig. 25-153 shows in outline form its scope.

Many hitherto console functions have found their way into microphone control via AES-42. Although the scheme is not limited to these, the Neumann TLM-103-D digital microphone, for example, allows gain, microphone pattern, absolute phase, high-pass filter, an in-built compressor/limiter/de-esser, and a peak limiter’s parameters to be controlled. It’s easy to see where that’s headed; no need for console channels as we’ve known them.

The normal connectorization is via the old familiar XLR, although the XLD is suggested for circumstances where confusion with other XLR-using systems could potentially result in damage. As would be expected, signal formatting owing much to the familiar AES-3 is used to retrieve the audio, which ordinarily comes differentially down a shielded pair; user bits in the data stream relay fixed data such as the microphone’s manufacturer, model number, and available controls; variable data such as instantaneous parameter value are also available by this means. Now the fun begins—power is sent phantom style (common mode and with reference to the shield) back up the line; instead of its merely being regulated down to power the microphone and its electronics, it is also modulated with control data and a synchronizing word clock, which are filtered off and
used to instruct the microphone’s processing. The microphone’s sample rate may either free run, in which case it is a master (but will probably need SRCing to work in a system of any complexity), or it can be slaved to the synchronizing word clock. The latter is favored, if available.

Present digital microphones using AES-42 have a choice of termination, depending on whether the system into which it is plugged already speaks AES-42 in that particular microphone’s dialect (and so control from that system is implicit), or via an external interface box which permits a computer running the appropriate and proprietary control software to talk to the microphone and audio data recognizable as AES-3 or S/Pdif stripped off for use.

An interesting side note is that Neumann, a major influence over the scheme and early adopter, make claims that such an arrangement results in better overall dynamic range than traditional microphone connections. The premise is that conversion of the capsule audio down to the common low-level microphone interconnection standard of 150 Ω/sent through a wire/low-noise amplification/then conversion of that signal to an A/D convertor within the console, is intrinsically noisier than the more direct connection of the capsule with optimum impedance transfer to the convertor within the microphone itself, without intervening transformations and stages. Their claims of convertor performance so used are impressive.

25.25.2 Moving Audio—Multiple Paths

More than a stereo pair calls for more radical answers, and as is typical with fast-moving development tended to outstrip standards-making—never mind the commercial impetus to try to capture users within a proprietary format. Two formats, one from pro audio, the other from semi pro, stand out from the earlier days of multitrack recorder/console interconnection:

25.25.2.1 AES-10—MADI

This format is very common for the interconnection of digital reel-to-reel recorders (whoever thought we’d be weeping nostalgic for those?) and older large-format
digital consoles. It carried up to 56 audio channels (now 64) originally down inexpensive TV-style 75Ω coax (plenty enough for a 48 track recorder) and owed a lot to FDDI, an older communications network backbone format. Being unidirectional meant that a MADI link in each direction to a recorder was necessary. Latency was quite low, and the availability of chipsets made implementation fairly straightforward. An oldie-but-goodie, it is still used to an extent in the pro audio world by some manufacturers for overall system interconnection and intra console knitting.

25.25.2.2 ADAT

ADAT is a simple (both in hardware and signal format) unidirectional fiber-optic interconnection, originally, to get 8 audio signals into or out of the once highly popular Alesis ADAT VCR-based 8-track recorders (which can be thanked as being the likely tipping point of recording from uptown to basement). It is still an interconnect of choice in semi-pro recording equipment, where “pieces of eight” is adequate or sensible, as when additional functionality is marketed in such a modular fashion.

Being a strictly hardware interface it is wholly deterministic (audio arrives exactly when expected) and with very low latency. Although inexpensive chipsets are available, the format lends itself to low-impact implementation in (possibly already existing) FPGAs (Field-Programmable Gate Arrays) within a product design, so incurring near-zero add-in cost.

An ADAT frame, which can carry up to eight 24 bit audio words, is 256 bits long at a clock rate of 12.288 MHz for 48 kHz. There is a 16 bit preamble containing a 10 bit frame-sync period and four user bits for control/messaging. (The arithmetically astute will wonder where the other 46 bits went; they are used throughout the frame after every 4 bit nibble—except in the frame-sync period—as synchronization zero-value bits). The bits are scrambled (Manchester-encoded) to non-return-to-zero to remove any tendency to have a dc component. Some of this—in particular, the syncing and NRZ—had a lot to do with coping with the vagaries of VCR tape transports, but as a long-standing standard with millions of installed instances it holds up very well and doesn’t warrant the potential confusion revisitation and redesign would incur. It is hard to envisage a simpler robust multichannel self-clocking interface, and its designers deserve full credit!

25.25.2.3 USB

A somewhat surprising development has been the adoption of the humble USB connectivity of PCs to move moderate amounts of audio about. This reflects the massive shift over recent years from the large-scale studio-as-shrine approach of the recording business to small-scale home or demo studio recording becoming the new mainstream.

Conceived as a replacement and expansion for RS-232 serial connections (and related mouse/keyboard interfaces) for PCs, the early USB implementation (e.g., v1.1) was hard pressed to reliably move a stereo pair of 44.1 kHz about, but the upgraded USB2 with its nominal 480 MHz data rate changed all that. As an example, Fig. 25-154 shows a 1U rack-unit box by Tascam (beneath the laptop, above the mega mic preamps) that readily simultaneously transports 16 audio paths to, and 4 back from, a PC running DAW software, all via USB2. USB2 seems to have eclipsed Fire Wire (IEEE 1394), a similar-speed (if network-capable) interconnection that hitherto briefly reigned in the sphere of small-scale PC audio transport to external A/D and D/A boxes and such.

Figure 25-154. A modest-sized DAW running on a USB link between the audio interface unit (center) and the laptop. The (almost free) DAW software allows for 48 simultaneous recorded tracks, with significant audio processing. Complete with shown external mic-amps and computer, the cost of this outfit is about that of a decent microphone; its 1990 equivalent in facilities and performance would have cost the same as a decent car, while the 1970 version would have equated a decent house, which would have been needed to fit it all in, too.

It is not at all uncommon for small mixers— analog or digital—to present their outputs and accept a returning pair of inputs via USB; small hand-held recorders likewise; microphone preamplifiers; even
USB microphones, which only work in that context. The PC to which they are connected can recognize such simple interconnections as just an external Sound Card, and has generic drivers built in to cope. Zero-effort connectivity. Better performance and more advanced control and features can be achieved with special drivers installed in the PC, but the instant connectivity thing is hard to beat.

One rightly has to be circumspect about jitter performance on a transport mechanism that certainly was never characterized for digital audio streaming with very stringent clock recovery requirements; in the case of the small DAW setup described, since A/D and D/A are in the same box, and assuming the clocking is done conscientiously within, the overall performance is limited by that, any vagaries of the link, its latency, or computer timing being irrelevant as long as the clocks remain synchronous with the data. Such are the dangers of any transport scheme where the clock is solely implicit to the data, with no external reference.

Of far more concern, however, is the computer’s operating system’s handling of audio, which can make a land of horrors transcending any worries about link jitter; this is typically addressed by the loading of unit-specific drivers (ASIO in this case) into the computer, which blow right by the operating system’s clunky hardware abstraction scheme, and instituting delay buffers capable of absorbing most temporal irregularities. Nevertheless, a USB (and perhaps more so FireWire) link’s performance is often dropout-limited by the host PC’s handling of (deferred procedure calls), the stacking up of interrupts and time-related routine calls that take longer to address and clear than the link’s buffers can sustain. Sometimes a lot of effort has to be put into disabling features/programs/peripherals (like wireless networking in particular), updating or finding the right/better drivers, optimizing this and that, installing replacement hardware, and general hair tearing, just to get a PC to adequately pass/process meaningful amounts of audio. The PC really is not a shining beacon of a streaming-audio-friendly environment!

25.25.3 Digital Audio Networking

25.25.3.1 CAT-5/RJ-45 interconnectivity types

The following communication schemes all typically use the widely available (even from the local stationery store) networking style cabling, exemplified by CAT-5 or CAT-6 cable terminated in the little plastic RJ-45 phone like connectors, and indeed often share the same terminating MAC and PHY electronics. What actually goes through them can differ wildly though. As will become plain, this enabling technology has also expanded the notions of what can be done in the context of moving large amounts of audio around, blurring the distinctions of transport, mixing, and processing.

25.25.3.2 TCP/IP—Audio over Ethernet

Ethernet, using its handmaiden TCP/IP platform, is highly popular—ubiquitous—and there is a large base of skill in operating and maintaining networks based on it. This has lent impetus to trying to use it for things for which it wasn’t really intended and is not particularly apt, such as moving professional audio. Immense effort and marketing has gone into making it work adequately. Probably best placed elsewhere.

Any Internet user knows how facile it is to move audio around, either in chunks as files or drip fed as streaming, either on a local network or the internet itself. A seemingly sensible follow-on would be to wonder if the self-evidently already existent methodology could be used for moving large quantities of audio around in a digital audio network.

Well, the short answer is “Yes.” Given the existence of Ethernet connectivity and a good IP stack (network operating firmware) in each of the required connected units, a significant number of uncompressed audio channels can be moved around successfully by such a network. However, the long answer begins. Aspects of its performance at best are eclipsed by alternative methods. The only real advantage is the previously mentioned wealth of user familiarity with, and labor skilled in, TCP/IP networking. There are significant drawbacks.

In the Internet example, the audio is almost always compressed by MP3, WMA, AAC, Ogg-Vorbis, or whatever format to radically reduce file size or to fit within a required streaming rate. Except for a few arguable examples such as news, remote, or commercial distribution for radio broadcast, compressed audio has no place in professional audio. So suddenly the necessity of uncompressed audio payload can be ten times or beyond the size of domestic audio. Network congestion effects loom that much closer, that much sooner.

TCP/IP is a packetized system and incurs at best a minimum packet assembly/disassembly time at the ends in addition to the relatively quick transmission times. The packets are ordinarily comparatively small—in a streaming sense—multiplying the processing/depro-
cessing overhead and bandwidth wasted in sending packet headers. This can be tweaked, however.

This all incurs latency (i.e., a delay between input and output) that may or may not be acceptable. Live applications—say, broadcast or sound reinforcement—might well have issues, particularly if many links’ latencies become cumulative. These are relatively minor latencies, though, compared to what’s to come in a real environment. Oh, yes. It gets worse….

Congestion is paradoxically key to TCP/IP’s main limitation for audio, considering it was designed to—and does—handle congestion superbly for its intended use. In the absence of any other network traffic that may contend with a primary audio stream, the packetized audio will likely arrive unmolested and in order, and a fairly high density (lots of audio) may be passed from a point A to a point B. In short, in a point-to-point dedicated link, audio via TCP/IP can work reasonably well.

Unfortunately, that’s not what the network concept promises: multiple independent streams from multiple sources and with multiple destinations sharing the same wire infrastructure. As soon as other traffic hits the network—say, another audio stream from point C to point D—try as the carrier-detect collision avoidance mechanisms inherent to Ethernet might, packets from one stream will unavoidably tread on those from the other. One of TCP/IP’s great strengths is that it recognizes such events and deals with them handsomely; each stream gets the opportunity to resend its broken or unacknowledged (i.e., lost) packets, and the receive stack knows to reassemble the stream in the correct order from the now possibly out-of-order and certainly delayed packets. So what’s wrong with that?

25.25.3.2.1 Buffering Latency

The network has lost any tenuous claim to determinism—predictability—it may have shown, since collisions and recovery therefrom are unpredictable both in frequency and recovery time. Determinism is, in short, knowing exactly and consistently when recovered audio is ready for use—absolutely essential for streaming-type or real-time audio or dropouts occur. A pure, isolated, low-density point-to-point TCP/IP link can be close to deterministic and with a relatively short latency, predictable from the above-mentioned packetization, framing, and transmission times. Even so, it’s only close—other traffic still exists on the link, in the form of ACK (acknowledge) replies for each sent packet: Yes, collisions can occur between the real data and its own ACKs! Real-world, where multiple paths on the network are in use, significant collision-recovery times get thrown into the mix and this now unknown added time becoming even more so and approximately geometrically longer as the amount of traffic increases. There is also the very strong likelihood, nay—certainty, that packets that have been stepped on and repeated will arrive out of sequence, the repeats only getting through sometimes many frames after several in-sequence packets have progressed.

The workaround—trading a fixed, known, longer latency for a shorter but unusually unpredictable one—is by instituting a fifo buffer (first in, first out) at each receive point. In order to allow time for packets to be eventually received and juggled back into order, this fixed deliberate buffer latency has to be incurred; the more traffic, the more latency is required, and on a busy network this can be in the tens or hundreds of milliseconds to encompass worst-case congestion effects. Although acceptable in some circumstances this is difficult to swallow for many audio applications—particularly those where there is a requirement for humans to listen to themselves live through such a system. Consequently, lowish-latency and pseudo-deterministic audio links are usually recommended to be placed on discrete one-to-one links with little risk of contention. Which really rather begs the rationale behind using TCP/IP, and the promise of “networking” upon it. Oh, well. All of these ills are exacerbated if any other traffic is permitted on the same network—which finishes off the naive notion of running significant amounts of audio on an existing office network. Worse yet is expecting sensible behavior if incoming or outgoing real-time audio is expected through the Internet—build-out latencies may have to be far, far longer to absorb the hairiness of the unknown out there! Again, this may be acceptable in some circumstances—after all, if one is using the Internet, the likelihood is that the audio is going a long way away, where no frame of reference in time exists to its source.

One saving grace of the general move to gigahertz Ethernet (as opposed to the more commonplace 100 MHz variety) is that everything happens much quicker, and that for normal practicable amounts of traffic the collision rate and recovery times go right down and so the build-out buffering latency can be radically reduced; TCP/IP as the basis for an audio network reaches a lot closer to the promise, as opposed to the highly marginal on-the-edge behavior of any meaningful size system at 100 MHz. The advantage is not so much that ten times the traffic could theoretically be handled, but that a similar amount of traffic can be handled well; latencies in the single-digit milliseconds are readily achievable, which, if not too many passes through the
system are attempted (remember, the per-pass latencies add up), is a generally acceptable performance.

25.25.3.2.2 Latency—How Much Is Too Much?

Despite many learned researchers’ effort, most data concerning the audibility of latency is based on the anecdotal and apocryphal. But there is no substitute for being on the wrong end of a broadcast presenter ripping off his headphones and spewing invective as establishment of an incontrovertible benchmark.

We won’t even discuss delays that are long enough to be discernible as a delay, or a discrete echo; that is obviously way too long, and everyone, trained or not, has a hard time speaking normally when fed such into headphones or monitors. No, it’s that mushy area less than, say, 50 ms delay—a period of time below which the ear/brain attempts to integrate all correlated sources into one—that is of concern.

Latency is an issue where a performer is listening directly to a delayed version of him or herself; two situations to keep in mind are a DJ wearing headphones or a stage performer with in-ear or conventional floor/side-fill monitors. An important thing to note is that very different answers from these people as to what is noticeable, annoying, or untenable are garnered depending on whether they are introduced cold to a system with delay, or are steadily introduced to it, particularly in the cases of headphones/in-ears.

Talking, one hears oneself not only by what’s coming through the headphones, if they’re open-frame headphones (i.e., not enclosed), by room spill, but also by bone conduction within one’s own head. This latter is distinctly band limited, and what is passed is usually just the fundamental and possibly early harmonics of vowel sounds. Interference between this and what is being stuck in the ear causes a nonflat perceived frequency response, with cancellation notches and corresponding reinforcement summations. (It is the same mechanism as the audio effect flanging.) This is in general no real problem—one quickly accepts that sound as being normal, the sound of oneself wearing headphones. Deliberately introducing a different delay by even only a millisecond or two is immediately perceptible—the interference cancellations/summations change—the sound changes. This is why many tests attempting to establish acceptable latency by steadily increasing delay have resulted in unrealistically low values; the relative changes in coloration with even small changes in delay are very easy to perceive, even by the unskilled—and immediately flagged as a problem.

Conversely, if one were to present a subject with a delayed headphone feed even quite a bit larger than this (without previously having had chance to establish a reference), the interference-related sound would readily be accepted as normal.

In daily use on countless radio stations are air chain processors with delays in the 10–15 ms region; this, in addition to other latencies in the loop path from microphone to headphones listening off-air, means delays approaching 20 ms are commonplace and to a greater or lesser degree, accepted. Much more than that, though, engenders complaints of the sound being disconnected or hollow and distracting.

Time-alignment experiments conducted on large-scale rock’n’roll sound systems reached broadly similar results; 20 ms monitor delay was as much as could be tolerated by most performers, although some could detect far less, but most readily acceded not to be too bothered by it. Delay between the performer and the PA, particularly in a large venue, proves relatively unimportant for two reasons: firstly, the performer has much more present (louder) monitoring to which he’s likely paying much more attention, and, secondly what scatters back from the PA is quite diffuse and decorrelated anyway. In all cases, the threshold of unacceptability is very crisp—definitely a straw-that-breaks-the-camel’s-back situation.

The main thing to be considered in all this is that latencies add: each pass of a signal through a signal link or network; each piece of gear or processing to which it is subjected; each propagation delay adds up to often be significantly bigger than one might expect. Just one more teentsy-weensy little few link milliseconds through a TCP/IP pipe might just break it.

25.25.3.3 UDP

UDP—User Defined Protocol—essentially uses the same (fabulously inexpensive and readily available) Ethernet-style connectivity, hardware, and chip sets but with a far simpler messaging protocol than TCP/IP and better suited to the application at hand. It is then of no surprise that the majority of wide (more than two paths) commercially available audio transports use a UDP variant. One hundred MHz Ethernet hardware using UDP can afford very low latency and wholly deterministic audio paths, with, for example, typically 64 discrete paths bidirectionally at 48 kHz sample rate. One GHz hardware/firmware allows correspondingly greater capacity.

As mentioned, most manufacturers’ audio transports use this mechanism or something like it; there are
countless varieties, all proprietary and utterly incompatible, of course, since there is a strong commercial impulse to keep everything in house. A standard, AES-50, attempts to bring sanity and compatibility into the gigahertz realm, with the myriad 100 MHz schemes already considered a lost cause.

At its simplest, a big packet consisting of a header and then however many audio words of whatever width is constructed, then sent down a dedicated Ethernet hardware circuit, every sample period; at the receive end the simple format is readily decoded and the constituent samples recovered. It is a reasonable assumption that a dedicated line the packet will be unimpeded and arrive intact, and such links typically run raw with no mechanism for error trapping. Of course, it is entirely possible to build in error detection and correction in case bits get hurt somewhere. It would have to be a fairly weak link for this to get exercised much, and such mechanisms raise the bugaboo of TCP/IP systems—building out a fixed latency to allow for the randomness of the errors. In short, these systems run just fine without and typically do.

Audio is only part of the whole picture. Metadata accompanying it, logic switching contingent on control, control data and metering data all have to be considered and accommodated within the link for it to be a fully usable system in any meaningful context.

Such UDP links are typically bidirectional (but sometimes unidirectional) end-to-end closed links. In and of themselves, they don’t constitute a network, which can loosely be described as anything to anywhere—any source connected to the network may be picked up by any destination. There are two general schemes for turning these one-to-one links into networks: cascading them node-to-node, with a modified signal passing along each link (Serial), or arranging them all to radiate from a central hub (Star).

25.25.3.3.1 Serial or Loop Networking.

In this methodology a single unidirectional line is run passing through each area that needs access to the network; access is achieved by nodes or breakout boxes of varying complexity depending on the requirement, each of which has a unique address for programmability purposes. At the simplest, a small fixed number of inputs to the network and outputs from the network may be offered at the node, along with unique control data. These may be analog ins/outs or digital ins/outs or a combination, and each may either look at (in the case of outputs) any of the (say) 64 program slots, or select a slot into which to place their audio (in the case of inputs).

More advanced nodes could, by way of example, look at many slots, mix them, mix that with local input material, and even place the composite mix into a slot(s) in the network. A frequent application is to retrieve audio from a slot and replace it with local input material. Signal processing specific to a local need (e.g., crossover/eq for a speaker cluster) can be done within such a node; indeed, such products can be thought of primarily as a processor that just happens to have wide connectivity through the network and is marketed as such. Third-party or multiple vendors can be interoperable, providing they’re all licensees of the same networking protocol.

This modified stream is then sent downstream to the next node, and so forth. The stream can be unidirectional (serial) or looped back upon itself (surprise, loop), whereupon the originating node seemingly perversely sees as its input the stream after it has passed through all the other nodes.

Such networks tend to be quite efficient, since they are able to reuse slots along the way. Disadvantages are:

• That serial anythings tend to be badly affected by single-point failures—in other words, one node failing makes orphans of all the others downstream of it, bisecting the net.
• It takes an appreciable time to receive the packet of slots, disassemble it, modify slots to whatever degree, reassemble it, and send it on its way, and such processing latency is obviously cumulative with that from previous and successive nodes. That said, latencies can be low, in the handful-of-sample-period range, trivial compared to those of 100 MHz TCP/IP systems.
• The network cabling routing has to be carefully thought through and follow a logical progression of where the audio needs to go next. This sometimes isn’t easy.

25.25.3.3.2 Star Network Topology.

In contrast to relying on the packet addressability of an IP-style Ethernet network—which belies the need for centralized command and control—UDP-style networks which dumbly if faithfully and with low fixed latency propel a fixed amount of audio from one end to the other of a straight pipe, requires a central switch: this unpacks each incoming stream, decides which elements within them need to go where, and assembles outgoing streams appropriately. Such routing systems were long
commonplace in broadcast installations, and the morphing of the concept to using high-bandwidth UDP pipes was a natural and welcome progression from running lots of discrete signal lines.

Having a central hub from and to which all network runs are connected is a concept as old as the phone system. As such, it has similar strengths and weaknesses in that cable runs are logical and obvious, but reliability hinges on that of a central server. Although this would seem a vulnerability, a single point of failure, parallel and redundant methodologies are common, as will be seen.

The switch in audio terms is in fact a router, which accepts large numbers of sources and can redistribute them in any combination to large numbers of destinations. Ofttimes many sources and destinations are local to the router, but more often high-density audio pipes as described above of, say, 64 discrete signals bidirectionally, spur out to remote locations, where these pipes are terminated in input and output terminations of whatever nature and complexity are desired. (If all the outputs need to be analog on XLRs, so be it. AES pairs, no problem—termination styles are easily accomplished to suit the application. If local-specific signal processing is desired, no problem.) These pipes are simply arranged to look like multiple sources and destinations to the router and are treated as such. The router also parses any metadata, logic control, or metering that accompanies each audio path and routes or deals with each of these accordingly. (Losing the meta data or sending it to the wrong place is like the airline losing your bags: it isn’t the end of civilization, as you’ve arrived, but you’re nowhere near as equipped to accomplish what you have to do.)

This centralized router model works well in the broadcast environment, radio or TV, where much of the engineering work is clustered in a central racks room anyway; likely many of the sources and destinations of the router would be local to it in that room, easing interconnection, with spokes of high-density audio transport issuing out to each studio and production area—Something of a natural for the star topology.

Live sound benefits from this method more than others (such as serial), too. A typical setup is for two consoles (house and monitors) to each be recipients of all stage audio sources or at least major subsets of them. In this instance the router would receive the outputs from the active stage boxes as sources and distribute them as required by transport links to the two consoles.

Returning from the consoles to the router are:

1. House—main mixes and/or speaker processor outputs
2. Monitors—many, stage monitor mixes

These enter the router and are then sent by further links to the desired amplifier racks for the flown and/or stacked PA and sub-low cabinets, or indeed straight to the powered speakers themselves; and to the amplifier racks for the stage monitor speakers and the transmitter rack for in-ear monitoring.

Additional feeds, such as for recording, are assembled in the router and sent to the band’s DAW or the recording truck and terminated accordingly.

25.25.3.3.3 Mixing in the Router

A progression from the notion of a router being a simple crossbar or summing switch is that it becomes a soft matrix, where the relative levels of sources and destinations may be varied. In other words, a mixer. Or a number of smaller mixers than the total capability described by possible numbers of inputs and outputs.

And, taking a step further forward, given the already signal-processing-intensive environment, the console-style signal processing on mixer inputs, outputs, and submixes becomes relatively easy to implement.

Nodes in a TCP/IP system, or breakout boxes in serial network schemes, often contain varying amounts of processing, all the way from simple access to slots to being a full-scale mixer. It is common for the router to have processing capability, indeed for it to be where the mixing/processing parts of consoles reside; it makes sense, since all the possible component signals to be mixed exist within the router or can be got there expeditiously enough through one or several links. Fig. 25-155 shows a large-format TV audio mixing console in which there is not a shred of audio—it is merely a control surface, controlling the signal processing/mixing elsewhere within a processing router: Fig. 25-156. That the console system is or is part of a router means that the number of available mix sources is limited only by the size of the router and can so extend to the thousands. From an operating perspective, however, the console is limited to mixing only as many sources instantaneously as it has faders; this can be multiplied by paging the surface, such that it can flip-flop either entirely or on a fader-by-fader basis to control multiple other channels; instantaneous channel counts can thus run into the hundreds, and on big live shows (such as election night) often does.
There are two other major applications for this router-as-console solution. One is radio studios—several, if relatively small, consoles within a single complex: they can all share the same hardware and resources of a single router, indeed may all be in the same box, yet to all intents and purposes be discrete operationally.

It is a natural live sound solution, too, where as described above there may indeed be multiple fair-sized console systems (house, monitors, recording) but that all share common sources from the stage and yet have very separate destinations (PA, monitors, recorder). The mixing router not only performs the signal routings, but it is also home to all the console-type signal processing required for all three operations.

A valid concern for each of the above applications is that of single point of failure. Large routing mixers typically address this with fail-safe measures, meaning each host microcomputer has a hot standby ready to take over if the main one should hiccup, and spare signal processing/mixing DSP boards equally stand ready to be reassigned on-the-fly to take over from one that may have halted. Some designs even have an entirely separate router, operating in parallel to the main one, ready to take over in the case of a failure. Although they could be perceived as expensive precautions, they look really inexpensive in relation to dead air.

26.1 General

To operate a sound recording or reproducing system properly, some method for determining the signal levels in different parts of the system to avoid overloading, noise, and distortion is required. This is the purpose of the volume indicator (VI) meter. A VI meter is a meter used to measure levels of audio-frequency signals. The term volume indicator is generally associated with meters calibrated in decibels. Until recently, volume unit (VU) meters were devices to measure power with respect to 1 mW of power across a 600 Ω line. Today VU measurements are made with respect to many different bases.

VU meters were first used by the telephone company. They were used to measure the level of the signal being sent down the line. The lines were open wire pair of AWG #6 wire spaced 12 inches apart, which translated to a characteristic impedance of 600 Ω as determined with the equation

\[ Z = 276 \log \left( \frac{2D}{d} \right) \]  

(26-1)

where,

\( D \) is the spacing of the two wires,
\( d \) is the diameter of the wire.

Today, most amplifying devices have a high-impedance input and a low-impedance output as specified by a 1978 I.E.C. standard requiring the output impedance of a device to be less than 50 Ω and the input impedance to be greater than 10 kΩ. Since very little power is transferred between 50 Ω and 10 kΩ, it makes more sense to make measurements as voltage gain rather than power gain.

It is important to know what kind of measurement reference is being used. The following are some of the common references:

dBm. The original definition of the dB. It is power level in dB referenced to 0 dB or 1 mW and a 600 Ω load.

dBW. Power referenced to 1 watt.

dBf. Power referenced to 1 femtowatt (1 × 10⁻¹⁵ W).

dBV. Voltage referenced to 1 Vrms. dBV is not affected by impedance.

-10 dBV. A voltage reference level used by many consumer products and is equal to 0.316 Vrms.

dBu. Voltage referenced to 0.775 Vrms. It is not affected by impedance. The u stands for unterminated.

+4 dBu. The pro-audio voltage reference level of 1.23 Vrms.

dB FS. Digital audio reference level equal to full scale, which is the maximum peak voltage level before digital clipping of a data converter. Full-scale value varies with each design.

dBA. An unofficial method of stating loudness measurements using the “A” weighted curve on a sound level meter.

dBC. An unofficial method of stating loudness measurements using the “C” weighted curve on a sound level meter.

dB-SPL. Sound pressure level referenced to 0.0002 μbar where 1 μbar = 1 dyne/cm² or the threshold of hearing.

dBr. An arbitrary reference level that must be specified. It can be used for many different references as long as it is specified.

DIN Scale. The DIN scale as used in Germany and Austria uses +6 dBu as the reference level for the 0 dB mark. This is equivalent to 1.55 Vrms.

26.2 Standard VU Meters

A volume unit (VU) meter is a special form of VI meter used for monitoring broadcast, recording circuits and sound reinforcement systems. Such meters employ special ballistics that average out complex waveforms to properly indicate program material that varies simultaneously in both amplitude and frequency. For complex waveforms, such as speech, a VU meter reads between the average and the peak values of the complex wave. No simple relationship exists between volume measured in VU and the power of a complex waveform. The indicated reading will depend on the particular wave shape at the moment. For sine-wave measurements, a change of one VU is numerically equal to a change of 1 dB.

VU meters are designed to have a dynamic characteristic that approximates the response of the human ear. When a speech waveform is applied to a VU meter, the movement will indicate peaks and valleys in the signal. The average of the three highest peaks in 10 s (disregarding occasional extremes) is taken to be the indication of the meter movement.

Many meters marked as VU meters are not actually such meters, since they do not have the special ballistics and characteristics of the standard VU meter.
Chapter 26

The VU meter is a device whose standard has remained the same since 1961. The meter consists of a 200 mA dc D’Arsonval movement fed from a full-wave, copper-oxide rectifier mounted within the meter case. VU meters are calibrated in reference to 1 mW of power into a 600 Ω load. A typical moving coil VU meter is shown in Fig. 26-1.

In the 1920s and 30s copper-oxide rectifier power-level meters were inaccurate and not satisfactory for program monitoring. The development of an entirely new meter was jointly undertaken by the Bell Telephone Laboratories, Columbia Broadcasting System (CBS), and the National Broadcasting Company (NBC). The results of this research were not only the development of a new type VI meter but also the standardization of a new reference level of 1 mW, a unit that was adopted by the electronics industry in May 1939. The current standard is ANSI C16.5-1961, formerly the Acoustical Society of America (ASA) C16.5-1961.

The characteristics of the dBm VU meter are as follows:

- **General.** The meter consists of a dc meter movement with a full-wave, copper-oxide rectifier unit (mounted in the instrument case) and responds approximately to the root-mean-square (rms) value of the impressed voltage. This value will vary somewhat depending on the waveforms and the percentage of harmonics present in the signal.

- **Instrument Scale.** The face of the instrument may have either of the two scale cards shown in Fig. 26-2. Each card has two scales: a VU scale ranging from −20 to +3 VU and a percent-modulation scale ranging from 0 to 100%, with 100% coinciding with the 0 point on the VU scale. The normal point for reading volume levels is at 0 VU or 100%, which are located to the right of the center at about 71% of the full-scale arc.

- **Dynamic Characteristics.** With the instrument connected across a 600 Ω external resistance, the sudden application of a sine-wave voltage, sufficient to give a steady-state deflection at the 0 VU or 100 scale point, shall cause the pointer to overshoot not less than 1% or more than 1.5% (0.15 dB). The pointer shall reach 99 on the percent scale in 0.3 s.

- **Response Versus Frequency.** The instrument sensitivity shall not depart from that at 1 kHz by more than 0.2 dB between 35 Hz and 10 kHz, or more than 0.5 dB, between 25 Hz and 16 kHz.

- **Impedance.** For bridging across a line, the volume indicator, including the instrument and proper series resistor (3600 Ω), shall have an impedance of 7500 Ω when measured with a sinusoidal voltage sufficient to deflect the meter to 0 VU or the 100% scale point.

- **Sensitivity.** The application of a sinusoidal potential of 1.228 V (4 dB above 1 mW in a 600 Ω line) to the instrument in series with the proper resistance (3600 Ω) will cause a deflection to the 0 VU or 100% point.

- **Harmonic Distortion.** The harmonic distortion introduced in a 600 Ω circuit, caused by bridging the volume indicator across it, is less than 0.3%, under the worst possible condition (no loss in the variable attenuator).

- **Overload.** The instrument must be capable of withstanding, without injury or effect on the calibration, overload peaks of ten times the voltage equivalent to

![Figure 26-1. Moving coil VU meter. Courtesy Simpson Electric.](image1)

![Figure 26-2. VU meter scales.](image2)
a reading of 0 VU or 100% for 0.50 s and a continuous overload of five times that voltage.

### 26.2.1 Meter Ballistics

*Meter ballistics* are the mechanical and electrical characteristics built into the meter movement. A given characteristic may be obtained by shaping the pole pieces and counterweighting the pointer mechanism. Shunts are sometimes used across the meter terminals, but this use will reduce the sensitivity of the movement.

The ballistics characteristics of a typical old-style VI meter or voltmeter and a standard VU meter, when a 1000 Hz signal is applied for a period of 1 s, are shown in Fig. 26-3. Note the VU meter comes to a steady state at the end of 0.30 s, while the VI meter continues to oscillate showing peaks and valleys over a period of 1 s. An ac voltmeter would be even worse than the old style VI meter as it would never settle down and would constantly overshoot. This clearly indicates why the ballistics of the VU meter are desirable for monitoring program material containing complex waveforms.

![Figure 26-3. Comparison of the original VI meter and the present VU meter ballistics when a 1000 Hz signal is applied for 1 s.](image)

A VU meter reads the rms value of the waveform. On a sine wave, the rms VU indicator of the peak is only 3 dB above the reading; however, on voice or music, the peak may be 10–12 dB above the VU reading. This difference is called the *crest factor* and is illustrated in Fig. 26-4.

![Figure 26-4. Crest factor caused by the peak of music or voice being greater than \( \sqrt[3]{3} \) rms.](image)

8–14 dB peaks present in the program material are not indicated by the meter because the meter movement cannot follow small instantaneous peaks. Even if they could be seen, it would be too late to reduce the level. Therefore, the meter must either be set or caused to indicate in a manner that will not overload the system in which it is operating.

Since VU meters do not include the true peak values of program material (complex waveforms), it is quite easy to overload a recording system. To protect against these unseen peaks, a lead or margin of safety is inserted in the VU meter circuit.

To insert a lead into a VU meter circuit, the VU meter is connected across a bridging bus with a sine-wave level of +14 dBm. A 400 Hz or 1000 Hz signal is sent into the input of the recording console. The mixer control is set to its normal operating range, and the signal level is adjusted to bring the bus level to +14 dBm (the VU meter reads 100% or 0 dBm).

Remove the input signal and return the VU meter attenuator to its +6 dBm position. This inserts an 8 dB lead or margin of safety in the VU meter by making it 8 dB more sensitive. Thus, it protects the system against unseen peaks up to 8 dB. The program material is now mixed in the usual manner. Some recording activities, because of the heavy peaks and overloads encountered in some types of music, use a 10–12 dB lead in the VU meter.

Radio transmitters are adjusted in a similar manner. However, in this instance, the percent modulation indicated by the VU meter indicates the percent modulation of the radio transmitter.
26.2.2 Reference Levels

In the early days of broadcasting and recording, both 10 mW and 12.5 mW into a 500 Ω line were used as a reference level. However, later this was changed to 6 mW. In May 1939 the present standard of 1 mW into a 600 Ω line was adopted. This reference level was selected as a level that would conform to the telephone company's standards of limiting the signal level on a transmission line to a value that would produce a minimum of crosstalk and still provide a satisfactory signal-to-noise ratio (SNR). The 1 mW reference level is a unit quantity and is readily applicable to the decimal system, being related to the watt by the factor $10^{-3}$.

Zero level is a reference power level of 1 mW of power into a 600 Ω load. This is equivalent to a voltage of 0.775 V.

26.2.3 VU Meter Impedance

The VU meter and its attenuator impress a 7500 Ω impedance onto a circuit. The VU meter system consists of an indicator movement, a variable attenuator, and a series resistor of 3600 Ω, Fig. 26-5. Meter manufacturers supply only the meter movement; the external circuitry is added later. A 200 μA D’Arsonval meter movement with an internal resistance of 3900 Ω and a full-wave, copper-oxide or selenium rectifier are contained within the meter case. The attenuator is variable in steps of 2 dB, presents a constant impedance of 3900 Ω to the meter movement, and prevents the ballistics of the meter from being affected when the attenuator setting is changed.

![Figure 26-5. A 7500 Ω VU meter, calibrated for 1 mW reference level or 0.775 V across 600 Ω.](image)

Standard VU meters are designed to read 0 VU, or 100%, with 1.228 V (+4 dBm) applied to the instrument. If the meter is used with the attenuator but without the 3600 Ω series resistor and is connected across a 600 Ω load in which 1 mW of power is flowing, the movement will be deflected to the 100% calibration point. This method is not recommended since the impedance looking back into the meter is only 3900 Ω and loads the 600 Ω circuit. It is the usual practice to keep the impedance of bridging devices at a ratio of 10:1 or greater.

Increasing the input impedance of the VU meter from 3900 Ω to 7500 Ω creates a 4 dB loss across the 3600 Ω resistor. If a signal of 1 mW (0.775 V) is impressed across the input terminals of the circuit in Fig. 26-6, it will not deflect the meter to the 0 VU calibration but only to the −4 VU (or decibel) mark, or approximately 65%. This means that if the meter is to be deflected to the 100% point, the input signal must be increased to a +4 dBm. This is the reason why 1 mW of power will be indicated at the −4 dB calibration mark.

Attenuators used with VU meters start at a +4 dBm. The bridging loss caused by the VU meter being inserted into the circuit is the drop in signal level caused by the absorption of power by the meter circuit. As a rule, the power absorbed is quite small and may be ignored. However, at high powers, it may become important. Bridging loss may be calculated by the equation

$$\text{dB}_{\text{loss}} = 20 \log \frac{2B_R + Z}{2B_R}$$  \hspace{1cm} (26-2)

where,

- $B_R$ is the VU meter input impedance,
- $Z$ is the line impedance.

A 7500 Ω VU meter has a bridging loss of 0.34 dB.

26.2.4 VU Impedance Level Correction

VU meters are calibrated for 1 mW of power across a 600 Ω load as −4 VU, therefore when a VU meter is connected across any other impedance, a correction must be added to the indicated reading to give a proper VU reading. The equation for the level correction is

$$\text{dB}_{\text{corr}} = 10 \log \frac{Z_2}{Z_1}$$  \hspace{1cm} (26-3)

where,

- $\text{dB}_{\text{corr}}$ is the decibel amount added to the VU reading,
- $Z_2$ is the impedance for which the meter is calibrated,
- $Z_1$ is the impedance of the circuit bridged.

A typical example of applying a correction factor is as follows: a VU meter calibrated for a line impedance of 600 Ω is bridged across a 16 Ω loudspeaker line and indicates a level of +1 dBm. The true VU would be

$$\text{VU} = 1 \text{ dBm} + \text{correction factor}.$$  \hspace{1cm} (26-4)

The correction factor from Eq. 26-2 is
$$dB_{corr} = 10 \log \frac{600}{16}$$

$$= 10 \times 1.574$$

$$= 15.74 \text{ dB}$$

The correction factor of 15.74 dB is added to the meter reading of +1 dBm for a true level reading of +16.74 dBm. Typical correction factors are shown in Table 26-1.

**Table 26-1.** Correction Factors in dBm to Be Applied to a VU Meter When Connected Across an Impedance Other Than 600 Ω

If a VU meter is connected across a line impedance different from that for which it was originally calibrated, the voltage supplied to the meter will either be lower or higher than the original calibration; therefore, the meter would indicate incorrectly. Two circuits are shown in Fig. 26-6, one a 600 Ω circuit and the other a 16 Ω circuit. Both are dissipating the same amount of power; yet the voltage for the 600 Ω circuit is 0.775 V, and for the 16 Ω circuit it is 0.127 V. As can be seen, if a VU meter is connected across the 16 Ω circuit, it will not deflect the same amount as for the 600 Ω circuit, although the same amount of power is flowing in each circuit. To arrive at the correct power level in the 16 Ω circuit, a correction factor must be applied to the meter indication.

![Figure 26-6. Voltage across lines of different impedance but with the same power in milliwatts.](image)

### 26.2.5 Voltages at Various Impedances

If the line voltage for a given level at 600 Ω is known, voltages for other line impedances may be calculated using

$$V_x = V \sqrt{\frac{Z}{600}}$$  \hspace{1cm} (26-5)

where,

- $V_x$ is the unknown voltage,
- $V$ is the voltage for 600 Ω,
- $Z$ is the new impedance.

As an example, assume voltage $V_x$ is required for a line impedance of 150 Ω at a level of +4 dBm. Referring to Fig. 26-7, the voltage for a level of +4 dBm at 600 Ω is 1.23 V. The new voltage may now be calculated using

$$V_x = 123 \sqrt{\frac{150}{600}}$$

$$= 0.615V$$

Voltages for a line impedance of 600 Ω for levels between 0 and +50 dBm may be taken from Fig. 26-7. Voltage across 600 Ω can be calculated from dBm with the following equation

$$V = 0.6 \times 10^{\frac{dBm}{10}}$$  \hspace{1cm} (26-6)
26.3 Wide-Range VU Meters

Standard VU meters measure only the upper 23 dB of the signal level. From the practical standpoint, this limits the display to about 20 dB below the reference level of the 0 indication.

This short range of operation limits its usefulness, particularly when it is connected across a bridging bus for monitoring program information. A wide-range program-monitor meter, Fig. 26-8, displays the program information over a 60 dB meter scale, spread from -57 dB to +3 dB. The large spread of program material permits the very low-level signals to be observed as well as the noise between program pauses. The wide-range VU meter was not designed to replace the conventional VU meter; however, its characteristics are compatible with the VU meter. In addition, a dc output is provided for connection to a linear tape recorder for logging program levels over a range of 60 dB. The 0 dB indication may be set to represent a reference level from -22 dBm to +18 dBm.

The basic component is a logarithmic amplifier, Fig. 26-9, with a nonlinear feedback circuit, a preamplifier, a 15 kΩ bridging input transformer, a reference-level selector switch, and a sensitive indicating meter movement.

26.4 Bar Graph VU and Spectrum Analyzers

The United Recording Electronics Industries (UREI) Model 970 Vidigraf is a bar graph display generator that operates any National Television System Committee (NTSC) standard video monitor or (with an inexpensive accessory) black-and-white television receiver. The system provides both a VU level display and the frequency-spectrum-level information. It is designed primarily for multitrack recording studio applications. However, its dc to 20 kHz input capability suggests its use for a wide range of dc or ac analog voltage measurements.

The 970 Vidigraf's modular construction provides users with complete flexibility to adapt the system to their specific needs. A maximum of four 16-channel input display modules may be installed for VU level, automation control voltages, or frequency-spectrum viewing. Each module may be individually switched to the video generator in the single mode. In the dual display mode, the screen is split vertically to accommodate the information from any two input modules simultaneously. Instantaneous identification of the input channel sources and/or frequencies, as well as vertical scaling indices are automatically provided by the built-in

Figure 26-7. Relationship of VU and dBm to power in watts and voltage in a 600 Ω line.
programmable character generators. This eliminates any need for screen overlays or masks and ensures accurate positioning of the alphanumeric information regardless of screen size or width and height adjustments.

Some typical displays are:

- 6 or 32 simultaneous VU channels.
- 16 or $2 \times 16$ bands of frequency spectrum (1 or 2 channels).
- 16 VU channels, plus channels of automation control voltages.
- 16 VU channels, plus 15 bands of frequency spectrum and 1 composite level.

One **VU module** provides 16 bar graphs with standard VU ballistics over a display range of 30 dB. Each bar has two shades of gray, with the lighter shade above the 0 dB reference. When a signal is applied to any of the 16 inputs, a bright bar moves up and down with the signal level. The 0 dB reference point can be continuously adjusted to any standard from 0 to +8 dB. The VU module is user programmable to display a logarithmic scale of $-20$ dB to $+3$ dB when measuring audio signals or to read linearly from 0 to 10 for display of ac or automation dc control voltages.

The **spectrum module** provides a visual real-time display of VU level versus frequency of an audio signal. It is useful for setting equalization and adjusting frequency balance. This module provides 16 bar graphs with visual characteristics similar to those of the VU module. One bar is assigned to the full spectrum of the audio signal, and the other 15 channels display increments of the frequency spectrum, centered on standard ISO $\frac{1}{2}$-octave filter frequencies. Two independent controls adjust the level of the full spectrum bar relative to the spectrum analysis bars.

### 26.5 Power-Level Meters

A **power-level meter** is a VI meter calibrated in decibels. As a rule, this type of meter is normally used with test equipment for steady-state measurements and is not used for monitoring program material because its ballistics are more like those of a voltmeter.

### 26.6 Power-Output Meters

A **power-output meter** is used for measuring the power output of audio amplifiers and other devices. It may also be used to determine the characteristic and internal output impedance, the effect of load-impedance variation, and other applications involving the measurement of output power and impedance with respect to frequency. The power output meter may be calibrated in watts and/or dBm. The power output meter is a test instrument and not used for monitoring program level because of its ballistics.

### 26.7 Peak Program Meters

The **peak program meter** (PPM) is used extensively in Europe and falls under four standards, the DIN-type DIN 45406, the BBC type, the EBU type, and the Nordic N9 type. These meters measure the peak program signal, which is usually $+6$ dB to $+20$ dB above the readings seen on the VU meter.

#### 26.7.1 DIN 45406 Standard

The PPM is popular in Europe. It is designed to have a fast rise time, 30 times as fast as a VU meter, and a much slower fallback or decay time.
The DIN 45406 and the IEC 268-10 have an integration time of 10 ms and a decay time of 1.5 s for 20 dB of fallback and 2.5 s for 40 dB of decay. The indicator range is −50 dB to +5 dB. The scale marked for 100% reading is 0 dB which is the reference level of +6 dBu or 1.55 Vrms, Fig. 26-10A.

The RTW 1019GL analog peak program meter + loudness meter + phase correlation meter is shown in Fig. 26-10A. The 127 mm (5 inch) 201 element bar graph display has a 1 dB per division scale from +5 dB to −10 dB changing logarithmically to −50 dB. Roll-off above 20 kHz is 12 dB/octave. The meter includes a +20 dB gain increase and a peak memory/reset circuit. The integration time is selectable between 1 ms and 10 ms. The balanced input is transformer isolated.

The meter panel also includes a three-color phase correlation value display with memory. The correlator indicates the phase correlation \( r \) of stereo signals. If both channels are in phase—e.g., a mono signal on both channels—the reading is +1 \( r \). With only one or no signal at the input, the meter will read 0 \( r \).

26.7.2 British Broadcast Standard

The British Broadcast Standard, BS 55428 Part 9, has an integration time of 12 ms and a decay time of 2.8 s for decay from 7 to 1. The indicator range of 1 s to 7 is equivalent to a −12 dB to +12 dB. The scale mark for 100% reading is 6 and is referenced to +8 dBu or 1.95 Vrms.

Fig. 26-10B shows an analog RTW 1034GL British standard scale IIa analog peak program meter + loudness meter + phase correlation meter. The 127 mm (5 inch) 201 element bar graph display measures from −12 dB to +12 dB. The meter includes a +40 dB gain increase and a peak memory/reset circuit. The integration time is selectable between 1 ms for digital audio and 5 ms for analog audio. The balanced input is transformer isolated. The meter panel also includes a three-color phase correlation value display with memory.

26.7.3 Nordic N9 Standard

The Nordic Recommendation N9 has an integration time of 5 ms, a decay time of 1.7 s for 20 dB, and 3.4 s for 40 dB of decay. The indicator range is from −42 dB to +12 dB. The scale mark for 100% reading is 0 dB and is referenced to +6 dBu or 1.5 Vrms, Fig. 26-10C.

Fig. 26-10C shows an analog RTW 1039GL Nordic Recommendation N9 analog peak program meter + loudness meter + phase correlation meter. The 127 mm (5 inch) 201 element bar graph display measures from −20 dB to +12 dB. The meter includes a +40 dB gain increase and a peak memory/reset circuit. The integration time is selectable between 1 ms for digital audio and 5 ms for analog audio. The balanced input is transformer isolated. The meter panel also includes a three-color phase correlation value display with memory.

26.8 AES/EBU Digital Peak Meter

With the advent of digital equipment, new meter standards are being written to work with the AES/EBU digital format. This requires being capable of sampling 32 kHz, 44.056 kHz, 44.1 kHz, 48 kHz, and 96 kHz with an AES/EBU digital format.

The attack time is one sampling period and the decay time is 1.5 s for a change from 0 dB to −20 dB. The indicator range is from 0 dB to −60 dB.

The RTW 11529G digital peak program meter + loudness meter + phase correlation meter, Fig. 26-11A, has a 127 mm (5 inch) 201 element bargraph display. Its sampling rates are from 27 kHz to 96 kHz and it includes a dc filter and has indicators for 44.1 kHz, 48 kHz, and 96 kHz, emphasis, error, and overload.
The meter also includes peak memory, peak hold, +40 dB gain, and a three-color correlation correction value display.

The RTW 11528G AES/EBU Digital PPM, Fig. 26-11B is especially useful for radio and TV broadcasting applications. The meter features AES/EBU inputs and outputs. The digital signal can be displayed once as it is without any weighting (sample precise display), which corresponds to the digital standard that has a scale range from –60 dB to +9 dB but with a fixed head room of –9 dB FS, which is marked 0 dB, and highlighted and superimposed with an integration time of 10 ms. It can also be displayed with a superimposed and highlighted loudness display. Finally, it can be shown as a 10 ms integration time–only function, as a quasi analog display. Its sampling rates are from 27 kHz to 96 kHz.

Both the RTW 11529G and the 11528G include an over indication with a selectable overload detector range, 9 to 24 bit overload response word length, and number of overload samples.

26.9 Loudness Meters

Loudness meters place VU and PPM meters on a single panel, providing an indication of the entire dynamic condition of the signal. It also eliminates the condition that eyeball wobble could develop in the attempt to follow two adjacent meters with differing ballistics. The use of two pointers with such differing ballistics on a single scale would demonstrate that the PPM would read consistently higher levels than the VU meter, and the large differential of decay with respect to rise time of the PPM in comparison to the equal rise and decay times of the VU meter would also be difficult to interpret.

Three types of scales are used on loudness meters:

- Based on +14 dB of headroom.
- Referenced at 100% for broadcast transmission.
- Based on 20 dB of headroom.

The head room available to mixers in postproduction is not the same as allowed in broadcast. The U.S. standard in digital (SMPTE) is 20 dB below FS (full scale) and the EBU standard used in European and many Middle Eastern countries is –18 dB below FS. When film and post material is sent to the broadcast facility, the peak shall not exceed +12 dB analog or –8 dB digital.

The music and recording industries do not have these requirements for their products, and therefore use the full dynamic range. Commonly, this material will peak fairly consistently at –1 dB on a digital reading meter, with the bar graph fairly consistently four or five LEDs under the peak. If this material makes its way to broadcast, it will be louder than audio on video by possibly as much as 8 dB. The result might be rejection and need to redo the material using the guidelines required, or quality control at the broadcast facility will make a judgement on the loudness and turn it down accordingly. Dialnorm on HDTV was designed for these irregularities.
The alarms on the left side of the remote are for Phase Error, Bit Stream Corruption, and Full Scale. Fig. 26-13 is a block diagram of the loudness meter of Fig. 26-12.

With signal input both meters read the audio in the same dynamic way. Each meter displays 20 dB of Peak Amplitude above the 0 VU persistence reference level, and therefore, 0 reference is the same on both.

The use of a dot display for Peak information and a bar display for Persistence information allows a single display for both ballistics. Each lamp in the display is therefore driven by two drivers, one for peak, the other for persistence. This representation presents a display of a dot riding on top of a bar graph. In order to make this display useful, there has to be a meaningful relationship between the two ballistics. The peak display has a rise time of two time constants, or 10 μs, which is 1000 times faster than the PPM. The decay time for the peak display is 18 ms/dB.

Equal energy, properly weighted for program material, will be discerned as equal in loudness. Since energy can be displayed as a function of amplitude and time, an oscilloscope can be used to confirm that large amplitudes of short tone bursts can be equal to longer tone bursts of lower amplitude.

Average power is defined as equal to the area under the curve divided by the time interval. Since the area is equal to the input energy, \( W \) or watts, during the interval,

\[
P_{ave} = \frac{W}{t}
\]

(26-7)

where,

- \( W \) is in watts,
- \( t \) is in seconds.

Thus, the averaging-type metering can provide an indication of power.

The persistence display has a time constant of 270 ms and a rise time of approximately 600 ms or twice as long as that of a VU meter.

Perceived loudness to the ear from source to source is determined by which circuit (peak or persistence) is first to illuminate its respective set of red LEDs. Program adjustments for equally perceived loudness should be holding either the peak or persistence excursions to its corresponding red LED area.

The relative loudness characteristic of the Peak to the bar graph has been retained by way of red LED reference points on both meters. This is the window of 12 dB of separation of the Peak from the Average for maintaining equal loudness. The +12 dB analog and −8 dB digital are the same scale points on both meters.

### 26.10 Surround Sound Analyzer

The surround sound analyzer method translates the important details of surround signals into a graphical display suited for instant evaluation. Successful mixing of surround signals is important. Besides the artistic and aesthetical aspects, there are fundamental technical preconditions for obtaining professional results.

Reality is often far from the ideal, particularly during live broadcasts and in audio production for video or TV. This makes it even more important to know, even in the most hectic working environment, how the surround mix will be perceived by the listener.

The RTW Surround Sound Analyzer—e. g., integrated in the RTW SurroundMonitor, Fig. 26-14—is a
unique tool showing all the important parameters of a surround signal at a glance. It gives detailed information for all individual channels as well as the overall effect of the mix.

The visual display of the Surround Sound Analyzer provides level and phase relations of all channels. The dynamic response of the display elements is a direct representation of the acoustic image so the balance of the surround sound can be observed.

The volumes of the four channels L, R, sL, and sR are displayed as diagonal white level bars originating from a common center point. Their tips are connected through cyan lines. The square formed by this figure, the total volume indicator (TVI), is a direct measure of the total volume and the balance of the acoustic image.

The curvature of these lines shows the channel correlation, positive values through an outward deflection (roof), negative values through an inward deflection (funnel).

The volume of the Center channel is indicated by another upwards-pointing level bar with yellow connecting lines, showing the perceptibility and dominance of the Center in relation to L and R.

Direction and width of front, side, and rear phantom sources are represented by lines between the loudspeaker symbols, called the Phantom Source Indicators (PSI). Their color changes with channel correlation. A separate correlation indicator for the two surround channels is available at the bottom of the display.

A cross representing the dominance vector indicates the position of the subjectively perceived center of gravity of the mix.

The Surround Sound Analyzer displays a correctly-scaled graphical representation of the relative volumes in the surround sound field. The interaction of levels (volume or sound pressure level) and the correlation of all channels in the production of the overall surround sound are displayed graphically.

The display in the Surround Sound Analyzer can be set to correspond to the volume or the reference sound pressure level by calibrating the instrument and the studio monitoring equipment accordingly. The axes of the 45° coordinate system use a dB volume level or dB-SPL scale and have a reference mark that is also displayed in the volume level and SPL displays in the peak program meter of the instrument. The balance between the Center channel and the L and R front channels is critical for all surround sound productions. The Center channel is displayed with its own display elements to show the volume differences between the Center channel and the L and R channels.

In addition to the signal level, the correlation level (and aligned to that the generation and the location of phantom sound sources) is important for multichannel sound productions, primarily in relation to downmixes or possible sound-faking erasements when generating a mono signal. The correlation level of the sL and sR surround channels is also important. Highly anomalous
frequency-dependent correlation levels induce an unimpressive envelopment effect of the sL and sR surround signals. For monitoring this, the Surround Sound Analyzer features a correlation meter for the sL and sR surround channels. Fig. 26-15 shows the display and examples of various patterns.

Figure 26-14. RTW SurroundMonitor 11900 for AES/EBU digital and analog standards with Surround Sound Analyzer. Courtesy RTW GmbH & Co.KG, Cologne.

References

Center channel level indicator (yellow line)

Total Program Volume (TVI - Total Volume Indicator). The area enclosed by the lines is a measure for the total volume level, the spreading of the area across the four quadrants is an image of the balance of the sound characteristics. The shapes of the lines show the correlation level: a distinctive roof for $r$ towards $+1$ a funnel for $r$ towards $-1$, a straight line for $r$ between $-0.25$ and $+0.25$. The correlation level also is shown by the different colors of the lines of the phantom source indicators: green ($+1$ to $+0.25$), yellow ($+0.25$ to $-0.25$) and red ($-0.25$ to $-1$).

27.1 Introduction

In the past 100 years approximately 30 billion phonograph records have been produced and sold. Music of the most famous composers and performers, orchestras, and bands, and sounds of events have been immortalized in intricate excursions of the analog record groove. Millions and perhaps billions of discs are still in the hand of the audiophiles, archives, musical libraries, DJs and radio stations.

The contents of all of these records can never be completely rerecorded onto the compact discs or another medium, so it is important that we can preserve, restore, and reproduce analog recordings.

The information contained in this section is directed toward the new generation of engineers and technicians so they may understand the reproduction techniques that led to digital technology. As we witness the decline in popularity of analog LP discs, remember that many developing countries around the world are still very much dependent on analog technology and in some cases what we consider the old 78 rpm format is the only source of prerecorded music and entertainment available to them.

Early recorded sounds had a high-frequency cutoff of 2–3 kHz. It took over 100 years to reach the sophistication of today’s recording technology only to take a couple of steps backward in sound realism by approximating the waveforms at the high frequencies and limiting them to 20 kHz with brick wall filters. Theoretically digital recording is fine, but the human ear deserves a higher sampling frequency. Perhaps only a select few can really hear the difference, but then how can we argue with them? In other fields, such as television, the trend is toward high-definition TV, in VCRs and camcorders there is a SVHS system, and yet tube-type audio amplifiers are still sold at premium prices because of many so-called golden ear audiophiles don’t want to give up the tube sound. The same is with LP records. For the average listener, CDs are great as long as they don’t hear pops and clicks and cannot break the stylus or the tonearm.

This chapter will discuss playback equipment. To understand the production of records/discs, refer to the Handbook for Sound Engineers–The New Audio Cyclopedea First or Second Edition.

27.2 Disc/Record Dimensions

The analog record has been standardized to 7 inch, 10 inch, and 12 inch discs and 33⅓ and 45 revolutions per minute (rpm).

Excerpts from the latest EIA standard for producing analog disc records are as follows.

27.2.1 Record Diameter

The diameter of records are:

- 12 inch LP disc, 33⅓ rpm: 11.875 ± 0.031 inch (301.6 ± 0.8 mm)
- 10 inch disc, 33⅓ rpm: 9.875 ± 0.031 inch (250.8 ± 0.8 mm)
- 7 inch disc, 45 rpm disc: 6.875 ± 0.031 inch (174.6 ± 0.8 mm)

The recorded surface shall start with at least one turn of unmodulated groove.

27.2.2 Maximum Outer Diameter

The maximum outer diameter of a recorded surface shall be:

- 12 inch LP disc, 33⅓ rpm: 11.500 inch (292.1 mm)
- 10 inch disc, 33⅓ rpm: 9.500 inch (241.3 mm)
- 7 inch disc, 45 rpm disc: 6.625 inch (168.3 mm)

27.2.3 Groove Dimensions

The groove dimensions shall be:

- Minimum top width (monophonic only): 0.0022 inch (0.56 mm)
- Maximum bottom radius: 0.00025 inch (0.006 mm)
- Included angle: 90° ± 5°

On stereophonic records, the instantaneous groove width should be not less than 0.001 inch (0.025 mm). The average groove width should preferably be not less than 0.0014 inch (0.035 mm).

27.2.4 Stereophonic Groove

The stereophonic groove shall carry two channels of information. The two channels shall be recorded in such a manner that they can be reproduced by movement of a reproducing stylus tip in two directions at 90° to each other and at 45° to a radial line through the stylus tip and the center of the record. The reproducing stylus tip motion shall be tangential to, or lie in a plane through, the stylus tip and the record center, preferably inclined at an angle of 20 ± 5° clockwise to the normal to the record surface through the stylus tip, as viewed from the
record center. In practice, angles of between 0° and 25° may be encountered.

27.2.5 Channel Orientation

The groove shall be recorded for reproduction with the right-hand loudspeaker(s), as viewed from the audience, actuated by movement of the groove wall, which is farther away from the center of the record.

27.2.6 Channel Phasing

The phasing of the two recorded signals shall be suitable for reproduction on equipment so connected that movement of the reproducing stylus tip parallel to the record surface (as with a monophonic record) produces in-phase signals across the output terminals of the phono cartridge.

27.2.7 Channel Levels

The levels of the two recorded signals should be such that peak excursions of the groove should not exceed 100 μm or 0.004 inch in lateral plane and 50 μm or 0.002 inch in vertical plane.

27.2.8 Speed of Rotation

Records shall be recorded for reproduction at one of the following speeds:

<table>
<thead>
<tr>
<th>50 Hz Electric Supplies</th>
<th>60 Hz Electric Supplies</th>
</tr>
</thead>
<tbody>
<tr>
<td>45.11 rpm ±0.5%</td>
<td>45.00 rpm ±0.5%</td>
</tr>
<tr>
<td>33½ rpm ±0.5%</td>
<td>33½ rpm ±0.5%</td>
</tr>
</tbody>
</table>

(Note: 16¾ rpm and 78 rpm speeds omitted.)

27.2.9 Lead-In Groove Pitch

The lead-in groove pitch shall be 16 ±2 lines/inch (l/in).

27.2.10 Lead-Out Groove

The pitch of the lead-out groove shall be 2–6 l/in. The top width of the lead-out groove shall increase to a minimum of 0.003 inch (0.076 mm) when the pitch exceeds ¼ inch (6.4 mm).

27.2.11 Finishing Groove

The diameter of the finishing groove shall be:

- 12 inch and 10 inch discs: 4.187 ± 0.31 in (106.4 ± 0.8 mm)
- 7 inch discs: 3.875 ± 0.078 in (98.4 ± 2 mm)

27.3 Signal Equalization in Disc Recording

To overcome the limitations found in the basic disc-cutting and reproducing process, special equalization of the signals before and after the recording was developed. When all signals that appear in the program bus are analyzed, we can see that the amplitude is the highest at low frequencies and the lowest at high frequencies. The relationship between the frequency of the signal and its amplitude where amplitude is inversely proportional to frequency is called a constant velocity characteristic, Fig. 27-1.

If the signals are recorded without equalization as they arrive, the low-frequency excursions would take all the space. The high frequencies would be of such a low amplitude that during the playback, high-frequency signals could be very close to the noise level of the system. The SNR then would be extremely small. This problem was recognized in the early days of disc recording, but the remedy used was only partial. At first only the low end of the audio spectrum was equalized. The cutting head sensitivity was decreased at low frequencies so that the amplitudes in midrange and at high frequencies could be recorded at higher levels. Then, the playback amplifiers were adjusted to boost the low frequencies to compensate for the losses intro-
duced in recording. From this point on, the equalization used for cutting was called preemphasis, and equalization used in playback equipment, postemphasis.

The 1 kHz signal was chosen as the reference point because it was a convenient halfway point between the low and high frequencies. As time went by and further improvements were made, the equalization was extended to the higher frequencies as well. What emerged from the long and at times controversial subject of equalization are the RIAA and NAB equalization curves. The first curve was used by the Record Industry Association of America (RIAA) and the second, which is almost identical to the first curve, by the National Association of Broadcasters (NAB).

People still debate about two versions of the recording equalization. The DIN (Deutsche Industrie Norm) standard used in European countries calls for additional equalization at the extreme low end during playback to improve the SNR and stability of the system due to mechanical disturbances—i.e., turntable rumble—which can affect the overall performance of the system.

The NAB (RIAA) curve used presently in the playback equipment is shown in Fig. 27-2. The numerical values for the characteristic are shown in Table 27-1. For recording, the inverse curve is used. It means that if the playback signal is boosted +19.3 dB, the same signal should be recorded at the level of –19.3 dB so that the overall result will be 0 dB deviation from the ideal flat response curve.

![Figure 27-2. NAB (RIAA) standard reproducing characteristic.](image)

Equalization is used to record the sound at the most advantageous levels for the best results as far as distortion and noise are concerned and to reproduce it so that the original balance between the frequencies can be restored. The RIAA curve is used for phonograph discs. Tape recorders record signals on tape, and tape recording has limitations that differ from the limitations found in mechanical recording and, therefore, require different preemphasis and postemphasis for best results.

The RIAA curve covers the range from 20 Hz–20 kHz. The DIN curve, as shown in Fig. 27-3, extends the control over playback down to 2 Hz where the equalization returns back to 0 dB. As can be seen from the graphs, the curves have complex shapes; equalizer circuits use capacitors and resistors, and their values determine the amount of signal equalization that can be expressed as a function of a time constant in microseconds as derived from the equation

\[ T = CR \]  

where,
\( T \) is a time constant,
\( C \) is capacitance in farads,
\( R \) is the total effective resistance of the supply network in ohms.

This is part of the equation to determine the attenuation at various frequencies:

\[ \text{attenuation}_{dB} = 10\log(1 + \omega^2T^2) \]  

where,
\( \omega \) is \( 2\pi f \),
\( T \) is \( CR \) of Eq. 27-1.

The RIAA curve consists of three time constants; 75 µs to roll off the high frequencies, 318 µs to produce the slope below 1 kHz with a knee at 500 Hz, and a
3180 \mu s time constant to flatten the low end of the curve. In today’s modern amplifiers, the equalization is accomplished by placing the network with proper time constants into the negative feedback loop of the amplifier, thereby achieving lower distortion, better SNR, and improved signal-level-handling capability of the circuit.

Because the recording space on the record disc is limited, records are cut with constant amplitude characteristics of the signals in the upper half of the frequency range. When reproduced by the pickup, these signals are equalized to a constant velocity characteristic. In playing back these preemphasized disc recordings, different equalization has to be used for different types of cartridges. For instance, dynamic cartridges, which include moving-magnet, moving-iron, moving-coil, and variable-reluctance pickups, are constant velocity devices; therefore, they respond to the speed of the stylus movement. The faster the stylus is deflected, the higher the output voltage. Ceramic or crystal cartridges are pressure-sensitive devices, and they respond to the force applied to the stylus. They are called constant amplitude devices, and when records with constant velocity recording are played with ceramic cartridges, no additional equalization is required. The combined characteristics of both the recording and the cartridge complement each other, returning the signals to their original form. Only a minimal amount of signal grooming may be necessary to compensate for the effects of capacitive loading and nonlinearity of the cartridge.

27.4 Turntables

To play a record, the turntable or device to rotate the disc at the required speed is needed. This is the basic requirement for all turntables. The construction and execution of the requirement may differ greatly between the models and the designs of different manufacturers. The history of evolution of the record drive mechanisms takes us from the days of hand-cranked cylinder machines, through the age of spring-wound phonographs with mechanical governors for speed control, and into the age of electrically driven machines with electronic control. Today the accuracy of turntable speed is measured in small fractions of 1% in deviation from the desired speed.

27.4.1 Drive Systems

Turntables are driven by electric motors. The method by which the power from the motor is transferred to the turntable platter classifies the drive mechanism. The turntable platters can be belt driven, puck or idler driven, and driven direct.

The first category, the belt-driven type, encompasses all models that have motors mounted to the side of the platter with the belt stretched over the motor pulley and outer rim of the platter, Fig. 27-4A. Some platter designs have an additional internal rim to hide and to protect the belt.

Many turntables have synchronous motors or motors with some type of speed control mechanism, such as a centrifugal switch that disconnects the power to the motor when the speed exceeds the preset value. The later types of motors are usually low-voltage, battery-driven motors used in portable equipment. Also, in portable turntables there is electrical feedback to control the speed of the low-voltage motor.

Another version of the same idea uses a low-voltage ac motor driven by a self-contained crystal-controlled oscillator allowing variation of the speed of the platter and achievement of great speed precision. The only source of speed variation can come from belt slippage or a defective belt. Belt-driven turntables are normally the quietest turntables. The speed selection of the belt-driven turntable can be accomplished either by changing the speed of the motor or by having the stepped pulley on the motor and by shifting the belt from one pulley onto another.

The second type of turntable is a puck-driven or idler-driven turntable, Fig. 27-4B. The coupling between the platter and the motor shaft is achieved through the intermediate idler wheel or puck, which has the outer edge covered with neoprene rubber or polyurethane for positive drive and to isolate the motor vibration from the platter. The idler wheel rotates on the shaft that is attached to a sliding bracket. When one side of the idler pulley (or puck) is in contact with the inner side of the rim of the platter and on the other side with the motor shaft, the idler wheel will transmit the motor rotation to the turntable platter. The mechanism is designed so when the motor is turned off the idler wheel
The advantage of the rim drive is that it provides positive torque to the platter, and if the motor is strong enough, it can bring the turntable to the desired speed almost instantly. The mechanism is simple, and it is the most reliable type of drive. Unfortunately it is also the noisiest because of the positive coupling between the motor and the platter idler or puck that transmits a certain amount of the motor vibrations to the platter and consequently to the record, as shown in Fig. 27-4C.

The third kind of turntable drive is the direct drive where the motor drives the shaft of the platter directly. There are also variations of the design. Some turntable designs are very sophisticated, using the platter itself as a rotor of the motor and drive is provided by the self-contained, quartz-controlled oscillator. The motion is extremely accurate and the speed of rotation may be displayed on the digital display, which is part of the control panel. There is also a weak point in this seemingly perfect drive. Because of the slow speed at which the turntable rotates, and because the motor has a finite number of poles, there is a slight cogging action in the platter motion, which may manifest itself with increased loads. This handicap is only related to turntable platters with fairly small mass and small moments of inertia. If the platter is heavy, it will overcome this problem.

The performance of the turntable depends very little on the type of drive used but more on the correct execution of the design by understanding the problems involved. The ideal turntable should have the following properties:

- It will start fast without hesitation.
- It will rotate with exact speed without variations.
- There will be no motor noises or vibrations heard while the system is in operation, they will not be transmitted to the platter.
- The turntable should be adequately shock mounted and isolated from the surface on which it sits to prevent the transmission of rumble and vibrations from the room. These loud sounds can actually shake the platter and the tonearm.
- The platter should be treated against ringing either by using a turntable mat with damping properties or by undercoating the platter.
- The turntable must be easy to maintain and to repair.

Not many turntables meet all these criteria; therefore, in order to know how to evaluate the unit, it is important to know how they work.

**Speed of Rotation.** Before evaluating the entire system, there are tests that can be performed on the turntable alone. The first one is speed of rotation. There are many ways of checking the speed of rotation, but the simplest one is by using the stroboscopic disc.

A stroboscopic disc is a circular disc containing a number of black-and-white bars, which are used for checking the speed of turntables and other rotating machines, Fig. 27-5. The disc is placed on the turntable,
and the bars are observed under a fluorescent or neon light source fed from the normal ac lighting circuits. When the speed of the turntable is correct, the black bars appear to stand still. If the table is turning too fast, the bars speed up and drift in the direction of rotation. When running slow, the reverse takes place. Stroboscopic bars may be painted around the rim of a turntable and illuminated by a 115 Vac neon light mounted close to the table edge for constant observation. The equation for calculating the number of bars on a 60 Hz stroboscopic disc is

\[ \text{bars} = \frac{2f}{60} \frac{1}{\text{rpm}} \]  

(27-3)

where,

- \( f \) is the frequency of the stroboscopic light used to observe the bars,
- \( \text{rpm} \) is the speed of the turntable in revolutions per minute.

**Starting Time.** Starting time is the time it takes for the platter to reach its operating speed from a complete stop. This time period is important to know for professionals who have to begin playing the song or selection at the exact moment. To check the starting time requires either a stop watch or timing device and a stroboscopic disc or the test record. As soon as the lines on the stroboscopic disc appear stationary, the turntable has reached its operating speed. In playing the record test tone, the pitch changes as the correct speed is attained. Starting time may vary anywhere from a fraction of a second to two or more seconds, depending on the construction of the turntable. Turntables used by disc jockeys have to start as fast as possible without overshoot, which means that the speed should not, even for a moment, exceed the desired speed. If this overshoot occurs as the program material is already being transmitted, the variations of the speed will be most objectionable.

**Acoustical Noise.** The third test concerns the acoustic noise the motor and the turntable are producing. Normally, this test can be easily performed in a quiet listening room when everything is turned off and only the turntable is energized. If the turntable noise is clearly heard and it overshadows the normal room noise, turntable drive is below an acceptable performance level. A second part of the same test is conducted when the turntable is turned off and the system is

![Figure 27-5. A stroboscopic disc used for checking the rotational speed of a turntable. Courtesy Fairchild Recording Equipment Corp.](image-url)
adjusted to a normal listening level. When the record with the quiet groove is placed on the turntable, a slight hiss can be heard when putting your ear to the loudspeakers. When the record with the quiet groove is placed on the turntable and the stylus is placed into the groove, listening to the increase in noise will show the extent to which the turntable transmits the building rumble. If the power to the turntable is turned on, the noise contributed by the motor drive can be measured. During this test, slightly tapping the base of the turntable can determine if the shock mounting is adequate and whether or not loud music will add coloration to the signal being reproduced. In summary, what is required from the good turntable is that it reproduces only what is recorded on the disc and is insensitive to all other sources of vibration.

27.4.2 Turntable Design in the 21st Century

One of the most important features of turntable design is the ability to keep noise and rumble created by motors and bearings from being picked up by the cartridge stylus. Many inexpensive turntables have a direct drive between the motor and the platter and inexpensive bearings, allowing motor noise and vibration to be transmitted to the platter and then to the cartridge stylus. Remember, it doesn’t make any difference to the signal whether it comes from the stylus moving versus the disc or the disc moving versus the stylus.

VPI turntables, Fig. 27-6 use inverted bearings instead of conventional bearings. In this design the bearing assembly is in the platter rather than in a bearing well below the platter. The spindle and ball are attached to the chassis and the bearing well is inverted and placed in the platter itself. With this design the drive belt pulls through the center of the bearing assembly rather than many inches away from the center of the assembly, reducing teeter-totter effects to near zero for better stability.

All motor assemblies are completely separated from the turntable platter and tonearm, so there is no mechanical connection between the motor and the chassis except through the belt. This gives much lower noise levels due to isolation from the source of noise.

The VPI HR-X turntable uses a dual motor flywheel assembly to drive the platter. Two synchronous motors, driven by a perfect sine-wave ac power supply, drive a 14 lb flywheel spinning at 300 rpm, which in turn drives the platter. In this configuration the platter is driven by a non-electromotive source as opposed to other tables that are driven by the motor or combination of motors. Running the platter with no motor or multiple motors produces a velvety black background and perfect speed stability.

27.5 Tonearms

Tonearms can be classified into two categories: pivoted and tangential tracking, Fig. 27-7A and 27-7B.

Contemporary tonearms are designed to cope with a variety of problems. However, rarely can one find a tonearm with nearly perfect geometry and correct design to establish correct performance. Most tonearms have built in antiskating devices, adjustable counterweights to accommodate a variety of cartridge weights and tracking forces, vertical height adjustment to set the tonearm parallel to the record, and a variety of features to facilitate installation and operation of the device. All tonearms are at best a compromise. Very few tonearms are dynamically balanced, and most rely on dynamic unbalance to produce vertical tracking force. The dynamically balanced tonearm is the tonearm that is capable of playing a record with the turntable tipped at almost any angle without changing the tracking force and tracking ability.

Tonearm Geometry. Tonearms are designed to retrace the modulation of the groove in the same way as it was recorded. Design of the tonearm takes into consideration the diameter of the records or the turntable, and the distance between the center of the platter and the
pivot point of the tonearm. Older tonearms suffered from a tangent error because the cartridge was aligned properly at only one point on the record. Today’s pivoted tonearms have a built-in offset angle at which the cartridge is positioned so it is always perpendicular within a couple of degrees to the radius of the disc. This reduces distortion in the lateral plane and improves tracking. There are many protractors available today using different approaches to help position the cartridge as accurately as possible in the tonearm to minimize tracking error.

When a disc is being cut, the cutting head is carried across the face of the recording disc following the radius. However, in playback, the pickup is at the right angle to the radius of the disc only at two points, because the pickup arm is pivoted in such a manner that it swings across the face of the disc in an arc, as shown in Fig. 27-8.

Generally, the manufacturer of the arm supplies a template and mounting instructions for a particular arm. In the absence of such information, the pickup arm is mounted in such a manner that the tangent error is at a minimum. One method of mounting the arm is shown in Fig. 27-9. Regardless of where the pivoted arm is placed, a tangent error cannot be eliminated entirely.

The error can be made so small, however, that it can be neglected. In offsetting the tonearm by bending it into an S or J shape, Fig. 27-10, it is possible to position the cartridge so that at two points on the record the error shall be zero. The deviation from this ideal groove-cartridge interface will be only 2–3° in the horizontal plane.
Offsetting the tonearm introduces the skating force that pulls the tonearm toward the center of the record. In tonearms without the offset angle the skating force is zero at one point and increases as the tonearm moves away from this position. The zero tangent error point in this tonearm coincides with the zero skating force position, point A in Fig. 27-8.

Theoretically, the pivoted tonearm without the offset angle and without any tangent error has to be infinitely long. The tonearm designed by the Rabinoff brothers revived the principle of tangential tracking used by Edison and found application in many turntable systems. In this system the tonearm motion has been achieved using servomechanisms and utilizing various types of arm position sensors. These tangential tracking turntables practically eliminated the tracking error and are quite popular with many hi-fi enthusiasts. There are also drawbacks to this design. Usually, such tonearms cannot be moved as fast as pivoted counterparts, and this may become a handicap in operations when speed of positioning the tonearm is of essence. The advantage of tangential tonearms is that they are shorter, lighter, and can be made more rigid to prevent many tonearm resonances found in some inferior pivoted tonearms. But the mechanical complexity of tangential tracking tonearms requires the use of modern technology including special integrated circuits and sensors.

Effective Tonearm Length. Fig. 27-11 defines the turntable platter and spindle location in relationship to the effective tonearm length, which is the distance between the stylus tip and the tonearm pivot.

Modern tonearms have a built-in stop preventing them from moving farther than the locking groove so only three dimensions are of importance: effective tonearm length, vertical pivot-to-spindle distance, and the offset angle.

The accuracy of the cartridge tracking and mounting depends on the effective length of the tonearm. If the effective length of the tonearm is 7.87 inches and it is properly mounted (7.04 inches away from the turntable spindle), the cartridge will track to within $+2\frac{1}{4}^\circ$ and $-1\frac{1}{2}^\circ$, providing the cartridge is mounted at an offset angle of $27.8^\circ$. If the tonearm is longer, the lateral tracking error gets smaller so that the tonearm with the effective length of 10 inches will have a maximum tracking error of less than $1^\circ$ at the smaller disc radius and a $1.7^\circ$ error at the maximum radius.

Since the linear speed of the outer grooves is higher and the wavelengths are longer, tracking angle errors have lesser effect on the signal quality. Therefore, tracking errors should be minimized at the inner grooves for consistent quality of playback signal at all radii.

Skating Force. Skating force is a force that can upset the best aligned tonearm and cause considerable tracking error. The skating force is the result of tonearm geometry and the friction between the stylus and the record groove. Because of the offset angle and the overhang, one vector of this force pulls the stylus in a direction away from the pivot point of the tonearm and the second vector pulls the tonearm toward the center of the turntable, Fig. 27-12A. If this skating force is not compensated for, the stylus will be deflected toward the outside of the disc at the angle much greater than the error angle encountered in tracking the groove at different radii, Fig. 27-12B.
The skating force compensation consists of applying a force to the tonearm that is equal to but opposite in direction to the skating force, Fig. 27-13. For all practical purposes, the skating force is constant for all radii of the music groove if the tracking error is small and the tonearm alignment is correct. There are slight variations of the skating force due to heavy modulation and groove wall plastic deformation caused by the sharpness of the new stylus, but the largest deviation in skating force is due to the variations in record material. From the study of various materials, it was established that the softest materials produce more friction and larger skating force. Lacquer masters produce up to 25% more friction (i.e., skating force) than vinyl records. Styrene records, today’s 45 rpm discs, have approximately 30% less friction than vinyl, requiring less antiskating compensation than vinyl LPs.

There are many different ways to generate the antiskating force. It is incorrect to assume that increasing the drag on the horizontal motion of the tonearm will compensate for skating. Skating force is independent of groove spiraling speed; drag is not. Also, because of the
variable pitch common to all present-day recordings, the speed with which the tonearm moves across the record varies and at times may even be zero. Because of this variation, the mechanism that generates the antiskating force should be able to generate a uniform force at all times, regardless of the motion of the tonearm. Antiskating force can be generated by using springs, magnets, weights with pulleys, electrical devices, and mechanical linkages and weights, Fig. 27-14. Any method to apply the clockwise bias in a horizontal plane to the tonearm to counteract the skating force produces positive results; however, compensation may not be accurate for all types of systems.

The effectiveness of the antiskating force mechanism depends to a high degree on the dynamic behavior of the tonearm. If the tonearm is not dynamically balanced (and most of them are not), any tilt of the turntable may result in a change of skating force, endangering the tracking ability of the pickup. As was previously mentioned, the dynamic balancing of the tonearm implies that the pivot point of the tonearm is also the center of mass. In most modern tonearms this center of weight is shifted toward the cartridge end in order to produce tracking force, Fig. 27-15. In a dynamically balanced tonearm, tracking force is produced by using either a spring or a permanent or electromagnet (solenoid). A properly dynamically balanced tonearm could play a record with the turntable being in any position and is completely insensitive to jarring of the turntable or floor vibrations.

**Vertical Tracking Angle.** An important adjustment of the tonearm is in positioning the cartridge over the surface of the disc. Cartridges are mounted in tonearms so that the mounting surface of the cartridge is parallel to the record surface, Fig. 27-16A. Sometimes tilting the cartridge fore or aft results in lower tracking distortion. Some cartridges are designed to produce the lowest distortion when playing vertical modulation that was recorded at the vertical cutting angle of 25°, Fig. 27-16B. At the same time most of today’s records are cut with the vertical angle of 10°–15°. So in order to reduce the distortion during playback, matching the two angles by moving or tilting the cartridge backward a few degrees may help reduce tracing distortion.

**Tonearm Resonance Damping.** A Shure Brothers, Inc. study revealed that the warp frequencies of LP records lie in the region from one revolution (0.5 Hz) peaking at 3 Hz and tapering down at 7–8 Hz. Because the audible range of frequencies starts at around 20 Hz, tonearm resonance placed between the warp frequency region and the audible region will allow minimum distortion of the signal due to tonearm bounce. As a result of this research, improvements were made in the tonearms by applying vertical damping to the tonearm. The vertical tonearm motion control was attacked by Discwasher, Inc., by designing a special damping mechanism named Disctracker, which attached to the cartridge. Shure Brothers introduced their stabilizer brush that attached to the cartridge similar to the brushes invented and used.
by Pickering and Stanton since 1971, except that the Shure stabilizer brush had its pivots filled with damping fluid. These devices helped to various degrees to stabilize the tonearm as the brush cleaned the record groove.

The other approach was to adjust the effective mass of the tonearm by pivoting only the front part of the tonearm and selecting a cartridge with compliance that would match the mass of this portion of the arm, Fig. 27-17. Dynavector tonearm is an example of such design. Another variation is the design by Sony that employs electronic control of the tonearm motion. Instead of relying on weights, springs, or magnets, the Sony tonearm uses linear dc electromotors driven, operated, and controlled by electrical signals. Unfortunately, not all functions of the tonearm are controlled automatically and are subject to misadjustment.

Figure 27-15. Examples of how dynamic balance of the tonearm can be achieved.

Figure 27-16. Schematic representation of the moving system of a pickup, illustrating the vertical tracking angle.

27.6 Phono Pickup/Transducers and Styli

In order to reproduce signals recorded on the phonograph record, a transducer (phonograph pickup, phono cartridge, or needle) converts the groove modulation into the electrical signals. Unlike microphones, loudspeakers, and other types of devices or transducers that convert one form of energy into another, the phonograph pickup has to perform more than one function. The phonograph pickup or cartridge, so called since the invention of the removable stylus or needle assembly, has to convert modulation of the record groove into the electrical signals, and at the same time support the tonearm at
the proper height above the record surface, all the while moving the tonearm across the surface of the record.

The phonograph cartridge is an electromechanical device designed to track or follow the excursions of the record groove and to convert this motion, with the help of a tracking mechanism-stylus assembly, into electrical signals.

Cartridges are classified by the principle by which they convert mechanical motion into the electric current or signal, *electrodynamic* and *piezoelectric*. There are also pickups designed to operate using strain gauges, variable capacity, and light as sensors.

**Electrodynamic-Type Cartridges.** Electrodynamic-type cartridges are subdivided into three categories: *moving magnet*, *moving coil*, and *induced magnet* or *moving-iron* type. The electrodynamic principle consists of using a magnetic field that, when it intersects the coil windings, generates electric current. The construction of the cartridge classifies the type. If the magnet is attached to the stylus tube or cantilever and the coils are stationary, it is called a moving-magnet cartridge. If the magnet is made stationary and the coils move in the magnetic field, it is a moving-coil cartridge; and if the magnet and the coils are made stationary and there is a slug of soft magnetic iron moving in place of a magnet while being magnetized by the stationary magnet, it is called a moving-iron or induced-magnet cartridge.

**Variable-Reluctance Cartridges.** Since the introduction of the original variable-reluctance pickup, Fig. 27-18, many different versions of its design have appeared. The magnetic structure consists of two pole pieces A, with a small permanent magnet B between them. The coil C is mounted with a soft rubber insert D. The stylus, which is also the armature, is held in the exact center of the magnetic structure by the rubber insert. When the stylus is actuated, its movement causes a voltage to be generated in the coil. Because of its construction, the frequency response extends beyond the normal audio-frequency band. Output voltage is on the order of 100 mV at 1 kHz, with an output impedance of 500 Ω. The recommended stylus pressure is 15–20 g. The stylus weighs 31 mg and is removable. Although the recommended pressure is 15–20 g, the pressure could be as low as 7 g. The frequency response is ±2 dB, 20 Hz–20 kHz.

**Moving-Coil Cartridges.** Modern moving-coil cartridges are represented by a variety of designs. All of them have coils that move, but not all of them are entitled to be called moving-coil type. Designs that depend for their functioning on the motion of the soft iron core rather than on the motion of the coil itself should not be classified as a pure moving-coil device. There the motion of the coil is coincidental. Fig. 27-19 shows the cross sections of moving-coil stylus assemblies as they move during the playing of the record. The magnetic flux is directed by the iron core or armature of the coil. If the coil is made stationary and the core is vibrated, the signal will still be generated. This fact prevents it from being classified as a pure moving-coil device.

The advantage of this design is extremely low output impedance, making the cartridge insensitive to capacitive loading and allowing the use of very long cables without altering the frequency response of the device. On the negative side, the output of the cartridge is very low, measuring in the tenths of a millivolt requiring an extra 20–30 dB amplification to bring the electrical signal to the required level as referenced to an established sensitivity of 1 mV/1 cm/s of recorded velocity. A step-up transformer or an extra stage of amplification usually introduces additional noise and the effect on capacitive loading. Other drawbacks of such design are the weight of the cartridge and the need to use a heavier tracking force.

One of the debatable points about MC cartridges is the sound they produce. MC cartridges have a very fast response to transients because of the very low inductance and the impedance of the coils and the very rigid cantilever, which has to be strong in order to move a relatively heavy coil assembly. Another factor in this type of design is the construction of the coil assembly, which may have a number of turns in the coil unsupported and free to vibrate, producing random signals at higher frequencies. Also lead-in and lead-out wires may not be secured properly and can vibrate in the magnetic field producing random coloration of the signal.
dressing, coil impregnation, and gluing techniques control the purity of the sound produced by this design.

Step-up transformers require winding ratios of 1:10 or more. The transformer’s high-impedance secondary winding is reflected back into the primary, and any loading of the secondary in excess of the specified value affects the signal output level and electrical damping of the coils. Theoretically, shorted coils produce maximum damping, while an unterminated winding of the transformer’s secondary will emphasize electrical resonances and unchecked mechanical motion. It is important to locate the step-up transformer near the preamplifier input to minimize the capacitive load of the shielded wires between the transformer and the input stage of the amplifier. Because the levels handled by this input transformer are extremely low, good transformer shielding is necessary.

In lieu of the step-up transformer, a preamplifier may be used. Additional preamplification, obtained from active gain circuits, requires super low-noise circuits in order to preserve an acceptable SNR. There have been many such pre-preamplifiers designed using the most exotic devices and circuits, operating with batteries or special ac power supplies with maximum filtering and voltage regulation and using magnetic shielding.

**Moving-Magnet Cartridges.** The most popular high-performance stereo cartridges are the moving-magnet type. Moving-magnet cartridges offer one of the most sensible ways to design the stereo cartridge with a replaceable stylus. This cartridge has low dynamic tip mass, high compliance, and fairly high output. By using the most powerful rare earth magnets and using the most modern manufacturing methods, the frequency response is extended from almost direct current to well past the threshold of hearing, Fig. 27-20.

**Induced-Magnet Cartridges.** An example of an induced-magnet or variable-reluctance pickup is manufactured by Bang and Olufsen of Denmark. It consists of a small armature in the form of a cross, made of Mumetal, which swings between four pole pins, Fig. 27-21A. A stylus bar constructed of aluminum tubing 0.002 inch (0.05 mm) thick is attached to the Mumetal armature cross at one end. The stylus is secured to the other end of the tube. Four pole pins with four coils are placed at each end of the cross. With a 45° motion to the right, a reverse voltage induction takes place. Such action permits the coils to be connected push-pull, thus reducing harmonic distortion induced by the nonlinearity of the magnetic field. In addition, the coils provide an effective hum-bucking circuit.

Crosstalk between the left and right channels is minimized, since such components are bucked out. Modulating one channel 45°, the cross arms on the orthogonal channel rotate without changing the spacing; therefore, there is no induced voltage in this channel, assuming the positioning of the unit, with respect to the groove, is correct.

A cross-sectional view of the magnetic circuit is shown in Fig. 27-21B and is similar to the magnetic structure of a loudspeaker employing a center magnet. Thus, a closed magnetic circuit, which prevents leakage...
of the magnetic field, is provided and being nonmagnetic, it cannot be attracted to the steel turntable plate. It also provides an effective shield for the coils. The stylus bar pivots on a nylon thread, bonded to a plastic support. The armature cross bears on a resilient disc, Fig. 27-21C, which controls compliance and supplies damping for the moving system. The rotational point of the system is at the junction of the armature cross and the nylon thread support. The output voltage is 7 mV for each channel for a 5 cm/s cut. The stylus has an angle of 15° at 2 g of tracking force and may be operated at a pressure of 1–3 g. Compliance is $15 \times 10^{-6}$ cm/dyn for both directions of motion. Frequency response is 20 Hz–20 kHz ±2.5 dB.

**Semiconductor Pickup Cartridge.** A *semiconductor pickup cartridge* operates on the principle of the strain gauge. The pickup mechanism employs two small, highly doped silicon semiconductor elements 0.008 inch × 0.005 inch whose resistance varies as a function of the stylus deflection, Fig. 27-22. The elements are mounted on laminated beams of lightweight epoxy with gold-plated surfaces. A notch in the beam under the assembly acts as a hinge for stress concentration. In this structure, two beams are used, each driven by an elastic yoke, coupled to the stylus. Aside from the compliance of the yoke and mounting pads, a mechanical advantage of over 40:1 can be attained in the beam and stylus lever. This mechanical transformer provides high compliance and reduces the mass of the elements reflected to the stylus. The stylus is elliptical in shape and set at an angle of 15°.

Since the semiconductor elements are sensitive modulating devices and not generators as in the conventional pickup, very little energy is required for their operation. The compliance at 1 kHz is approximately $25 \times 10^{-6}$ cm/dyn and the frequency response is from 20 Hz–50 kHz. A power supply, two single-stage preamplifiers, and one inverter stage are required. As the elements are deflected by the stylus action, the resis-
tance of the semiconductors, about 800 Ω, changes slightly, causing a varying dc voltage across the output. This dc signal is ac coupled to the preamplifiers in the power supply, providing an output voltage of 0.4 V for each side. The cartridge employs mechanical equalization that, in combination with the RC equalizer at the output of each preamplifier, results in an RIAA reproducing characteristic.

Piezoelectricity. Piezoelectricity is pressure electricity. The voltage generated by the crystals in piezoelectric cartridges is proportional to the amplitude of the stylus displacement. The output voltage of the average piezoelectric pickup is considerably higher than for other type pickups. Piezoelectric pickups are treated electrically as a capacitive-reactance device since the impedance rises with a decrease of frequency. Simple RC networks are used with this type of pickup to obtain a frequency response corresponding to the standard RIAA reproducing characteristic. Records recorded using a constant-amplitude type with the output voltage 10 mV for a peak velocity of 5 cm/s. Ceramic pickups are not affected by magnetic or electrostatic fields.

RC equalizer networks for both crystal and ceramic pickups are shown in Fig. 27-24. The networks are connected between the output of the piezoelectric pickup and the input of the preamplifier. The characteristics of these networks are such that they correspond to the standard RIAA reproducing curve. Using a pickup with a compliance of $15 \times 10^{-6}$ cm/dyn or greater, the response can be within ±2 dB.

The stylus bar is made from heat-treated, thin-walled aluminum alloy tubing, with one end flattened to hold the stylus at the desired angle. The other end of the stylus bar is held in place by the stylus mounting block. The coupling yoke is connected at a point about midway on the stylus bar. This point is chosen because it affords the most desirable electrical performance and substantially reduces the mechanical impedance of the yoke and ceramic elements as seen by the stylus tip.

Better designs have four output terminals, two for each channel, to ensure the complete isolation of one side from the other. Damping in the form of a viscous material is used to control the frequency characteristics.

The internal impedance of the average crystal pickup is approximately 100 kΩ, with a capacitance of 0.001 to 0.0015 μF.
27.6.1 Cartridge Styli

Stereo Disc Groove. The playback stylus is the first link between the information stored in the record groove and the playback system. The quality of the reproduced sound is influenced by the precision with which the stylus follows the groove modulation.

In stereophonic recordings with 45°/45° modulation, the two channels are isolated from each other because modulation of each channel is at 90° to the other, Fig. 27-25.

To minimize the effects of vertical excursions at low frequencies, the phase of both channels is adjusted so low-frequency signals are in phase in order to produce lateral modulation. The phase relationship of the two channels determines the location of the sound image between the two loudspeakers, and in some cases the phase is a deciding factor as to whether there is going to be a signal reproduced at all.

Stylus Tip. The function of the playback stylus of the cartridge is to follow all deflections of the groove. Since the stylus is attached to the end of the cantilever, any motion of the stylus tip is transmitted to the other end of the tube or shank, where the electrical signals are generated by a moving magnet, a moving coil, or a crystal. The stylus has rounded off edges that are polished for smooth tracking. Ideally, the playback stylus should be centered in the groove, and its centerline should match that of the cutting stylus. There are always minute imperfections in the alignment of the stylus and of the groove. Therefore the shape of the playback stylus is made to compensate and allow some misalignment of the stylus in the record groove.

The stylus touches the groove walls at two points. The contact area is curved and is a part of the tip radius so that if the stylus is slightly tilted due to misalignment of the cartridge or the tonearm, tracking will not be affected.

Spherical Stylus. There are several types of styli today. The simplest and the oldest one is the spherical tip. The spherical stylus is a tiny diamond or sapphire cylinder with one end ground to a cone shape with its tip polished to an accurate sphere. The included angle of the cone is about 55°, and the tip radius is about 0.0007 inch or 0.7 mil. Because grooves can be as narrow as 0.001 inch, the stylus tip has to be equal to or smaller than the groove in order to track it. The standard tip radius dimensions for today’s spherical stylus range from 0.0005–0.0007 inch (12.7–17.7 μm).

Elliptical Stylus. The second type is the elliptical stylus. From the front it looks like a spherical stylus; however, there are two flats polished in the front and the back of the stylus. The side radius of the elliptical tip is much slimmer than that of the spherical stylus. The intersections of the two flats are polished to form small radii called the tracing radii, which measure about 0.0002 inch (5 μm). These small side radii are actually in contact with the modulation of the groove and,
because they are small, they follow the high-frequency excursions of the groove more easily.

**Stylus Characteristics.** All playback styli are designed to contact only the walls of the groove; therefore, the stylus tip has to ride without touching the bottom of the groove. Since the diamond gets slimmer as it wears down, the tip gets closer and closer to the bottom of the groove. When it starts touching it, noise increases because debris has accumulated on the bottom of the groove and is scooped up by the stylus. This is a clue to change the stylus in order to reduce the noise and to preserve the record from being destroyed by the sharp edges of the worn diamond.

Currently, almost all styli manufactured are made out of diamond. The quality and the price of the stylus depends on whether it is made out of a solid piece of diamond or a small chip bonded onto another material that acts as an extension or pedestal for the diamond tip. The technology of manufacturing diamonds has advanced significantly so that chip bonding and encasing can be favorably compared to solid or nude diamond tips. In view of the fact that the area of contact is only 0.2 millionths of a square inch \((0.2 \times 10^{-6} \text{ inch})\) and as long as this area is made out of a diamond, the overall performance of the stylus will not be affected. All this is true providing that the mass of the bonded stylus assembly is not higher than that of a conventional diamond and not larger than the nude stone.

The vertical tracking force applied to the stylus is divided between the two walls. Each wall is experiencing force that is equal to the total vertical force times the cosine of 45° or 0.707, Fig. 27-26. For instance, if the vertical tracking force (VTF) is 1 g, each groove wall will experience a force of 0.7 g.

**Stylus Cantilever.** The stylus is attached to some type of coupler or cantilever that connects it to the generating element of the cartridge, which could be a magnet, a piece of iron, a coil, or a ceramic element. Because of a very wide range of frequencies this stylus assembly has to transmit, the construction material and shape of the cantilever are very important. Theoretically, it has to be very light and rigid. Over the century of existence of mechanical sound recording, styli were made out of cactus needles, whale bones, and all kinds of metal, gems and stones, plastic, and wood. The final choice is centered around an aluminum alloy thin-wall tube. It is fairly strong, light, noncorrosive, nonmagnetic, electrically conductive, and easy to manufacture.

The average diameter of the aluminum cantilever tube is 0.03 inch (0.76 mm), and the length may vary from \(\frac{1}{4}–\frac{1}{2}\) inch (6–12 mm). A few exotic cartridges have cantilevers made out of solid ruby or even diamond and some from boron or beryllium copper alloy. Although ruby and diamond are extremely rigid materials, because of manufacturing difficulties and high weight/length ratio, they are made very short. This, in turn, brings the pivot point much closer to the stylus tip that moves in a much smaller arc when reproducing groove modulation. Since the grooves are modulated by the cutting stylus that has its pivot quite a distance away and is moving in an arc of much larger radius, the larger the difference between the motions of the cutting and of the playback stylus, the larger the distortion.

On the other hand very long playback cantilevers are unable to produce sufficient motion of the generating element that results in a very low electrical output.

**Compliance.** The amount of force required to move the playback stylus depends on several factors; the first is the compliance of the stylus, and the second is mass.

Compliance of the cantilever or the stylus is the ability of the stylus assembly to react to the groove modulation. It is measured in \(\text{cm/dyn or } \mu\text{m/mN (metric)}\) and gives the amount of stylus tip deflection for the given force. Compliance is measured statically and dynamically.

Static compliance is the amount of deflection of the cantilever when a constant force is applied to the stylus tip. Dynamic compliance is a measure of tip deflection
analog disc playback 1033

as it is reproducing the frequency of known amplitude at which the measurement is being made.

**vertical resonance.** the second variable in the equation is the tonearm/cartridge vertical resonance. tonearms and cartridges resonate between 5 Hz and 15 Hz; the most desirable range is between 8 Hz and 12 Hz. resonance below 8 Hz will produce instability of the tonearm and will result in poor tracking of moderately warped records.

Stereo cartridges have fairly uniform compliance in all planes of stylus motion. Cartridges with higher compliance work best with light tonearms, and heavy tonearms should be set up with cartridges having low compliance. if the stylus compliance is low, the tracking force applied to the stylus should be higher than for a high-compliance stylus.

27.6.2 Cartridge Voltage Output

the output voltage of the cartridge depends on its design and the type of generator system used. ceramic or crystal cartridges produce the highest voltage. next are the moving-magnet cartridges and then the induced-magnet pickups; the last group is the moving-coil cartridges. the moving coil cartridge produces higher power output than other types so they can work with step-up transformers to increase the output voltage 10–20 times or 20–26 dB. on the other hand, some high output voltage ceramic cartridges are connected to the loss pads and response-shaping networks to reduce the voltage down to the average output level of the moving-magnet cartridges. today most of the preamplifiers are designed to accept moving-magnet cartridges.

27.6.3 Electrical Loading

with various output levels and different source impedances, cartridges respond differently to electrical loads. For instance, crystal or ceramic cartridges are the most susceptible to capacitive loading. the entire frequency response is dependent on the loading of the cartridge. in the moving-magnet cartridge, only the highest portion of the frequency range is affected by the capacitive loading. the moving-coil cartridge is almost completely immune to the loading effects. once it is connected to the step-up transformers, the secondary of the transformer becomes very sensitive to loading, and excess capacity can play havoc with transformer resonance and the impedance of the secondary transformer winding. therefore, cartridge manufacturers specify the recommended resistive and capacitive loads.

the most common resistive load is 47 kΩ (50 kΩ for Europe), paralleled by 200–400 pF of capacitance for the moving-magnet cartridges, depending on the manufacturer and on the cartridge model. the capacitive loading for the cartridge includes capacitance of all interconnecting cables and tonearm wiring to ground (or between the conductors), capacity added by the connectors and switches. finally the internal wiring of the preamplifier circuit and preamplifier input circuit capacitance, which varies widely depending on the circuit design, adds capacitive loading to the cartridge, fig. 27-27. in many cases the total capacitance that appeared as a capacitive load for the cartridge exceeded 1000 pF, which resulted in an electrical resonance peak around 7–8 kHz followed by premature response rolloff at frequencies above this point.

27.7 Phono Preamplifiers

Phonograph cartridges require a special type of amplification to reproduce the recorded sound the way it existed during the recording session. the electrical signals from the cartridge, measuring only a few millivolts rms have to be amplified into signals of many volts. this has to be accomplished with:

- minimum distortion.
- flat frequency response.
- excellent SNR.

the phono preamplifier has to amplify a cartridge signal without:

- changing its phase.
- adding more than a small percentage of harmonic and intermodulation distortion.
- adding to the noise content of the original signal from the cartridge.
- needing enough reserve power to handle any unusually high transient signals.

the average required voltage amplification is 40–50 dB and is dependent on the output of the cartridge. the dynamic cartridge produces 4–5 mV of output for the average recording signal. a preamplifier gain of 45 dB will boost the signal output to nearly 1 V, the level required to drive most power amplifiers to full output. the noise contribution of the cartridge and of the recording medium requires the preamplifier noise level to be at least 70 dB below the average input signal of 10 mV.

the frequency response of the circuit should follow the RIAA characteristics, with the low frequencies
It is not unusual for a cartridge producing an output of several millivolts for the average modulation to produce 100 mV voltage peaks. Cartridges are designed to produce an output voltage of around 1 mV for each centimeter per second of recorded velocity or for the average recorded level of 5 cm/s, the cartridge output is 5 mV. Some preamplifier circuits when overloaded by fast spikes can recover in a matter of microseconds and resume their normal operation while others are incapable of recovering fast and once overloaded stay in this unbalanced state long enough to produce audible distortion of lower-level signals that may follow. Direct coupled stages, which don’t employ large capacitors and inductors, have much higher slew rates and consequently react much faster and with less distortion to audio signals.

The average moving-coil cartridge produces from 0.1–0.6 mV output with the source impedance of a few ohms and an inductance of a few millihenries, so 20–30 dB of additional voltage gain is required from the pre-preamplifier. Because the output level of the cartridge is so low, an extra demand for low-noise performance is placed on the circuit. To maintain the same SNR as in high-output moving-magnet cartridges, the pre-preamplifier (or head-amplifier) circuit should have 20 dB lower noise than the preamplifier for the moving-magnet cartridges. One of the ways to achieve this lower noise is by using a step-up transformer. The power supply for the low-level amplifiers requires excellent regulation and extremely low ripple voltage.

The preamplifier input for the moving-magnet cartridges requires a 47 kΩ input resistance and a low, preferably adjustable, capacitive load. The proper termination of the moving-magnet cartridge is very important for the correct performance of the transducer. Moving-magnet cartridges have a resistive and inductive nature, so designers specify the capacitive load. If the specified capacitive load is higher than the total capacity of the circuit, the preamplifier should have a provision to add capacitance to the cartridge termination as required. If the total capacitance is larger than needed, cables can be made shorter or replaced with ones having lower capacitance.

### 27.8 Laser Turntable System

The Laser Turntable (LT) is manufactured by the ELP Corporation, Japan, Fig. 27-28. It features a contact-free optical pickup system allows records to be played thousands of times without damage to the record. The LT operates with five laser beams, three of which stabilize the groove and two that read the analog audio informa-
tion from the record. The first two beams aim at the left and right shoulders of the groove for tracking. The next two read the stereo sound at 10 microns below the shoulder (the standard position). The final beam maintains the height between the laser head and the surface of record to manage thicker or warped records. The LT eliminates acoustic feedback and sound alteration and will play warped and rippled records (up to 5 mm deviation). For convenience, the LT comes with a remote control and can be paused and scanned much like a CD player.

The same audio information on records is engraved from the shoulder to the bottom of a record groove. The laser reads audio information that is 10 microns below the shoulder, Fig. 27-29, therefore, the laser picks up audio information which has not been touched or damaged by a pickup. It plays the virgin audio information on the groove without digitization.

The incident area of the laser beam on the groove is one-fourth the contact area of the best stereo needle and twenty-six times smaller than a mono needle, Fig. 27-30. The laser beam travels to the wall of the groove and back. The reflection angle is transferred to the audio signal. Therefore, the LT maintains analog sound through the entire process, without any digitization. As a result, the LT cannot differentiate between an audio signal or dirt on the record, so the vinyl record must be absolutely clean and free of debris.

The laser beams must reflect from an opaque surface in order to be read. Clear or colored records are transparent, or translucent, and will not reflect light to the sensors. Other types of records that may have difficulty include:

• Vertical cut records like the early Edison “Diamond Cut” series. The modulation is up and down rather than lateral.
• Rounded groove shoulder.
• A groove with a rounded bottom produces distortion.

No Acoustic Feedback or Sound Alteration. Feedback is typically caused by sound from the loudspeakers (or from elsewhere) reaching the turntable and mechanically picking up the vibrations, to be amplified again. There is no needle singing. The LP is safely in a drawer and the laser reads only the undulations of the groove, therefore there is no need for elaborate vibration isolation pads. The LT will not hear outside noises such as
footsteps on the floor, door slamming, or other vibrations in the area.

**Operating the Laser Turntable.** When a record is placed in the drawer and the play button pressed, the record tray closes and the LT scans the disc to identify the various bands or cuts. The bands are displayed on the front panel Record Profile LCD display. A single vertical line above the bands indicator shows the position of the laser pickup head. The vertical indicator travels across the record as it is played, showing its exact position on the record, and which band is playing.

On the initial scan the laser head moves from the inside (spindle) to the outside track while marking the bands. The machine then moves into the first band and measures the distance from the head to the record surface. After a few seconds the record will begin playing from the beginning.

The LP can repeat the same record up to five times, repeat a cut, listen to a segment of the cut, play a single groove segment repeatedly, or play selected bands in any order.

When a record starts to play, the message window displays the rpm of the platter. When a record is playing, the display shows the elapsed running time, the elapsed time of the current cut, the remaining time of the side, and total time of the side.

### 27.9 Record Care Suggestions

One of the most effective ways to keep the sound from the record free of noise and unwanted pops and clicks is to keep the groove and the stylus clean. The causes for dirty records are obvious; accumulation of airborne dust, finger grease, cigarette smoke, and anything that can be attracted by the static charges that exist on the surface of the vinyl disc. The dirt around the playback stylus is mainly due to raking the groove. Dust particles, as they settle down on the record surface, are attracted by the stylus, especially if it has a static charge on it. Better cartridges have their styli electrically grounded to bleed any static potential from the cantilever assembly to ground.

#### 27.9.1 Brushes

One method to keep room dust out of the record groove is to have the cartridge work with the dust-collecting brush. In sliding over the surface of the vinyl record, the electrically insulated brush produces a static charge of its own that attracts and holds the dust particles from the surrounding area. The stylus cantilever, which is metallic and electrically neutral because of grounding, stays clean and free to vibrate and track the modulation of the groove.

### 27.9.2 Record-Cleaning Machines

The groove modulations in vinyl LP’s are so small, on the order of the wavelength of light, that any compound, be it liquid or solid, will cause distortion in the reproduction of those grooves. The diamond stylus can be equated to a rock, and the vinyl record to Jell-O. Picture a rock running through jell-o at a high velocity. Anything that changes the way this rock moves through the Jell-O will cause changes in the recorded sound.

In the groove is a conglomerate of fungus, mold, dirt, ash, pollution, mold release compounds, various cleaning fluids and preservatives, etc. All these substances affect the way the stylus reads the groove and will affect the sound. A good vacuum cleaning machine will allow you to scrub the record with cleaning solution and then vacuum the record surface clean of the fluid carrying the contaminates away with it. A record cleaned on a good vacuum cleaning machine is microscopically clean and will sound it.

One of the great shocks in audio is the first time you hear a record you know very well cleaned by a vacuum cleaning machine. The sound is cleaner, clearer, crisper, with the sound of the hall or acoustic space very easy to hear. A clean record will not wear out. It is not the stylus that ruins the records it’s the stylus going through grunge and pressing the grunge into the vinyl groove that kills the sound of records.

Vacuum record cleaning machines all work the same way; a record is placed on a turntable, the turntable turns the record while the machine or the operator scrubs the record, the vacuum nozzle then sucks the contaminated fluid off the disc. A higher price gives you quieter operation or greater sophistication in application of cleaning fluids. In the end the result is pretty much the same. VPI’s HW-16.5 (in production for almost 30 years), Fig. 27-31, is an inexpensive record cleaner. The VPI HW-27 Typhoon Record Cleaning Machine is twice as powerful as other cleaning machines. It includes a 7.9 A 120 Vac vacuum motor and an 18 rpm turntable motor, Fig. 27-32.

It is strongly advised that before using any cleaning device the instructions be followed precisely and some experimentation be done on a few records before the entire library is cleaned or covered with a preservative coating. A word of caution, if too much record preservative is used, it will do more harm than good. Not only does the excess of material not lower the surface noise,
but it contaminates the stylus tip to the extent that it is no longer able to stay in the groove. Accumulation of the cleaning or antistatic substance on the stylus tip also increases its dynamic tip mass, interfering with tracking of high-frequency modulation. Consequently, cleaning the cartridge stylus becomes as important if not more important than cleaning records.

27.9.3 Record Storage

The worst enemies of records are dust, heat, and mildew. To protect records from contamination they should be kept covered in their sleeves. Sleeves should be static free if possible. Records should be stored either vertically or horizontally (freshly pressed LPs are stacked one on top of each other to prevent warpage). If stacking horizontally, sizes should not be intermixed, and the stacks should be neat and not too high. If stored vertically the records should not be loose and should not be leaning; this will introduce warpage. Record cleaners or preservatives should not be applied prior to storage because there is a good chance of mildew forming on the records if they are stored damp.

Warning: Old 78 rpm records should never be washed with solutions containing alcohol or other chemicals that dissolve shellac, the major binding ingredient in the record material. Vinyl LP records are much more forgiving and can be cleaned with alcohol solvents. The safest and most effective cleaning solvents are simple household liquid soaps that can do the job well if certain precautions are followed.

Record cleaners or preservatives should not be applied prior to storage because there is a good chance of mildew forming on the records if they are stored damp.

27.9.4 Cleaning Records

Warning: Old 78 rpm records should never be washed with solutions containing alcohol or other chemicals that dissolve shellac, the major binding ingredient in the record material. Vinyl LP records are much more forgiving and can be cleaned with alcohol solvents. The safest and most effective cleaning solvents are simple household liquid soaps that can do the job well if certain precautions are followed.

Records should not be washed unless necessary. Dry clean them first with a soft brush or lint free velvet cloth. If the record must be washed, use distilled water; never use hot water or water containing dissolved minerals. Record labels should be protected by placing a piece of thin plastic over the labels. Use a soft camel hair brush or piece of moistened velvet with a couple of drops of liquid detergent or shampoo applied to clean the grooves in a circular motion. Rinse thoroughly with distilled water, and then wipe with a clean lint free cloth. The record can be blow dried with a hand dryer set to the cool position (never hot). Most of the dirt in the groove is dust attracted by the static charges that exist on the record surface. Washing or rinsing the record surface dissipates these electrical charges, allowing the dust to float away.

Turntable mats are the greatest contributors of dust contamination because turntables are left to stand open for prolonged periods of time, accumulating dust on the mat. When clean records are placed on the mat, the underside of the disc picks up most of the dust off the mat. It is important for the mat to be cleaned, even washed.

Vinyl records (and CDs) are sensitive to heat. When the record is pressed under very high pressure, vinyl is flattened into a thin plastic disc that is forced to cool down under pressure until the vinyl is no longer pliable. Then the disc is cooled down further to room temperature. The forces applied to the plastic during stamping remain in the record. If the record is exposed to elevated temperatures again, the forces retained within the material will be released and the disc will warp. Once this happens, the disc is destroyed. Leaving the disc in a closed car or on a window sill on a sunny day will accomplish this.

28.1 Introduction

Many things have changed since the first, second, and third editions of this book were written. Magnetic recording is may still be the dominant storage technology, but its dominance is slipping. The everyday use of analog reel-to-reel recorders and longitudinal DASH digital tape recorders is virtually gone as are helical scan modular digital multitrack recorders. Computer-based systems storing data on random access hard disk drives are still popular, but as the price comes down on memory-based recorders that have no moving parts at all, these devices will certainly win out in the end.

The driving factor behind this shift is economy in both the acquisition and operating costs of the newer formats. The new systems utilize techniques and components that were developed and are mass produced for the consumer and computer markets, not just the very limited professional audio market.

We will first explore the underlying technologies common to all magnetic recorders, old and new. In spite of the rapid growth of digital techniques in audio, analog recording is by no means dead. Many albums are still recorded and mastered using analog audio recorders. In addition, the audio (and video) archives of the second half of the twentieth century are stored in vaults on millions of reels of analog tape. As a result, we will need qualified tape recorder operators and maintenance technicians for many years to come.

Unfortunately, however, much of the knowledge about analog audio recorders and the mentors who taught this information are slipping away. This chapter will provide an overview and in some cases more detail than the casual reader requires. A full treatment of the theory and practice of analog recording and specifically magnetic recording is clearly beyond the scope of this work. We hope that this will whet the appetite of some and spur others on to write more comprehensive treatments.

The roots of the modern-day tape recorder can be traced to Germany in the mid-1930s. Two German companies, AEG and IG Faben, worked together to develop the concept of recording on a coated tape. AEG built the machine and IG Faben developed the magnetic particles and manufacturing methods for the tape. Although few people outside Germany took note, the German tape recording industry flourished, with 5 million meters of tape being produced in 1939, Fig. 28-1.

The German machines, using a form of plastic tape, were vastly superior to English recorders using steel tapes and American recorders using spools of steel wire.

At the end of World War II, the victorious Allies set aside all of Germany’s patents as a form of reparation for the war. As a result, the wealth of German tape recorder technology was quickly and freely exploited in the United States and many other countries. Within just a few years tape recording replaced disk cutting as the primary method of recording information.

Magnetic tape offered several valuable advantages over phonograph disk recording and even the American fledgling wire recorders, including improved signal to noise ratio, lower distortion, and better frequency response. None of these quality features triggered the quick adoption of tape recording by the American radio networks.

The networks needed the ease of use, especially the ability to create undetectable edits by cutting and splicing the tape. The recorders also had an important secondary benefit—the ability to stop and quickly restart recording. (One does not stop a record cutting lathe in the middle of a cut!)

Both of these features stem from the nature of the tape recording. Tape recording is a serial process that distributes the audio events on a very long piece of tape. The time of the event is implicitly encoded in the position of the event along the tape. The editing scissors and tape now become a time machine that can alter the apparent time of an event by relocating the tape segment of the event to a new position in the reel. Editing is merely playing tricks with this time machine to remove or replace events to alter the program.

Ironically, more than 50 years later the pendulum has swung back, turning the serial nature of tape into a shortcoming. Most operations in a recording studio require one or more replays of previously recorded material. During a mixdown session, for example, the same song may be replayed 500 times before the final mix is finished. Each of these replays requires time to rewind to the head end of the desired selection. A 3-minute tune recorded at 30 in/s occupies 450 ft of...
tape. If the tape recorder takes 15 seconds to rewind the tape, the engineer would spend 500 15 second intervals waiting for the tape recorder to rewind. That is over 2 hours spent in rewind mode!

Contrast this sluggish operation with a digital audio system’s hard disk that can locate any position on the disk in less than 10 ms. 500 rewinds might now take less than 5 s!

### 28.1.1 The Family of Magnetic Recording Devices

All magnetic tape recorders are members of a larger family of storage devices that utilize moving storage media. Other members of this family include phonograph disk recorders, motion picture cameras and projectors, optical laser disks for video and audio, and magnetic disk devices for computer data storage. These storage devices share one very important characteristic—they all are complex electromechanical devices. In addition to electronic circuits that amplify, process, and control the basic signal that is to be recorded and retrieved, each device also contains numerous mechanical devices to move the media past the recording and reproducing transducers and also position the transducers for optimum performance.

All magnetic recorders share key features:

1. The recording process is instantaneous, requiring no intermediate processing before the signal can be replayed.
2. The record and playback processes exhibit reciprocity, meaning a single transducer may be used for recording or playback.
3. The storage medium can be easily erased and reused.
4. The parameters of the system (speed, track width, encoding scheme, etc.) can be customized for a broad range of audio and video applications.

### 28.1.2 Tape Recorder as a Transformer

A magnetic tape recorder can be visualized as a specialized form of transformer. In a conventional transformer, an electrical signal on the input or primary winding is converted to magnetic energy in the magnetic core of the transformer. This magnetic energy is then converted to an electrical signal in the output or secondary winding, proportional to the ratio of the windings. Transformers can be quite efficient and the losses are typically just a few percent of the total power passing through the device. The best audio transformers introduce only very small amounts of distortion to the amplitude and frequency response of signals passing through the transformer, Fig. 28-2.

![Figure 28-2. Transformer versus tape recording.](image)

For a tape recorder, the input and output windings consist of the record head and reproduce head. The magnetic core that couples these windings is a conveyor belt covered with magnetic particles in the form of the magnetic tape. A magnetic image is permanently impressed on the conveyor at the record head. When this image passes over the reproduce head, anywhere from milliseconds to years later, the magnetic image creates a signal in the head that is analogous to the original signal.

Unlike the fixed transformer core, the recording tape is fraught with numerous distortions, losses and imperfections that require attention. Virtually every component in the record/reproduce chain, including the heads, tape, signal electronics circuitry, and mechanical drive system, contributes to these errors.

### 28.1.3 Changes with Time and Space

Those of us who work in audio and acoustics are used to thinking of audio as a complex wave made up of discrete frequencies. These frequencies move through the medium (air) at a fairly constant speed. Distortions due to changes in propagation time are not often observed. In the equation

\[
\lambda = \frac{C}{f}
\]

where,

- \(C\) is the speed of sound in air and is essentially viewed as a constant.

In the analog tape recorder, \(C\), the speed of the tape past the tape head, is a variable. Changes in the speed of
the tape past the record/play heads will almost always be noticeable and, unless you are trying to sound like a small rodent, undesirable! The mechanism responsible for moving the tape past the heads in a constant and repeatable manner is called the transport.

28.2 Tape Transports

The beginnings of modern-day tape transports can be traced to Valdemar Poulsen, the Danish inventor of the magnetic wire recorder. Poulsen’s experiments in 1898 consisted of moving an electromagnet along a piece of steel wire to record and reproduce sound. He soon learned, just as every tape recorder operator today learns, that the relative motion between the transducer (the electromagnet) and the storage medium (the wire) must be uniform and repeatable.

Many of Poulson’s solutions to this problem, such as sliding the electromagnet down a long, sloping wire worked reasonably well but were hardly practical! The functions of his transport device, however, were the same as modern tape recorders, specifically:

1. To drive the tape (or wire) at a repeatable, and preferably constant speed over the surface of the transducer heads.
2. To maintain a fixed mechanical alignment of the tape as it crosses the heads.
3. To provide contact pressure between the tape and head by either tensioning the tape or pushing the tape against the head.
4. To provide the necessary auxiliary motions of the tape required for functions such as rewind, search, and editing.

The early German Magnetophon developed by I.G. Faben in the 1930s satisfied all of these requirements with a simple mechanical layout. Over 70 years later, today’s recorders have essentially the same layout, shown in Fig. 28-3. The reels of tape are mounted on the shafts of two motors that provide the high-speed spooling and the play-mode tape tensioning. The tape moves from the supply reel on the left to the takeup reel on the right. As the tape leaves the supply reel, it is steered by guides to pass over the erase, record, and playback heads. Following the heads is a constant-speed tape drive consisting of a rotating shaft called a capstan and a pinch roller to press the tape against the surface of the capstan. The tape then passes to the takeup reel, Fig. 28-3.

This layout was used on virtually every tape recorder ever built except for the infamous Ampex 400 built sometime in the early 1950s that placed the capstan/pinch roller assembly to the left of the heads.

The typical degree of precision that is available today in a professional recorder includes a tape speed variation of a few hundredths of a percent, mechanical alignments of less than one-thousandth of an inch (0.001 inch) and three-thousandths of a degree (0.003°), and tension variations of a few percent. Even these seemingly small variations create readily observable errors in recordings, leaving opportunity for future improvements.

28.2.1 Tape Metering

Ever since the early introduction of tape recorders to radio broadcasting, it was desired to have world standards that would permit tapes to be freely exchanged between facilities around the world. Furthermore, it was necessary to be able to freely exchange segments within a reel by editing. This requires absolute speed accuracy throughout the reel.

Broadcasters were concerned about the running time of a radio show. If the show was timed at exactly 30 min when it was recorded, it should also play in exactly 30 min on the air. A common timing accuracy specification of 0.2% means that the tape could play up to 0.2% of 30 min fast or slow or 3.6 s of error in either direction. This could result in either 3.6 s of overlap with the subsequent program, or 3.6 s of dead air silence while waiting for the next show to start.

A more demanding speed specification is the absolute speed error throughout the reel. If the tape machine runs 1% fast at the beginning of the reel, and 1% slow at the end of the reel, the overall timing might come out just fine. But when you cut a segment of music from the head of the reel into a song at the end of the reel, you now have a 2% speed jump at the splice, with a very noticeable pitch change.

A simple speed control technique is to clamp the tape to a surface that is moving at the desired tape speed, such as the outer periphery of a rotating drum. The tape is thus forced to move at exactly the same
correct speed. Various implementations use drums that range from over 2 inches in diameter to tiny shafts less than 0.1 inch in diameter. In general, the larger the drum, the more accurate the tape speed control. The very small spindles are usually employed at the very slow tape speed found with compact cassettes and consumer videocassettes.

The rotating drum is called a capstan, named after a device used on sailing ships to pull in cables and hawsers, and the clamping device is called a pinch roller. The simplest capstan is the shaft at the end of a motor. The diameter of the shaft is chosen so that the shaft’s circumference will move at the desired linear tape velocity when the motor is spinning at operating speed.

The actual linear velocity of the capstan surface is slightly lower than the tape’s speed. The effective speed of the tape is measured at the neutral axis of the tape, about ½ of the tape thickness into the tape for large capstans, but dropping down to about ⅓ of the tape thickness for small capstans. Remember that the total thickness of a tape is the sum of the backing and coating thicknesses. A nominal 1.5 mil tape is really about 2 mils thick—1.5 mils of backing substrate and 0.5 mils of oxide coating.

Other designs use a capstan/flywheel assembly that is driven by belts or rubber-tired idlers that engage the primary drive motor’s shaft. The resulting reduction in rotational speed permits the use of a larger capstan diameter. A good example with a belt reduction is the 3M Isoloop™ tape transport. At 15 in/s the capstan motor spins at 30 rev/s, but the large capstan turns only 2½ rev/s. The 12:1 speed reduction permits large diameters on all drive surfaces.

A flywheel in normally employed on the capstan’s shaft to smooth out any small speed variations. The effectiveness of the flywheel increases directly with increased flywheel moment of inertia, but inversely with the square of the diameter of the capstan. The large capstan diameter of the 3M transport required a flywheel weighing 6 pounds!

Any rotational speed disturbances in the capstan will show up as linear speed variation in the recording tape. This means that the capstan must spin at an absolutely constant speed. The simplest constant speed device is a hysteresis synchronous motor. Synchronous indicates that the motor runs at a speed that is locked to the frequency of the voltage driving the motor, similar to a clock motor (before battery operated clocks). The motor contains a pair of windings for each operating speed. The two windings are physically offset by ¼ of the distance the motor rotates during one cycle of the drive voltage. One of the windings in each pair is connected directly to the power source. The second winding is connected with a large capacitor in series with the winding to shift the phase of the current and the resulting magnetic field in the second winding approximately 90° with respect to the main winding. The physical and electrical shifts work together to create a rotating magnetic field.

Two-speed hysteresis synchronous motors are common in tape recorders, and a few three-speed motors are also used. The motor must be designed for the intended operating frequency of 50 Hz or 60 Hz and the phase-shifting capacitor chosen for the appropriate frequency.

Although the hysteresis synchronous motor is an economical solution, it has major shortcomings. First, the speed of the motor is only as good as the stability of the frequency driving the motor. We assume that ac source is stable. However the power companies only guarantee a certain number of cycles each day. At any given time the frequency of the grid at any location may be slightly high or low depending how much adjustment is needed to bring the daily total of cycles into compliance. Sometimes, however, it is desirable to run at other than nominal speed for special effects or pitch correction. This Variable Speed Oscillator (VSO) operation requires a versatile power source for the capstan motor that can be shifted in frequency. If the frequency is shifted very far from the nominal frequency, the phase-shift capacitor will no longer provide a true 90° of phase shift. The motor will begin to vibrate, the power of the motor will decline, and the motor’s temperature may rise. The maximum practical speed shift is then less than 15%.

A third problem is that the selection of speeds is quite limited. For 60 Hz operation, there can be motor speed pairs of 3600/1800, 1800/900, 1200/600, and 900/450 rpm. If the shaft of the capstan motor is used as the actual drive surface, the desired tape speeds will determine the diameter of the shaft. Slow tape speeds require very small capstan diameters. The resulting small contact area can create speed errors due to slippage.

All these problems can be avoided by substituting a servo-controlled motor for the hysteresis synchronous motor. A servo-controlled motor utilizes a speed-measuring device on the capstan in the form of a high-resolution optical or magnetic tachometer. This tachometer may provide as many as 1200 speed samples per revolution of the motor, a rate high enough to detect not only overall average speed, but even very small speed transients due to imperfections in other components in the tape path. By comparing the speed sensed by the tachometer to a high-accuracy reference derived
from a crystal oscillator, any variations or errors in speed are immediately detected. The control circuits use this error to generate corrections in the voltage driving the motor to cancel the speed error. The overall accuracy of this closed-loop system is primarily dependent on the accuracy of the tachometer and the reference clock.

The block diagram of a typical capstan speed control is shown in Fig. 28-4. Commonly referred to as a phase-lock servo, the system is, in essence, a clocked position detector. The servo automatically adjusts the motor voltage so that the tachometer will produce one pulse for each pulse of the reference clock.

The crystal oscillator/counter provides a highly accurate clock reference by dividing the frequency of the crystal oscillator down to a convenient lower frequency. The switching transition of the clock serves as a strobe to sample the position of the tachometer. If the motor is running exactly at the desired speed, each tachometer transition will coincide exactly with a clock transition. The phase comparator compares the tachometer and clock signals to determine which signal arrives first and the amount of timing error between the sources. The error signal generated by the phase comparator is amplified and passed through a low-pass filter that smooths the individual pulses into an average dc voltage that can drive a dc motor. This smoothed voltage is applied to a power amplifier, called a motor drive amplifier (MDA), that drives the motor.

The phase-lock servo permits convenient speed control at multiple tape speeds by selecting various points along the divider chain. The minimum speed is limited by the data rate from the tachometer and the smoothing provided by the low-pass filter. The maximum voltage and current available from the MDA typically sets the maximum speed. Speed ranges of 2:1, 4:1, and 8:1 are common in audio recorders with servo-controlled capstans.

Variable-speed operation for a servo system is much simpler than for the hysteresis synchronous motor. A simple variable-frequency oscillator can be substituted for the fixed reference to provide infinitely variable speeds!

The de facto standard for professional machines is that an external VSO frequency of 9600 Hz from accessories will drive a servo at nominal speed. This 9600 Hz signal can be substituted for the crystal’s countdown signal at an appropriate point in the countdown chain before the final speed-determining dividers. The VSO signal is thus able to control the machine at any of the machine’s running speeds.

If the tachometer is accurately mounted, if the tachometer samples occur frequently enough to provide precise sensing, if the control circuit sends the correction signal to the motor quickly so that errors are sensed as they start, and if the motor can respond swiftly to corrections in its control voltage, then the motor will turn at a constant speed. The string of “ifs” in the previous sentence is a clue to the complexity of this servo design. The results, however, of a good design are very impressive, with professional recorders being able to suppress mechanically induced speed variations to below 0.05% rms at 15 in/s (38 cm/s) on a routine basis.

The speed-sensing device need not be attached to the driving capstan for phase-lock operation. The tachometer can be mounted on a free-running idler that is driven by the tape, but the extra time delay introduced into the error signal renders the system more difficult to control. This delay usually requires a reduction in the

**Figure 28-4.** Capstan speed control block diagram.
stiffness and bandwidth of the servo loop, requiring either an improvement in the inherent errors that are to be corrected by the servo or a decrease in the expected level of performance.

A further extension of the free-running idler concept is to eliminate the drive capstan completely, as in machines manufactured by John Stephens. These machines relied on two high-performance spooling motors to perform all the speed control tasks. The Stephens recorders provided excellent speed control under normal conditions, but the large inertia of a 6 pound roll of 2 inch tape limited the responsiveness of such systems, rendering them vulnerable to abrupt disturbances such as tape splices or layer-to-layer adhesion of the tape.

### 28.2.1.1 Tape-to-Capstan Contact Enhancement

Constant tape speed requires that the capstan driving the tape must have enough traction on the tape due to friction to exert positive control of the tape. If we just wrap the tape around the capstan, the traction force due to friction will usually be too weak to exert full control of the tape. To maintain control, the capstan’s drive force must be at least equal to the difference in the tape tensions on the ingoing and outgoing side of the capstan, as shown in Fig. 28-5.

![Figure 28-5. Forces at the capstan.](image)

Active contact enhancement devices such as the rubber pinch roller push the tape against the capstan surface to maintain firm contact. Unfortunately, the pinch roller also produces numerous undesirable side effects, including:

1. Heavy side loads on the capstan that produce bearing wear and can even cause small diameter capstans to bend or tilt.
2. Speed errors due to the elastic deformation of the rubber roller at the point of contact.
3. Increased variations in speed created by imperfections of the rubber, eccentricities of the roller, and bearing rattle.

One way to avoid the problems of pinch rollers is to clamp the tape to the capstan using air pressure and a vacuum pump. Computer tape drives have frequently used hollow vacuum capstans to achieve rapid tape start/stop and shuttling. The capstan must be of porous material or have machined passageways so that air can be sucked from the surface of the capstan. The ambient air pressure will then push the tape firmly against the surface of the capstan. Since the air pressure differential will be somewhat lower than the maximum 14.7 pounds per square inch (psi) of nominal atmospheric pressure, there will need to be a substantial tape contact area to generate the required traction force.

Passive contact enhancement methods concentrate on maximizing the traction between the tape and capstan surface. Roughening of the capstan surface by sandblasting or coating the surface with urethane rubber or diamond-impregnated grit yields an improvement in the coefficient of friction. After heavy usage, however, the roughening will be polished away by the abrasive surface of the tape, or the urethane surface will glaze and harden, requiring reconditioning to avoid slippage.

Other passive techniques concentrate on eliminating any loss of contact due to air being trapped between the tape and capstan. This *air bearing effect*, which becomes evident at tape speeds as low as 30 in/s (78 cm/s), can be minimized by cutting bleed slots in the surface of the capstan. These slots are similar to the tread grooves on an automobile tire, providing escape paths for the trapped air.

### 28.2.1.2 A Word of Caution Regarding Urethanes

The standard roller rubber is neoprene, a fairly stable rubber compound that can resist ozone and smog. Many newer compounds, especially various urethanes, have also been tried with some success. Sometimes the new roller will give excellent results when new, but then it will glaze over and lose its adhesion to the tape. In other cases the roller’s elastomer will turn into a gummy ooze with the consistency of taffy.

The urethane is affected by temperature and humidity conditions, and by any solvents used to clean the tape path. Always check the cleaning pad after you clean the pinch roller. If the pad has just tape residue, you are providing proper cleaning. If, on the other hand, you see a residue that looks suspiciously like the surface of the roller, you may be dissolving your pinch roller!
28.2.2 Flutter

Regardless of the passive and/or active contact enhancements, servo design, and workmanship standards employed in a given transport, some residual amount of tape speed variation will still be present. The long-term or fixed component of this speed error is denoted as speed accuracy, timing accuracy, or drift. The small, rapid changes in instantaneous speed are referred to as **flutter**.

Flutter is further broken down into three frequency bands, based on perceptibility, Fig. 28-6.

- Speed variations at rates up to a few cycles per second are termed **wow**, with the listener perceiving a cyclic pitch variation in music. The most common source of wow is eccentric rotating parts.
- Faster flutter rates due to motor torque pulsations and rattling bearings add a fluttering sound to the music. As the flutter rate increases beyond a few hundred hertz, the listener no longer distinguishes the flutter components from the music. Instead, the listener notices a loss of crispness and clarity, with high frequencies created by percussion, strings, and brass sounding dull or mushy. These high-frequency scrape flutter components are generated as the surface of the tape scrapes over stationary elements such as fixed guides and heads, creating vibrations in the tape similar to the plucking of a stringed instrument.

Historically, wow and mechanical flutter have received much more attention than scrape flutter. In fact, tape recorders were used for music recording for nearly 20 years before the first transport with low scrape flutter was introduced. Even today designers of both transports and tapes treat scrape flutter more as an afterthought than as a primary problem, failing to quote any specifications for scrape flutter performance. Unfortunately for the user, the subjective evaluation of the clarity of a recording is very dependent on the amount of flutter in all three flutter bands.

**Weighted peak flutter** is an attempt to characterize a human listener’s perception of flutter. Many years ago, numerous tests showed that the test subjects most readily identified flutter disturbances that occur at a rate of approximately 4 Hz. Furthermore, the tests indicated that the listener responded to the peak levels of flutter, even though the peaks may have been infrequent. Based on these test results, flutter meters now include band-pass filters peaked at 4 Hz and quasi-peak metering.

Today, every professional tape recorder produced in the past 35 years includes components to reduce scrape flutter, but the typical weighted peak flutter meter is totally incapable of measuring these components to verify proper performance!

In addition, misbehaving servo-controlled transports can generate flutter frequencies at virtually any frequency. Unlike the older machines with all their mechanical resonances below 100 Hz, newer machines can have servo oscillations well beyond 1 kHz.

The entire flutter spectrum should be measured, especially when performing maintenance testing of professional audio recorders.

28.2.3 Tape Tensioning

Magnetic recording tape, like all elastic media, must be stretched slightly to produce tension within the tape. For normal recording applications, the tape is stretched approximately 0.1% to achieve a typical tension of 4 oz per ¼ inch of tape width. Since this small amount of stretch is less than one tenth the level of stress required to permanently deform the tape, no permanent deformation results.

Four separate and often conflicting functions are performed by tape tension on a tape recorder:

1. **Tape tension holds the moving tape firmly against the record and playback heads to achieve good high-frequency performance.**
2. **Tension stiffens the tape on the tape guides so that the tape position will remain constant.**
3. **Tension controls the stacking of the layers of tape on the takeup reel.**
4. **On machines without pinch rollers, the tension holds the tape against the capstan to create enough drive traction for proper tape speed control.**

The classic tape transport of Fig. 28-3 utilizes the supply reel spooling motor to generate tape tension over the heads in the Play mode. The supply motor is energized in the clockwise (rewind) direction with a reduced
voltage, generating a constant torque from the motor. To convert motor torque to tape tension, divide the torque by the radius of the tape pack (the lever arm).

However, the radius of the pack on the supply reel decreases as the tape plays off. By the end of a 10½ inch NAB reel, the radius has dropped to half the starting value, causing the tape tension to double. (Some plastic 7 inch reels have outside to inside diameter ratios of more than 3:1.)

The tape tension is further altered to some degree by every component that comes into contact with the tape. When tape slides over any stationary guide or head surface, the tape tension changes slightly due to the friction between the tape and the stationary surface. (The bearing friction and viscous drag of rotating guides is usually negligible.) The relative contribution of friction tension to the total tape tension ranges from a low of 5% for transports with only rotating guides to over 50% for transports with numerous fixed guides and/or large tape deflection angles around fixed guides.

The amount of drag tension generated by a cylindrical post is shown in Fig. 28-7. The tension and friction build up as the tape moves around the guide. The true expression for the total drag is an exponential function, but for tape paths with only small amounts of wrap, we can approximate the tension change with the expression:

\[
\text{Tension change} = K \times \text{tape tension} \times \text{angle of wrap} \times \text{coefficient of friction}
\]  

(28-2)

Note that although the diameter of the guide does not appear in the tension expression, the pressure exerted by the guide against the tape surface increases as the diameter decreases. This increased pressure makes small guides wear faster and accumulate dirt more quickly. Since a speck of dirt trapped on the surface of a small guide would also be more prone to scratch the tape surface, small-radius fixed guides must be kept very clean.

Older tapes may lose the surface lubricants that allow the tape to slide freely across the stationary surfaces. This may result in a squealing sound as the tape runs through the recorder. Even worse, when sticky shed debris from breakdown of the urethane binders in the tape collects on the tape guides, the tape may be dragged to a dead stop. These problems occur commonly when dealing with older archived tapes.

Some transport designs are more sensitive than others to changes in tape tension resulting from tape problems. Tape paths with either high amounts of drag tension or no pinch rollers may require a readjustment of the tape tension to maintain acceptable performance and avoid tape slippage.

28.2.3.1 Capstan-Derived Tensioning

Because of conflicting tension requirements at various point along the tape path, it is useful to break the total path into segments with different tape tensions. The classic tape transport, for example, has two distinct tension zones, one to the left of the capstan and another to the right of the capstan. One common approach is to use a driven capstan and pinch roller as an isolation device, with the capstan motor supplying the power needed to overcome the tension differential across the capstan, see Fig. 28-5. This isolation can then be used, for example, to achieve low head tension and high takeup spooling tension.

Carrying this strategy one step further, if one capstan can be used to isolate the head from the takeup system, then it should be possible to use a second capstan to isolate the heads from supply reel disturbances. This would provide the desired isolation on both sides as shown in Fig. 28-8. The difficulty is in generating a controlled tension between the capstans where the tape passes over the heads.

![Figure 28-7. Tension increase due to guide friction.](image1)

![Figure 28-8. Dual capstan transport showing multiple discrete tension zones.](image2)

The solution is to have slightly different surface velocities on the two capstans. If we need a 0.1% stretch...
of the tape to give us the desired 4 ounces of tape tension, then the outgoing capstan must have a surface velocity 0.1% higher than the incoming capstan. This can be achieved by using two hysteresis synchronous motors with slightly different capstan diameters. The Gauss high-speed tape duplicators used this technique with great success. A very similar technique is to use a nonstretching plastic belt to couple the drive motor to both capstans. If both capstan shafts are identical, but the pulley on the outgoing capstan is 0.1% smaller than the other pulley, the desired speed differential will be realized.

Many dual capstan cassette decks provide bidirectional operation. A simple trick is to use an elastic rubber belt to drive both capstans, Fig. 28-9. Since the belt is elastic, it will stretch slightly whenever it delivers a pulling force to a load. It must pull on the incoming capstan’s pulley with sufficient force to overcome the holdback tension, the friction due to the incoming pinch roller and capstan’s bearings, and the load caused by the elastic deformation of the pinch roller at the point of contact with the tape and capstan. As a result, the stretched belt leaving the incoming pulley will have a slightly higher linear velocity due to the stretching. As this stretched belt passes around the outgoing pulley, the higher linear velocity will turn the outgoing pulley slightly faster than the incoming pulley. The difference in speed generates the desired tape tension. Everything is symmetric, so if the motor is reversed, both the tape and the tape tensioning will reverse.

Yet another closed loop design, the 3M Isoloop™, achieves the effect of two capstan diameters by using a single capstan with multiple alternating rings of large and small diameters. The step between rings is so small, on the order of 0.1%, that specially contoured pinch rollers can press the tape against the smaller-diameter rings on the incoming side and against the larger-diameter rings on the outgoing side of the capstan, Fig. 28-10.

Unlike recorders that derive tape tension by controlling torque on the spooling motors, the tension of the closed loop drives varies slightly with tape thickness. Since the change in tape length is always constant, lower tensions are generated in thin tapes that stretch more easily. This decrease in tension is generally unnoticed since the thinner tape conforms more readily to the face of the heads, offsetting any pressure reduction.

28.2.3.2 Spooling-Motor-Derived Tensioning

The classic tape transport of Fig. 28-3 experiences a 2:1 tension change from beginning to end of reel. For nearly 25 years the recording industry was forced to struggle with recorders that had this doubling of tape tension, with attendant speed variations, splicing problems, and tape guiding variations. The advent of economical integrated circuits has led to more sophisticated designs that replace the constant holdback torque with an active tension servo control.

Tension servos fall into two categories—closed loop and open loop, Fig. 28-11. The closed loop servos directly sense the tape tension with a spring-loaded surface in contact with the tape. The tape pushes against the spring, causing a displacement of the sensing
device. The resulting output voltage or current provides an electrical signal proportional to tension that can be used to control the spooling motor drive voltage.

Numerous types of sensing devices have been employed by various manufacturers; including photo-cells, photo-potentiometers, rotary potentiometers, and Hall effect devices. Noncontacting photosensors and Hall devices have demonstrated longer lives than rotary potentiometers with sliding mechanical contacts.

Rather than directly measuring the tape tension, the open loop tension servos sense other parameters such as the rotation rate of the spooling motors and infer or calculate the amount of drive to the spooling motor necessary to achieve the desired tape tension. For example, the rotational velocities of the spooling motors can be measured with dc tachometers attached to the spooling motor shafts. The tape speed can be derived from the frequency of the tachometer pulses coming from the capstan servo motor. Dividing the tape speed by the reel rotation rate yields a value proportional to the tape pack radius. Tape tension times tape pack radius is equal to the required motor torque. Therefore,

\[ V_{motor} = \text{tension adjustment factor} \times \frac{\text{speed}_{tape}}{\text{speed}_{rotational}} \]  \hspace{1cm} (28-3)

If the calculation is executed with analog circuits, the multiplication is easily implemented by a potentiometer, but the division requires an analog multiplier/divider integrated circuit.

The same results can be achieved with a read-only memory lookup table that is programmed with the correct motor voltages for various combinations of speed and pack diameter.

MCI tape transports using the open loop tension control method described above provided very accurate tension control over a wide range of speeds and reel diameters. The major shortcoming is that the calculated method cannot detect tension abnormalities due to bent reels, motor problems, or changes in friction.

A further benefit of the diameter calculations is the ability to anticipate the end of a reel of tape. Both unintentional unthreading of the machine and abusive high-speed unthreading can thus be avoided.

The MCI tension control worked very well because an integrated circuit performed the analog division with high precision. Other tension controls, such as the Tentrol for Ampex transports, substituted a pair of adjustment potentiometers for the analog divider. The resulting straight-line approximation of the division process was not as accurate as the MCI method, but it was much better than the 2:1 tension change without any sensing and control.

### 28.2.4 Tape Guiding

For proper recording and playback of a magnetic recording to occur, the tape must move over the heads in a very precise path. This tape path should be the natural path that the tape would follow without any external vertical constraints. The purpose of the guiding system is not only to protect the tape and to overcome the slight reel-to-reel variations in tape such as twists and bends due to tape-manufacturing tolerances but not to force the tape to perform any unnatural acts. Any such use of brute force will lead to tape damage, excessive guide wear, and/or instabilities and jumping of the tape.

The tape guiding system deals with five aspects of the tape motion—height, azimuth, zenith, wrap, and rack—with primary concern for the motion of the tape at the heads. Each aspect is in turn composed of two
components: fixed errors due to misadjustment and dynamic errors due to tolerances and tape variations.

28.2.4.1 Tape Height

Height must be controlled so that the recorded tracks on the tape will pass directly over the pickup areas of the head. The required degree of height accuracy increases as the tracks become narrower. Table 28-1 shows signal loss due to height errors for several popular tape formats.

70 mil—4 track ½ inch, 8 track 1 inch, 16 track 2 inch
37 mil—4 track ¼ inch, 24 track 2 inch
43 mil—24 track 2 inch (on some systems)
21 mil—stereo compact cassette, 8 track ¼ inch

Sources of height error also include fixed errors in head and guide height and core placement tolerances within the head. A good alignment should contain no more than 1 mil (25 μm) combined error for the head and guides, but this degree of accuracy requires the use of optical measurement devices that are not commonly available in a recording studio. Typical maintenance shop practices will yield errors in the range of 2–3 mils (25–75 μm) on tape guide width result in a loose fit for many rolls of tape.

For a tape guide to position the tape accurately, the tape must fit snugly into the guide, but the guide must not squeeze the tape edges. The typical manufacturing tolerances of 2 mils to 4 mils (50 μm to 100 μm) on tape width and 1–3 mils (25–75 μm) on tape guide width result in a loose fit for many rolls of tape.

28.2.4.2 Head Azimuth

Not only must the tape passing across the head be at the correct height, but also the recorded signal on the tape must be parallel to the pickup gap in the reproduce head. Any angular error is referred to as azimuth error. Table 28-2 gives the amount of signal loss due to azimuth error for a 15 kHz signal at 15 in/s (38 cm/s), a 1 mil (25 μm) wavelength λ.

For a typical professional recorder with guides spaced 6 inches (15.2 cm) apart, the worst case combination of guide and tape sizes could produce a maximum dynamic guiding error of ±5 mils (125 μm) at each guide, yielding an azimuth error of ±0.1 or ±6 min. This error would generate a signal fluctuation of 3 dB for a 250 mil (6.35 mm) track width as indicated in Table 28-3. Overlapping heads or tracks offer no azimuth loss improvement.

\[ loss = 20 \log \frac{\sin(\pi W \times \tan \alpha)}{\pi W \times \tan \alpha} \]

where,

\[ W \] is the track width,
\[ \alpha \] is the azimuth error,
\[ \lambda \] is the wavelength.

After many years of decreasing track widths to fit more tracks on a tape, there is a resurgence of wider track formats such as 2 tracks on ½ inch or 1 inch tape and 8 tracks on 2 inch tape. Although these formats...
yield superior SNR and reductions in amplitude modulation noise, the wide tracks can create level stability problems. These wider tracks will have large signal variations at high frequencies if the tape guides permit even small dynamic guiding errors. As a result, when a transport is fitted with wide-track heads, the guiding is also usually modified to hold the tape more accurately.

For multitrack recorders, the time and phase relationship between audio channels that are recorded on separate tracks may be more critical than the level of short-wavelength signals. Azimuth errors contribute to differential timing errors between tracks, since the azimuth tilting causes one track to be reproduced slightly later than the other. As the distance between tracks becomes large, such as for 1 inch and 2 inch (2.5 cm and 5 cm) formats, the timing error becomes critical. A typical method to measure this timing error is to record the same high-frequency signal on two tracks, and then measure the phase difference between tracks. Table 28-4 shows the amount of worst-case phase difference and timing difference at a 1 mil (25 μm) wavelength introduced by a 0.5 dB head azimuth error for the outer pair of tracks.

The magnitude of both the height loss and the azimuth loss could be greatly reduced if the widths of the tape guides and tape matched perfectly. One method to achieve this objective is to use adapting guides with spring-loaded movable flanges so that the guide adjusts itself to the tape width. Some digital audio recorders with numerous very narrow tracks utilize spring-loaded guides to maintain close repeatability of the tape path.

A similar effect can be achieved with fixed-flange guides if a curvature is deliberately introduced into the tape path. Fig. 28-12 illustrates two possible methods to achieve this curvature. Typically, an offset of less than 5 mils (125 μm) is adequate to overcome the worst-case combination of clearance between the tape and guides and the maximum amount of natural bowing in the tape due to slitting and subsequent handling distortions.

Although the dynamic guiding variations are greatly reduced by forcing the tape to maintain a distorted tape path, the increased force applied to the edges of the tape produces new problems. Not only do both the guides and the edges of the tape experience higher wear rates, but scrape flutter is also increased dramatically. The edges of a tape are very rough due to the shearing action used in the tape-slitting process. When these rough edges slide firmly against the distorting guide flange, tape vibrations are excited, producing scrape flutter.

28.2.4.3 Tape Guides

Tape guides come in many shapes, sizes, and basic types, as shown in Fig. 28-13. Each guide contains flanges that press against the edges of the tape to steer it. In all cases except the edge-only guide, the tape wraps around the guide to generate stiffness so that the steering force exerted by the flange can move the entire width of the tape and not just buckle the edge. Typically, at least 10° of wrap is required for adequate stiffness.
required to slide the tape up or down is determined by the tape tension and the coefficient of static friction. The tension component is identical for the stationary guide, but in this case the coefficient of sliding friction, which is typically half the static value, is used.

Although both stationary and rotating guides are commonly used in tape transports, rotating guides are slightly more prone to damage the edge of the tape. Guides with large rotating flanges can produce ruffles on the edge of the tape if the tape edge contacts the outer radius of the moving flange. Most guide designs taper the flange to minimize this hazard, but a small flat area at the bottom of the taper is still required if the guide is used for precise tape positioning.

The edge-only guide is very limited in effectiveness since any appreciable force on the edge of the tape may cause the tape to twist rather than move up or down.

### 28.3 Magnetic Heads

Although magnetic tape is covered in a later section, the following discussion of magnetic heads requires a few very simple assumptions regarding the composition and dimensions of the magnetic tape. First, assume that the magnetic coating consists of microscopic particles of magnetic materials that have been bonded to one surface of a thin plastic backing or substrate. Second, each magnetic particle is assumed to function as a small independent magnet, allowing patterns of varying magnetic polarity and intensity to be stored along the tape. Last, the thickness of the magnetic coating for the audio tape example will be assumed to be 0.6 mil (15 μm).

#### 28.3.1 Geometric Characteristics

Most of the characteristics of magnetic heads are controlled by the geometry of the head and the magnetic tape. Since wavelength on tape is determined by the recorded frequency in hertz and the relative tape-to-head speed, there can be many combinations of frequency and speed that will result in the same effects in a head. For example, the wavelength of a 15 kHz tone on a mastering recorder at 15 in/s will have the same wavelength as a 240 kHz signal on a high-speed tape duplicator running at 240 in/s. The geometric considerations for both applications are identical, despite the 16:1 difference in tape speed.

Not all of the characteristics are geometric, however. Eddy current losses, for example, depend on the frequency in Hz rather than the wavelength.

#### 28.3.1.1 Gap Length Loss

Each of the tiny magnetic particles on the surface of the tape produces a magnetic force or flux in the space surrounding the particle. This invisible magnetic effect, called a magnetic field, will interact with other nearby magnetic particles. To measure the strength of this field, a flux concentrator in the form of a reproduce head is scanned along the tape. The resulting electrical output from the head is dependent on the flux pattern recorded on the tape.

The reproduce head must be able to collect flux selectively from a very small span of tape. For example, flux patterns on a compact cassette may be as small as 100 millionths of an inch (100 × 10⁻⁶ in or 2.5 μm) in wavelength. To achieve this fine resolution, a small gap must be created in a ring of magnetic material, as shown in Fig. 28-14A.

The length of the gap ranges from two ten-thousandths of an inch (2 × 10⁻⁴ inch or 5 μm) for studio mastering recorders down to less than 30 millionths of an inch (30 × 10⁻⁶ inch or 0.75 μm)—the wavelength of red light for cassette and high-density digital recorders. Since no slicing technique is available to cut accurate gaps that short, the core is usually fabricated as two pole pieces that are fastened together with a shim spacer of the desired dimension inserted in the gap. Fig. 28-14B shows a typical studio head core drawn full size, with the critical gap area at the pole tips and adjacent tape magnified in Fig. 28-14C.

The operation of the gap, which serves as a sensing aperture, can be analyzed in terms of a flux pickup focused at the surface of the tape. The amount of flux picked up by the core, and thus made available to generate an output voltage in the winding, is determined by the net magnetic flux from pole tip to pole tip across the gap area. If the tape segment at the gap consists of a strong magnetization of only one polarity, the flux in the core will be maximized. If, on the other hand, the segment contains two strong portions of opposite polarity that cancel each other, the net flux in the core will be zero.

The efficiency of the gap due to this averaging effect is illustrated in Fig. 28-15. The output of the head declines, slowly at first, and then quite rapidly to zero as the wavelength decreases to the length of the gap. As the gap length becomes longer than the wavelength, an output of opposite polarity appears. When the wavelength drops to half the gap length, another null will occur. This pattern of diminishing peaks of alternating polarity is repeated over and over, with nulls occurring
at each wavelength that produces an odd or even number of complete cycles in the gap.

The example recorder at 15 in/s has only 1 dB of gap length loss at 40 kHz and 3 dB at 67 kHz, certainly not a dominating loss. At 30 in/s these losses become even more insignificant, with the −1 dB and −3 dB frequencies doubling to 80 kHz and 134 kHz.

Audio recorders are seldom designed to operate beyond the dashed lines shown in Fig. 28-15. With this constraint, gap length loss for professional machines can be held below 1 dB or 2 dB by choosing an appropriate gap length for a given application and minimum wavelength. Mastering recorders operating at 15 in/s and broadcast machines operating at 7.5 in/s have playback gaps ranging from 100–200 μinch, compact cassette machines operating at 1 7/8 in/s have gaps of 30–60 μinch.

Mastering recorders may also use the record head for playback in the sync mode. Since the record heads may have gaps ranging from 250 μinch to 1000 μinch, the sync response may suffer significant high-end loss. For example, a 1950s vintage recorder with a 1000 μinch record gap will reach its first null at 15 kHz for a tape speed of 15 in/s. As sync response became more important in the mid 1960s the recorder manufacturers tightened up the record gaps to 350 μinch or less to improve sync response.

If the gap length is inferred from the first measured null, this effective gap length may be 10% to 15% longer than the mechanical gap determined by the shim. Various proposed explanations include magnetic degradation of the inner surfaces of the pole tips due to manufacturing stresses and pole tip saturation. When in doubt, add 10% to the optically measured length or shift the response points down to 91% (1/1.1) of the theoretical values. For the ATR100 example, the −1 dB and −3 dB points would shift to 36 kHz and 61 kHz.
Use of an excessively short gap will cause an additional loss in overall head sensitivity due to shunted flux that jumps the gap rather than traveling through the core, as shown in Fig. 28-16. For this reason, the reproduce head gap length is usually chosen to give the largest acceptable loss at the shortest expected wavelength.

28.3.2 Spacing Losses and Thickness

The recording process magnetically aligns groups of the tiny randomly oriented magnetic particles so that they act as if they were a single larger particle. We could visualize these groups as little bar magnets that have dimensions determined by the tape and signal. The track width defines the vertical direction and the tape coating thickness sets the depth. The length is determined by the wavelength of the recorded signal. To simplify the example, assume that a 1.5 kHz square wave is recorded at a tape speed of 15 in/s (38 cm/s), yielding a wavelength of 10 mils or 0.010 in. The recorded image is similar to a series of bar magnets each 5 mils long with alternating polarity.

Actually, gap length loss and shunting loss are only a part of what determines the performance of an audio recorder. The most critical parameter is the relative thickness of the magnetic coating on the tape. The ratio of tape thickness to the shortest wavelength to be recorded has a profound effect on the frequency response, maximum output, noise, and signal-level fluctuations.

The magnetic particles at the surface of the tape are very tightly coupled to the core of the head, producing a maximum amount of playback flux in the core. Particles that are buried below the surface of the tape, however, produce a weaker flux in the core. The amount of flux that is lost depends on the spacing distance and the wavelength—just as a small font size is more difficult to read at a distance than a larger font. An approximate expression for this spacing loss is

\[
Spacing loss_{db} = 55 \times \frac{\text{distance}}{\text{wavelength}}.
\]  

(28-4)

One example of the use of this spacing loss formula is to determine the playback signal loss due to a piece of dirt on the surface of a reproduce head. Assuming a typical recording studio tape speed of 15 in/s (38 cm/s), a dirt speck only 0.0001 in (2.5 \( \mu \)m) high will produce losses at the following frequencies of

\[
\begin{align*}
150 \text{ Hz spacing loss} &= 55 \times \frac{0.0001}{15} = 0.055 \text{ dB} \\
1500 \text{ Hz spacing loss} &= 0.55 \text{ dB} \\
15 \text{ kHz spacing loss} &= 5.5 \text{ dB}
\end{align*}
\]

Note that this seemingly insignificant dirt particle has produced a serious loss in high frequencies.

Spacing loss due to dirt is not the major problem created by the “nearsightedness” of the gap since proper head cleaning will keep spacing distances to less than \( 10^{-5} \) inch, which is (0.25 \( \mu \)m), producing virtually no error at studio tape speeds. The problem is eight times more severe for cassette speeds of \( 1/4 \) in/s (4.8 mm/s).

The major spacing problem arises within the tape itself since the magnetic coating thickness spaces most of the particles away from the head with other particles. Consider the tape to be composed of several independent layers of oxide, as shown in Fig. 28-17. The average spacing loss for each layer, calculated using the midpoint of each layer to determine the spacing distance, is tabulated for the example with a typical 0.6 mil (15 \( \mu \)m) coating thickness.

\[
\begin{array}{c|c|c}
\text{Layer} & \text{Spacing} & \text{15 kHz loss} \\
\hline
1 & 0.05 & -2.75 \text{ dB} \\
2 & 0.15 & -8.25 \text{ dB} \\
3 & 0.25 & -13.75 \text{ dB} \\
4 & 0.35 & -19.25 \text{ dB} \\
5 & 0.45 & -24.75 \text{ dB} \\
6 & 0.55 & -30.25 \text{ dB} \\
\hline
\text{Total output} & +3.63 \text{ dB}
\end{array}
\]

(28-4)

The contributions of layers 2 through 6 fall off so rapidly due to spacing loss that their combined contribution is only equal to layer 1 by itself at this wavelength. Indeed, shaving off layer 6, which constitutes 17% of the coating thickness, would produce a loss of only 2% or 0.18 dB in output at this wavelength.

This coating thickness loss can be expressed as
where,

\[ x = 2 \pi \times \text{thickness/wavelength}. \]

Although this expression yields a drop of 6 dB per octave, as shown in Fig. 28-18, this curve is not the same shape as the response of a low-pass filter made from a resistor and capacitor. The response in Fig. 28-18 is down 4 dB at the intersection of the asymptotes rather than the typical 3 dB for a single pole RC filter. This difference in shapes means that a simple RC boost circuit will not properly correct for the thickness loss. Depending on the choice of RC boost frequencies, the difference in shape will produce an error of 0.5–1.0 dB in the midband response.

**28.3.2.1 Equalization Boosts**

This thickness loss of Fig. 28-22, must be corrected by applying compensating boosts in either the record or reproduce circuitry. Although this loss is a playback deficiency, the choice of whether to correct the loss during record or playback is somewhat arbitrary. The amount of record boost is limited by the magnetic saturation characteristics of the tape; playback boost is limited by the high-frequency noise characteristics of the tape and the reproduce head and associated circuitry.

The minimum amount of boosting required to achieve flat response can be considered to be a necessary equalization. The industry has developed a set of internationally recognized standards to promote compatibility of tapes. Each standard deals with the necessary and discretionary equalizations to define the exact characteristics of the recorded tape. Using the tape flux characteristics as a standard implicitly specifies the partitioning of equalizations between the recording and reproducing functions. Table 28-4 lists the commonly encountered standards.

Unlike the absolute nature of the reproduce characteristics, the record characteristics of the recorder must have enough flexibility to accommodate a number of different tape sensitivities and frequency characteristics. Once the reproduce section has been calibrated to the standard with a standard alignment tape, all further adjustments are to produce a recorded tape on the machine that accurately matches the standard tape.

The amount of thickness loss can always be reduced by utilizing thinner coatings, but any decrease in thickness also causes an equal drop in low- and midfrequency output and SNR. To preserve the existing standards, the tendency has been to adjust the coating thickness of new tapes to emulate the high-frequency losses of the older tape types while trying to achieve maximum low-frequency output. This somewhat self-defeating strategy has been overcome in recent thin-coat high-energy tapes.
that retain the low-frequency output capability of older tapes, but utilize new equalization curves optimized for the new tape thickness.

28.3.2.2 Fringing

Spacing loss is evident not only at high frequencies, but it also shows up at very long wavelengths. Magnetic information that is recorded off to the sides or fringes of the area normally scanned by the reproduce head core will begin to be sensed if the wavelength becomes longer than the separation distance. At studio operating speeds of 15 in/s and 30 in/s (38 cm/s and 76 cm/s), for which low-frequency wavelengths reach ½ inch and 1 inch (12.7 mm and 25 mm), this fringing leakage becomes very evident. For example, for the case of an oversized record track mentioned in Section 28.2.4.1, the signal level may rise by the ratio of the track width to the core width. A typical 24 track format on 2 inch (51 mm) tape would encounter a 1.3 dB rise at frequencies below 500 Hz for record and reproduce cores of 43 mils and 37 mils (1.1 mm and 0.9 mm).

A similar case arises when alignment tapes made with a single full-width record head are utilized for level and response checks. The sideways fringing will produce significant level and response errors. The actual amounts of error depend on both the track format and the playback head design. Some alignment tape manufacturers roll off the low frequencies in an attempt to offset the rise in a nominal head, but the amount of this fringing compensation is not absolutely correct for all head designs.

One additional pitfall to be avoided is the fringing differences between center tracks and edge tracks. Since the edge cores run very near the physical edge of the tape, these cores sense only one-half the amount of fringing flux sensed by the inner cores. During a frequency check from a full-width alignment tape, the two edge tracks should therefore be slightly lower in output at the low frequencies than the remainder of the tracks.

28.3.2.3 Contour Effect

At very low frequencies, the wavelength of the recorded signal may become as long as the magnetic core of the playback head. These long wavelengths enter the core at the gap and at the sides and rear of the core. The resulting flux in the core will consist of the desired flux from the gap plus additions and/or subtractions of the fringing flux leaking into the core at the sides and back. The voltage output of the head, which is dependent on the net flux coupled into the windings, will undulate at low frequencies as the wavelengths create varying levels of constructive and destructive interference due to the fringing flux.

The response curve in Fig. 28-19 illustrates the nature of the undulations or head bumps for a typical mastering recorder at 15 in/s (38 cm/s) and 30 in/s (76 cm/s) using a reproduce head that has a 0.5 inch (12 mm) core face. Two well-defined head bumps are usually evident for such mastering heads. The bumps shift up an octave in frequency for each doubling of tape speed, creating an even more severe problem at 30 in/s (76 cm/s).

Figure 28-19. Contour effect. Courtesy Sony Corporation of America.

Heads with either very small cores or only a small window in the head shielding at the gap area can produce numerous ripples in the low-frequency response. Such heads should be avoided unless the tape speed is slow enough to avoid serious problems within the normal band of audio frequencies.

The exact shape of the head bumps is determined by the size and shape of the reproduce core, surrounding shielding material, and angle of wrap of the tape. Since the user cannot adjust these parameters during the normal alignment procedure, the bumps can only be modified by adding an outboard equalizer, which cancels the bumps with an inverse response curve.

Recent improvements in the control of head bumps has reduced the magnitude of the bumps in present-day mastering recorders to less than 1 dB peak-to-peak at 15 in/s (38 cm/s) and 1.5 dB peak-to-peak at 30 in/s.
Chapter 28

(76 cm/s). Beware that this level of error will be introduced each time the tape is rerecorded during mixdown and subsequent protection copying. The total error can easily reach 5 dB or more for a typical sequence of operations.

28.3.2.4 Crosstalk

Fringing also produces playback signal leakage or crosstalk between adjacent tracks at long wavelengths. The unused area or guard bands between the cores of the head, which are nearly equal in width to the recorded track, usually provide enough of a physical gap to prevent flux from spilling from one track to the next. At long wavelengths, however, the fringing flux will jump the guard band, producing low-frequency crosstalk.

The crosstalk component due to fringing will initially decrease as the frequency is increased, but at midband the decrease will eventually bottom out. The remaining residual level of crosstalk is not due to fringing, but it is a direct transformer-like coupling of leakage flux between the adjacent cores in either the record or reproduce head. A layer of magnetic shielding material is typically placed between the cores of the head as a crosstalk shield to reduce this flux leakage.

28.3.3 Frequency Characteristics

28.3.3.1 Inductive Rise

Up to this point, most of the losses and response anomalies have been governed by the wavelength performance of the interface between the tape and the head. An additional set of characteristics due to the internal frequency-dependent operation of the head must also be considered.

The most striking characteristic in the frequency response of a conventional coil-and-core playback head is a continuous 6 dB/octave rise in output voltage with rising frequency. The core and winding of the head form an inductor in which the output voltage is proportional to the rate of change of the flux in the core as seen in the equation

\[
\text{head } V_{out} = N \frac{\Delta \phi}{\Delta t}
\]  

(28-6)

where,

- \(N\) is the number of turns in the winding,
- \(\Delta \phi\) is the change in flux,
- \(\Delta t\) is the time interval.

Any ratio of the form \(\Delta x/\Delta t\) is called a differential with respect to time, and the device creating this rate of change is called a differentiator.

If a sine-wave signal of frequency \(f\) is used for testing the output voltage of a head, the voltage expression can be further simplified to

\[
\text{head } V_{out} = 2\pi N f \times \text{flux}_{\text{max}}
\]  

(28-7)

28.3.3.2 Hysteresis Loss

The constantly changing magnetic flux in the core of the reproduce head gives rise to losses within the core of the head. One source of these losses is the amount of energy that is required to change the magnetization state of the core material. Every time the flux in the core reverses polarity, a small amount of energy is lost in overcoming the magnetic memory or hysteresis of the core material. The hysteresis power loss increases with both increasing flux magnitude and frequency.

28.3.3.3 Eddy Current Loss

The changing core flux generates a voltage not only in the winding of the head, but also within the core itself. If the core is metallic, this voltage will cause a current to flow within the core, as shown in Fig. 28-20. The core currents, referred to as eddy currents because of their similarity to swirling eddies in a stream of water, dissipate energy that should be going to the reproduce signal.

The amount of power \((P)\) dissipated in the eddy currents is given by the general power equation:

\[
P = \frac{1}{2} \rho \frac{d^2}{dl^2} \phi
\]
The previous discussion on the inductive rise of voltage with increasing frequency in the reproduce head also applies to these eddy components, producing a rapid rise in eddy current power loss.

The eddy currents of the solid core of Fig. 28-20A rise to an unacceptable level even before the upper limits of the audio band are reached. Fortunately, this drastic loss can be decreased by dividing the core into many thin insulated layers or laminations, as shown in Fig. 28-20B. For \( M \) laminations, each lamination would generate only \( 1/M \) of the core voltage and \( 1/M^2 \) of the loss power produced by a solid core. The core resistance for each lamination drops only slightly since the width of the lamination remains unchanged. The net improvement for \( M \) laminations is a \( 1/M \) reduction in the eddy current power loss. (Professional audio heads, which are typically constructed with laminations 2 mils (50 \( \mu \)m) thick, will contain 20 to 120 laminations per track, depending on the track width.) Reducing the core size and using high-resistivity core materials such as ferrites can achieve even further improvements.

### 28.3.4 Combined Characteristics

Fig. 28-21 illustrates some of the individual and composite effects of the foregoing reproduce head characteristics. The constant 6 dB/octave inductive rise of the head has been omitted in the illustration to accentuate the undesired departures from flat response.

Curves A, B, and C illustrate the gap length, tape thickness, and spacing losses, respectively.

Curve D represents a typical resonant rise due to head inductance and the capacitance of the head cable and head winding. The playback amplifier high-frequency response boost dictated by the National Association of Broadcasters (NAB) equalization standard for 15 in/s (38 cm/s) is represented by curve E. The combination of all of these effects in curve F yields a response that is flat within \( \pm 1 \) dB. This simplified model does not include relatively minor contributions at mastering speeds due to eddy currents and hysteresis, self-demagnetization effects, recording equalization, and the effects of nonuniform distribution of recorded flux due to coating thickness. In spite of these omissions, the dominant nature of the coating thickness loss is readily apparent. The equalization standards have been chosen primarily to offset this thickness loss.

The composite curve F represents the overall playback performance from an ideal tape of finite thickness. All the indicated response anomalies within the audio band must be either corrected or tolerated. In some cases, one effect can be used to offset others, such as shaping the resonance curve to compensate for the gap length loss. (Unlike the resonance, the gap length loss increases with decreasing tape speed, upsetting the compensation at lower tape speeds.)

### 28.3.5 Noise

The useful range of signal levels that pass through the tape recorder is limited by the maximum signal at which all the magnetic tape particles become completely magnetized or saturated and also by the amount of noise that remains when the input signal is removed. Noise in tape recorders has many sources; the electronics, the tape, and the heads themselves all contribute to the residual noise.

The distortion content of the signal from a tape recorder rises so dramatically near tape saturation that the normal operating range must be limited to less-than-maximum levels. For the purpose of specifying and comparing tape recorders, the distortion-free maximum operating level is typically considered to be the output signal level at which the THD, which is dominated by third harmonic and other odd components, reaches 3%. The ratio of the level for 3% THD at medium wavelength to the residual noise is defined as the SNR of the recorder.
28.3.5.1 Track Width

The second factor is the loss in SNR in narrow-track consumer tape formats due to the dissimilar ways that random noise sources and coherent signals increase. The noise due to the tape, heads, and electronics is a random combination of many small independent noise bursts. If two equal and independent random noise sources of this type are added together, the noise power is doubled, producing an increase of 3 dB on a voltmeter.

Coherent sources, on the other hand, are merely duplicates of the same waveform. If two identical sources are added together, the value at each point on the output waveform is exactly twice the value of either of the input waveforms. In this case the output voltage is doubled, or a 6 dB increase.

Consider the case of two tracks of a tape recorder that have recorded the same signal. If the output signals of the two tracks are added, the noise will add randomly and the signals will add coherently. The combined tracks have 6 dB more signal and 3 dB more noise, yielding a net SNR improvement of 3 dB. Using a single track of double the original track width would produce the same result if the noise sources were statistically independent in nature.

The tape noise will follow the 3 dB per doubling rate if the reproduce amplifier noise is less than the tape noise. The reproduce amplifier noise typically remains nearly constant regardless of track width of the head. The apparent noise will vary, however, as the gain of the amplifier is adjusted to compensate for changes in the head output due to increased or decreased track width. When tracks are made narrower, the amplifier noise that functions as a coherent source will eventually dominate the tape noise, creating a signal-to-noise loss of 6 dB per halving of tape width.

Fig. 28-26 compares the output voltage and signal-to-noise variation for various track widths, assuming that all noise sources are truly random for a noiseless preamplifier and a typical preamplifier. When the amplifier noise begins to dominate the other noise sources, there is a rapid loss of SNR with decreasing track width.

28.3.5.2 Thermal Noise

Both the core and winding of the reproduce head contribute random noise to the output signal. For the winding, the noise source is due to the thermal agitation of the atoms in the copper wire. The amount of thermal noise is given by the expression

\[
TN = \sqrt{4KTRB}
\]

where,

- \(TN\) is the thermal noise,
- \(K\) is the Boltzmann’s constant \((1.38 \times 10^{-23} \text{ joules/K})\),
- \(T\) is the absolute temperature in kelvin,
- \(R\) is the resistance in ohms,
- \(B\) is the measurement bandwidth in hertz.

A 100Ω resistor will produce 0.182 μV of noise voltage. Depending on the core size and number of turns, a playback head may exhibit a resistance from 10–1000Ω, yielding thermal noise contributions of 0.06–0.6 μV. The increase in noise due to more turns of finer wire in high-inductance heads is offset by a rise in head output voltage, producing little net change in SNR.

28.3.5.3 Barkhausen Noise

Another major noise source is Barkhausen noise, a noise due to jumps in the magnetic boundaries of the core material. The core metal consists of a collection of many microscopic magnetic zones or domains. When a magnetic field is applied to the core, the boundaries or walls of the domains will change as small domains merge to form larger domains. This merging occurs in discrete steps since the small domains act as single units that must each merge completely in one jump. The resulting step change in the magnetic field generates a noise burst in the head winding. Since the core contains millions of constantly switching domains, a statistically independent random noise is generated. Reducing the size of the basic domains will decrease the amplitude of the Barkhausen noise.
28.3.5.4 Magnetostrictive Noise

The magnetic core material also exhibits magnetostriction—a change in magnetic field due to stress. The microscopically rough surface of the magnetic tape will therefore produce a small magnetic field change in the core as the tape slides across the head. This field change generates a magnetostrictive noise component in the winding.

Both the Barkhausen and magnetostrictive noises are absent when no tape is moving over the surface of the head. The residual standby noise, which is measured under these conditions, is the absolute noise floor for the reproduce head and amplifier. The comparison of this standby noise level with the bulk-erased and biased noise levels is covered in the test and maintenance section.

28.3.6 Record Heads

The magnetic core and gap of a reproduce head obey the principle of reciprocity, which states that the roles of an excitation source and sensor can be interchanged. For a head used in the reproduce mode, external flux at the gap produces a voltage across the head winding. If, instead, a voltage is applied to the head winding, a concentrated external flux field will be generated at the gap and can be used to record a signal on a piece of moving tape.

The shape and strength of the magnetic field at the gap is the basis for the operation of a recording head. The flux generated in the core by the current in the winding must jump across the gap to complete a closed magnetic path. The gap, which is a very poor magnetic path compared to the core, produces an obstruction that forces the flux to spread sideways, as shown in Fig. 28-23.

![Figure 28-23. Record head flux field.](image)

An analogous situation occurs with a crowd of people moving down a hallway. If the hallway widens for a crossing corridor or small lobby, the crowd will broaden out into the open area and then narrow down again to reenter the continuation of the hallway. The broadening will increase if the pressure within the hallway should increase due to an emergency such as a fire. The stress is greatest at the transitions between the wide and narrow spaces since this is where people are squeezing to try to change the shape of the flow.

A magnetic tape passing over a record head gap experiences a similar buildup and decline in the magnetic recording field as it moves across the gap. To produce a permanent recording on the tape, the flux must first rise to a level sufficient to overcome the magnetic memory force of the tape, which normally keeps the magnetic particles on the tape from changing state spontaneously. In the central zone of complete excitation, the tape particles will follow any change in the input signal driving the head. As the tape particles exit the strong central zone, a well-defined point will be reached at which the driving flux drops below the memory force, leaving a fixed magnetic image impressed on the tape. This transition region in which the image freezes at the trailing edge of the gap is called the trapping plane.

The shape of the trapping plane depends primarily on the gap size and the thickness and magnetic characteristics of the tape. Since trapping planes that are narrow and vertical will produce short-wavelength recordings that are more easily reproduced, several techniques have been developed to sharpen the transition zone, as shown in Fig. 28-24.

![Figure 28-24. Focused-gap and cross-field (X-field) head.](image)
shunted flux raises the efficiency of the head by requiring less drive power.

The conductive shim is only effective at high frequencies at which large eddy currents are generated in the shim. As a result, focused gap recorders utilize bias frequencies that are approximately ten times higher than conventional systems.

In practical use the silver shim proved to be a major problem because the soft silver would smear onto the trailing pole piece of the head and short the head’s laminations together.

A second technique, which yields similar results, is the crossed field or X-field, Fig. 28-24A. This method typically places a second bias-only head on the back side of the tape to create a shaped bias flux field jumping from one head to the other.

28.3.6.1 Biased or Anhysteretic Recording

The magnetization of the tape particles is not easily changed due to the memory force or hysteresis of the particles. In fact, the particles have a form of inertia that must be overcome if a linear transfer is to be achieved.

If a rapidly varying signal of sufficient amplitude to just begin magnetizing the particles is added to the audio flux signal, the magnetic particles will more readily conform to changes in the audio waveform. The high-frequency biasing signal produces a hysteresis-free or anhysteretic recording.

Fig. 28-25 shows a typical waveform of the current in a low impedance Ampex record head that is recording 10 kHz at a level of 250 nW/m. The bias component of 7 mA_p-p is approximately ten times larger than the 10 kHz component at 650 μA. (The voltage waveform across the record head would be totally dominated by the bias component due to the 6 dB/octave rise in head impedance with increasing frequency, in this case 35 V of bias versus 500 mV of 10 kHz or 70:1.)

The audio and bias signals must be added together in a linear manner without generating any of the sidebands that are present in either amplitude or frequency modulation techniques. The short-wavelength bias signal can therefore be easily filtered out during playback by the gap and thickness losses so that only the audio signal remains. (The high level of bias signal transformer crosstalk that is present during sync/overdub operation requires a sharp notch filter in the playback preamplifier to remove the bias signal.)

Typical bias frequencies range from 100 kHz for slow-speed recorders to over 10 MHz for high-speed tape duplicators. Although high bias frequencies are desirable to permit easy filtering and thorough tape excitation, a practical upper limit for mastering recorders is reached at 500 kHz due to a combination of increased eddy current and hysteresis losses in the core and the increase in bias drive voltage required due to the inductance of the head.

Head losses can be reduced by using a very small core to reduce hysteresis losses and by choosing either thin laminations or a ferrite material to reduce eddy current losses. If, however, the record head will also be used for the reproduce function during sync/overdub, a small core will cause serious long-wavelength contour effects. The compromise hammerhead design shown in Fig. 28-26 improves the playback performance of the small core by adding extensions to the face of the core. The tips function only to play back low-frequency signals for which core losses are insignificant.

Figure 28-25. Record head current.

Figure 28-26. Hammerhead cores.
Heads with very low inductance typically require a step-up transformer to achieve adequate playback SNRs, but the transformer will also contribute some additional small amounts of distortion, noise, and frequency response anomalies.

Lengthening the record head gap will reduce shunting and give better bias penetration into the tape, but the short-wavelength sync/overdub response will suffer greatly.

A more straightforward approach to optimize the record head for both recording and playback is to use separate flux paths or windings for each of the functions. One simple method of switching windings and flux paths is to use parallel paths that can be selectively blocked. As shown in Fig. 28-27, when the high-inductance playback winding is shorted, flux will be blocked from the playback shunt magnetic leg of the core, effectively eliminating this path and thereby forcing all of the flux from the low-impedance bias winding to the front of the head. During reproduce, when the bias winding is shorted, the flux picked up from the tape will pass only through the reproduce winding. Although the cost of this dual-winding head is significantly higher than for a conventional single-path design, each coil can be optimized for its intended function without the need for compromise, yielding playback-to-record inductance ratios of up to 1000:1.

**28.3.7 Erase Heads**

A major advantage of magnetic tape recording is the ability to erase easily and reuse the magnetic tape. Although physical wear may eventually degrade the performance of the tape, the magnetic properties of the tape never wear out.

Erasure of the tape can be accomplished by remagnetizing the tape with either a very strong static field or a very strong alternating field. For audio applications the alternating field, which produces a completely random flux pattern that is very quiet, is used exclusively.

A very large electromagnet, known as a *bulk eraser* or *degausser*, is used for rapid erasure of an entire reel of tape, Fig. 28-28. The coil and core of the degausser are similar to a large recording head. The very strong flux field created across the eraser gap penetrates the magnetic tape, driving the magnetic particles to complete saturation. Any magnetic patterns on the tape are completely erased when all the tape particles are alternately saturated in one direction and then the other by the changing field.

![Figure 28-27. Dual winding record head.](image)

To leave the tape in a neutral stage, the strength of the erasing field must gradually decrease from hard saturation to zero. A common technique is to move the tape slowly away from the eraser so that the 60 Hz excitation field will drop gradually from one cycle to the next.

A few degausser models include control devices that gradually reduce the current in the eraser coil to zero, thereby eliminating the need for the operator to move the reel. Other models contain motor-driven actuators that slowly remove the tape from the field automatically.

A dc current or permanent magnet can also be used to erase unwanted signals from the tape, but the tape particles will not be left in a neutral state. A dc-erased tape will usually produce a very noisy recording that contains high levels of even-order harmonic distortion components.

Selective erasure of small portions of a reel of tape requires the use of an erase head on the tape recorder. The function of the head is similar to the bulk eraser in that the tape is slowly withdrawn from a saturating ac...
flux field. For a tape speed of 30 in/s (76 cm/s) and a
typical decay length of the erase head field of 0.005 in
(125 μm), the drop from saturation to zero occurs in
0.17 ms. If the tape is to experience at least 20 complete
cycles during the decay, the erase frequency must be

\[
 f_{\text{erase}} = \frac{\text{number of cycles}}{\text{decay of time}} \\
= \frac{20}{0.0017} \\
= 120 \text{ kHz.} 
\] (28-10)

A conventional coil-and-core head that has a very
long gap can produce the long flux field required for
erasure. Although such heads will produce approximately 50 dB of erasure, some of the original signal will
still remain. A second pass over the erase head will
provide the additional erasure that is required to erase
the unwanted signal completely.

The reason for the incomplete erasure is a phenom-

enon known as gap jumping. As the tape leaves the
saturation zone of the erase gap, the flux level experi-
enced by the tape particles will pass through a level that
creates a recording zone similar to the trapping plane of
the record head. Any audio variations in the erase field
would be recorded at this point. Such audio variations
are created by the unerased program that is starting to
enter the erase field at the other side of the gap. This
incoming flux adds to the erase head flux, creating an
unwanted recording at the trailing edge of the erase field
just as if the audio signal had jumped across the gap.

Complete erasure can be achieved without multiple
passes if the erase head contains two magnetically
isolated gaps. The tape is erased by the first gap, and
then immediately reerased by the second gap. A wide
center spacer isolates the two gaps so that flux cannot
jump both gaps.

Although both bulk erasers and erase heads are

capable of completely erasing all recorded material
from a tape, the residual noise level left by the erase
head will be slightly higher than the virgin-tape level
achieved by the bulk eraser. Possible sources of this
excess noise include small changes in the erase field
caused by the tape-to-head contact variations, the tape
particle-to-particle magnetic variations, and the
recording of Barkhausen noise from the erase core. The
record head biasing field also produces similar increases
in the noise level. The excess noise perceived by a
listener due to the erase and record heads may rise as
high as 6 dB above the virgin-tape noise floor.

28.3.8 Head Degaussing (Demagnetizing)

Early tape recorders used permanent magnets rather
than an ac high-frequency signal to bias the tape so that
small signals could be recorded without high distortion.
These fixed magnetic fields produced a very high back-
ground noise level that severely limited the SNR of the
taped recording. The introduction of ac bias upgraded
the tape recorder from a voice-grade recording instru-
ment to a true high fidelity recorder for music.

Modern recorders all use ac bias, but occasionally
the background noise on a tape will be well above the
normal level. The culprit is usually a permanently
magnetized head, guide, or capstan that is acting like
one of the old biasing magnets. The problem is most
commonly created by touching a magnetized tool such
as a screwdriver or razor blade to a component in the
tape path. On rare occasions a faulty electronic circuit
will create a dc current in one of the heads, leaving a
residual magnetic field. (Loud clicks or thumps may be
symptoms of dc currents.)

Since there are no commonly available instruments
which can detect the very small magnetic fields which
will result in noise, the best strategy is to frequently
demagnetize all magnetic components in the tape path
with a head degausser, Fig. 28-29.

The head degausser in Fig. 28-29 is an electromagnet
with an extended core. The extension probe conducts an
alternating magnetic flux generated in the coil to the tip
of the probe. The probe is passed close to the magnetic
components on the tape deck so that the alternating flux
can flood the components. The actual demagnetizing
occurs as the probe is slowly withdrawn from the
component, creating the gradually decreasing alter-
nating magnetic field mentioned previously in the
discussion of bulk degaussers and erase heads.

Caution! Before using a head degausser, always
verify that the tip of the probe is covered by a soft mate-
rial that will not scratch the face of the magnetic heads.
If necessary, wrap the tip with vinyl electrical tape or a
similar tape.

Degas the heads and other steel tape-guiding parts
with a commercial-grade head degausser as follows:

1. Although a typical head degausser will not disturb a
recorded tape that is more than a few inches from
the degausser, always remove all tapes from the
vicinity of the transport prior to energizing the
degausser.

2. Hold the degausser at least 1 ft from the tape trans-
port when applying power to the degausser. The
degausser will produce a large voltage in the play-
back and record heads, which will probably not
damage the respective electronics but will certainly “peg” any analog meters in the circuit. Turn off the power to the recorder before using the degausser.

3. Move the degausser slowly and smoothly from bottom to top along the gap line of each head, moving at a rate of approximately $1\_8$ in/s (3 mm/s). At the top of the head, smoothly withdraw the degausser 6 inches (15 cm) and then move smoothly to the next item to be degaussed.

4. To be safe, move the degausser at least 3 ft (1 m) away from the transport before disconnecting the power from the degausser.

5. Multiple degaussing passes on a component do not improve the quality of the results. A single slow, smooth pass is adequate.

The rapid collapse of the magnetic degaussing field at turnoff can easily undo all of the benefits of degaussing if the degausser has not been pulled away sufficiently. (For this reason, avoid degaussers that have momentary power switches that might be accidentally released in the middle of the degaussing routine.)

28.3.9 Tape Components

Modern magnetic tape consists of a powder of very small magnetic particles, which has been glued to one surface of a plastic substrate or base film. The backside of the substrate is coated with a very thin layer of carbon particles to improve winding characteristics and to reduce the buildup of static electricity.

28.3.9.1 Base Films

Although several base film materials were used in the past, including paper and acetate film, virtually all tape manufactured today uses polyester film (polyethylene terephthalate) such as Dupont’s Mylar™. Polyester is not only extremely strong and tear-resistant, but it is also relatively stable with respect to changes in temperature and humidity.

Depending on the intended application, the nominal base film thickness ranges from 1.4 mils (35 μm) for heavy-duty professional tapes down to a scant 0.25 mil (6.25 μm) for a C-120 cassette. To achieve reliable performance with these very thin films, the film must be not only very thin but also uniform in thickness from end to end and from edge to edge.

To enhance the strength of the thin base films used for cassettes, the polyester is prestretched or Tensilized. Although Tensilized tapes are more resistant to stretching than normal tapes, residual stresses that result from the Tensilizing process can produce physical distortion of the tape. For thin, narrow tapes these distortions are satisfactorily flattened out at the record and playback heads. The thicker, wider tapes used for professional formats, which would manifest severe contact problems due to these distortions, are considered to be strong enough without Tensilizing to provide adequate performance.

28.3.9.2 Binders

The glue or binder that holds the magnetic particles to the base film is a necessary evil that makes no active contribution to the magnetic performance of the tape. The use of new high-strength binders containing urethanes has improved both the durability and the recording characteristics of recent tapes.

The magnetic characteristics of the magnetic particles never wear out. The particles can be recorded and/or reproduced an unlimited number of times without any performance degradation.

The useful life of the tape is determined by three factors—the inherent strength of the tape, the amount of physical wear caused by the tape transport, and the performance required by the application. A typical test to measure the life of the tape would consist of many repetitive cycles on the intended transport while monitoring the
gradual (hopefully) drop in playback level at the shortest wavelength of interest. When these losses exceed the application’s requirements, the tape is worn out.

Some specialized audio transports designed for repetitive playback are capable of making over a quarter of a million passes on a tape. On the other hand, a poorly maintained studio recorder can destroy a master tape in ten passes or less! In general, if the abrasive forces exerted by the transport on the tape are well below the inherent strength of the binder, the tape will last virtually indefinitely. Any increase in the abrasive force due to dirty contact surfaces, excessive tape tension, or poorly designed tape guiding will accelerate the wear.

A very rapid catastrophic failure will occur once the abrasion force becomes sufficient to build up a small clump of debris on a contact surface. The friction between the debris and the tape surface is very high due to both the similarity of materials and the high pressure exerted by the tip of the clump as it pushes on the tape. The binder is overwhelmed, causing the clump to grow rapidly to the point at which the tape will show an obvious scratch or crease. If this situation should arise, the source of the problem should be corrected, and a copy of the damaged tape should be used for subsequent work.

From the magnetic performance standpoint, the combination of smoother magnetic particles and newer binders has enabled the tape manufacturers to use a smaller quantity of binder material to affix the magnetic particles. The ratio of useful particles to the magnetically inert binder rose from approximately 40% by volume for typical mastering tapes in 1970 to approximately 60% in 1980 with virtually no improvement since then. This improved magnetic density yields a higher maximum output for a given particle type and coating thickness.

28.3.9.3 Magnetic Particles

The ultimate performance of a tape recorder is determined not by the tape drive, heads, or electronics, but rather by the physical and magnetic characteristics of the magnetic particles of the tape. If basic performance parameters such as maximum output levels, noise, and distortion are truly determined only by the tape, the recorder is said to be tape limited. As a practical rule of thumb, if the noise and distortion products of the recorder are at least 10 dB lower than the products produced by the tape, the overall performance of the machine and tape will be within 0.5 dB of the theoretical levels of the tape alone.

Of primary importance in magnetic recording is the ability of each magnetic tape particle to assume and retain a magnetic pattern. These particles are chosen for their ability to maintain a magnetic field along one preferred direction or axis, permitting alignment of the particles for maximum performance. The amount of preferred orientation or anisotropy in the material depends on the nature and crystalline structure of the particles.

The shape of the particles determines the degree of physical alignment that can be achieved during the coating process. Smooth cylindrical or spherical particles that have no jagged edges or branches can be densely packed, yielding maximum output level.

The size of the particles is determined by the crystalline structure of each material. The residual noise of the tape decreases as the particles become smaller. Small particles with high anisotropy are therefore most desirable. Typical iron oxide magnetic particles for recording tape are cigar-shaped particles with a length-to-width ratio in the range of 4:1 to 8:1.

The newest recording products are abandoning particulate coatings in favor of thin layers that are plated or evaporated onto the surface of the plastic. These very thin layers of high coercivity materials are ideal for very short video wavelengths or very high digital bit densities. The new technology brings with it a whole new set of problems such as coating durability and how to include adequate lubrication in the metallic coating.

Coercivity. The coercivity is a measure of the magnetic force required to cause the tape particles to change magnetic polarity. High coercivity particles are more difficult to bias, record, and erase. On the beneficial side, they are also better able to resist external influences due to neighboring particles after recording, reducing the smearing of short-wavelength signals during storage.

Retentivity and Remanence. If the coercivity is considered to be the input drive, then the retentivity and remanence are the output of magnetism left in the tape. Retentivity measures the maximum output per unit volume of coating cross section; remanence (remanent flux), which is the output per ¼ inch of tape width, varies not only with retentivity, but also with coating thickness. Remanence specifications should be used to compare the maximum long-wavelength outputs of different tape types.
28.3.10 Magnetic Performance Curves

The input-output relationship for typical magnetic materials is very nonlinear. As shown in Fig. 28-30A, the magnetization characteristic curve can be broken into three zones. For low excitation levels, the initial output is very small and nonlinear. As the excitation increases, a fairly linear region is encountered, which produces low distortions. As the level continues to increase, the magnetic particles finally become fully magnetized or saturated. Further increase at the input yields no more magnetization in the material.

The nonlinear initial region must be avoided in audio recording if low distortion is to be achieved. The high-frequency bias signal provides enough excitation to jolt the magnetic particles into an active state. Optimizing the bias level yields the much more linear transfer characteristic of Fig. 28-30B.

Another representation of the magnetic characteristics is given by the B–H curves of the tape, as shown in Fig. 28-31. The curves show the amount of magnetic flux density created within the magnetic material by a cyclically varying intensity of applied magnetic excitation. Since the particles store part of the magnetic field, the path for increasing excitation differs from the decay path for decreasing excitation.

Magnetic recording tapes are typically characterized by the coercivity and retentivity described previously. These points on the B–H curve for full saturation are indicated by $H_c$ and $B_r$, respectively.

A figure of merit called squareness is commonly used to indicate the uniformity of the magnetic switching characteristics of magnetic coatings. As shown in Fig. 28-32, the squareness is the ratio of the remanent output value where the curve crosses the vertical axis to the saturated output. A perfect squareness of 1.0 would mean that every particle switched at exactly the same excitation level, yielding maximum output level and low distortion at high output levels.

The squareness ratio improves as more and more particles are aligned in parallel with the flux lines produced by the record head. The ideal case would be if all particles were exactly the same size with a perfect needle shape and all of the particles were stacked tightly like cordwood.

The early oxides had many branches or dendrites stick out of the sides of the needles. The dendrites interfered with the uniform packing of the particles, reducing the overall ratio of magnetic particles to binder. Later highly orientable particles (HOP) with reduced dendrites improved the packing factor. Additional work in coating techniques took advantage of the liquid flow of the coating during application to the base
film to align the particles, a technique known as rheological orientation.

As a result of these improvements, squareness ratios have increased dramatically. Over the past 30 years the squareness has improved from 0.8 to better than 0.9 for the best current audio tapes. This improvement translates to more available output and less harmonic distortion from the tape without requiring any increase in bias or record signal.

Table 28-5 summarizes the characteristics of several of the particles used for magnetic tapes.

28.3.11 Magnetic Tape Specifications

The performance of a magnetic tape involves many parameters such as maximum output level, distortion, noise, print through, and frequency response. As a result, the data sheet that characterizes this performance must include many operating characteristics. The user must be very careful, however, to determine the test conditions under which the data is derived, including record head gap length, tape speed, operating level, and equalization.

One form for presenting this data is shown in Table 28-6. The data entries are measured for one specific recommended bias setting. Some of the values, such as sensitivity at long and short wavelengths, are comparisons to the performance of a standardized reference tape. The notes contain important information defining the test conditions used to derive the data.
In contrast, the graphical data in Fig. 28-33 depicts how the various values change as the bias value is adjusted over a range of 16 dB. All values are absolute values without any comparisons to a reference tape. The parameters of the recorder used for testing are shown above the graph.

The bias point recommended by the tape’s manufacturer is the 0 dB value on the bottom scale. This value is a compromise value determined by simultaneously
evaluating the distortion, noise, and maximum output levels for each bias setting.

There are two common methods used for setting the bias level. One technique is to adjust the bias while recording a long wavelength such as 1 kHz. The bias is increased until the recorded signal peaks. The bias level is then further increased until the recorded signal drops by 0.5 dB.

A second technique is to use a short wavelength, typically 1.5 mils, and adjust for a significant amount of overbias. The bias is increased until the recorded signal peaks. The bias is then further increased until the recorded signal decreases from peak by several dB.

How do these two techniques compare? Find the sensitivity curves $S_1$ and $S_{10}$ near the center of the graph. These curves show how the 1 kHz and 10 kHz signals will change in level as the bias is increased. Note that the $S_1$ curve is very flat, changing only $\frac{1}{4}$ dB from peak over a bias range of 5 dB. In comparison, the $S_{10}$ curve is falling at a rate of approximately 1 dB/dB of bias increase.

The flat shape of the $S_1$ curve provides very little signal drop for a rather large bias change. A 0.1 dB error in the signal level adjustment, perhaps due to a sticky meter, may change the 10 kHz sensitivity by 2 dB or 3 dB. This error would require an additional record equalization boost of 2–3 dB to correct the overall response.

In contrast, the rapid signal level change when using a 10 kHz signal gives a much more precise adjustment and better uniformity from track to track. It is clear that both techniques are trying to achieve the same adjustment, but the short wavelength technique offers much better resolution.

This technique can be a trap for those who don’t understand what is actually happening. The $S_1$ and $S_{10}$ curves are really curves for the specific wavelengths of 15 mils and 1.5 mils, respectively. If the tape speed is doubled, these curves will now represent performance at 2 kHz and 20 kHz. The 15 in/s overbias specifications for 10 kHz must not be used at any other speed! For example, at 30 in/s the $S_{10}$ curve of the example tape has a downward slope of only 0.5 dB/dB of bias. Why? Because the wavelength is 3 mils, not the 1.5 mils of the previous example at 15 in/s. The manufacturer recommends only 1.5 dB of overbias at 10 kHz and 15 in/s. It is important to use the same wavelength at all speeds by shifting the test frequency to 20 kHz or 5 kHz at 30 in/s and 7.5 in/s, respectively.

As mentioned previously, the test data is very dependent on the characteristics of the recorder used during the testing. In particular, the shape of the $S_{10}$ curve...
varies greatly with changes in the record head gap length. Table 28-7 illustrates how this gap length affects the recommended amount of overbias.

28.3.12 Problems with Older Tapes

The archives of American tape recordings contain tapes that are up to 50 years old. Unfortunately, many of these tapes have problems that could easily damage or destroy their recordings. Some of these problems can be corrected, but others are irreparable.

28.3.12.1 Adhesion and Peeling Oxide

Adhesion is the binding force that firmly holds the oxide layer onto the plastic substrate. Two simple tests can be used to evaluate the strength of the adhesion—the Scotch tape test and the sharp edge test.

The Scotch tape test tries to rip the oxide from the plastic substrate by brute force. Start with a strip of Scotch Brand Magic Mending tape several inches long. Adhere about 3 inches of the sticky tape to the oxide surface of the recording tape. Rub the joint to assure complete binding of the tapes. The test is to peel back the sticky tape with a quick jerk parallel to the tape. If the oxide layer delaminates and peels off with the sticky tape, the adhesion is poor.

The second adhesion test utilizes a blunt edge to create a very sharp bend in the tape. Find a sharp perpendicular edge on a desk or a piece of plastic ruler that has no rounding radius. Place the backside of the tape sample against the sharp edge. Pull on the ends of the tape to establish a firm tension in the tape. While maintaining the tension, drag the tape over the edge in a 90° bend. If the oxide does not loosen from the backing, the tape passes the test. A poorly adhered tape may suffer complete delamination of the oxide, with a solid band of oxide peeling off and shooting away from the backing.

28.3.12.2 Brittleness

The polyester base films and urethane binders of modern tapes remain flexible under all normal circumstances. The base films and oxide layers of earlier tapes, however, could become brittle. Plasticizers were included in the binders and the acetate backing to provide flexibility in the tape. Unfortunately, these plasticizers can harden with age, causing the tape to become brittle. Harsh storage conditions can accelerate the breakdown of the plasticizers.

Brittleness cannot be reversed. The only remedy is to use a tape transport that is extremely gentle on the tape. Choose a transport with dynamic braking rather than harsh mechanical brakes. A transport with constant tape tension can be set for the lowest practical tape tension. Some decks also feature gentle start capability that ramps the capstan up to speed to smoothly accelerate the tape rather than just slamming a pinch roller onto a running capstan.

28.3.12.3 Splice Failures

In the early days, standard Scotch Brand cellophane tape was the only splicing tape. Later on, splicing tapes such as Scotch #41 and #620 were developed with improved characteristics. Although these tapes were fine for day-to-day operations, they have not survived the test of 50 years of storage. For example, the adhesive of both cellophane tape and splicing tape can ooze out and stick to adjacent layers of tape. A common remedy was to apply talcum powder to the sticky oozed adhesive to avoid layer-to-layer adhesion.

With even more time the adhesive can dry out completely, causing the splice to fail. In this case the only remedy is to replace the splicing tape with new tape. The newest splicing tapes, such as blue #67, replace the original latex adhesives with synthetic adhesives that do not ooze or dry out.

The tape operator must be watchful for two problems created by bad splices. First is layer-to-layer adhesion that can produce strong tugs that break older acetate tapes. Second is tape separation at a failed splice. DO NOT run the tape through the recorder at high speed if you suspect either problem may exist. If the tape tugs or separates at high speed, the loose end may be slapped around and broken off before you can stop the spinning reels.

If the tape is old, wind the tape slowly and carefully to examine each splice. Re-splice all splices if there is any hint that the splices may separate. Do not try to remove any of the old splicing tape adhesive that has
dried out on the recording tape. Sticky adhesive residue that could bond to adjacent layers, on the other hand, must be removed.

28.3.12.4 Print Through

The energy required to activate a particle to switch magnetic states depends on the size of the particle, with the overall characteristics of a magnetic tape being determined by the average size and characteristics of many particles in the coating. A more detailed analysis of the particles would yield a distribution of sizes, as shown in Fig. 28-34. Although the majority of the particles cluster around the average value, a small portion of the particles are either much smaller or much larger than the average. The small particles give rise to spontaneous recording as print through; the large particles produce noise bursts.

The small particles require so little activation energy to assume a new magnetization state that even the thermal energy of the particles may provide enough bias to cause the particles to be recorded by the stray magnetic fields due to adjacent layers of recorded material. This spontaneous recording is most evident as pre- or post-echo at the beginning and end of a recording. The strength of the print through image depends on both the percentage of thermal idiots in the coating and the ratio of remanence to coercivity of the tape. The remanence measures the driving force of the signals trying to print through. The coercivity, on the other hand, is the stubbornness of the particles to resist this imprinting. The effective coercivity of the small particles is diminished because the domain size is sub-optimal, rendering the small particles more susceptible to printing.

The milling process used to provide thorough mixing of the particles, binder, and additives prior to coating is a rather abusive process that can create thermal idiots by fracturing some of the desirable large particles into smaller, low-coercivity particles. Insufficient milling, on the other hand, provides an uneven particle dispersion that creates noise on the tape. The tape manufacturer must strike a compromise that yields both low noise and low print through.

Print through of a signal produces both pre-echoes and post-echoes. The pre-echoes are more troublesome in music, however, since the pre-echoes frequently occur in the quiet passages just before the loud note. The post-echoes, on the other hand, are frequently masked by the diminishing tail of the musical note and the room reverberation.

Fortunately, the print-through process does not produce equal amounts of pre- and post-echo, but unfortunately the more undesirable pre-print echo is the stronger. The vector magnetization components that arise during the recording process cause the levels of print on the outer adjacent tape layer to be several decibels higher than on the inner adjacent tape layer, as shown in Fig. 28-35. The more troublesome pre-print echoes on musical selections can therefore be minimized by storing the tape tails out to move the quiet lead-in to the inner layer. This will also bury the louder outer layer print through echo in the decaying signal at the end of the music.

The use of nonmagnetic leader tape between selections is also helpful to eliminate pre-echo on selections that begin with a rapid attack. Be aware, however, that paper leader tape can contain a small amount of magnetic debris that will raise the noise level as the leader passes over the playback head.

The user can take several steps that will minimize the amount of print through. First, the use of thicker base films increases the spacing between layers.
Second, avoiding elevated temperatures and stray magnetic fields during use and storage will decrease the excitation of the thermal idiots. Third, exercising the tape by shuttling the tape from reel to reel several times will partially erase the printed particles. The flexing and rubbing of the tape produce enough activation energy to neutralize some of the printing. For this reason, never copy a stored master tape without exercise. The worst possible print through level exists on the very first pass of the tape. In some cases print through can drop as much as 4–6 dB with five shuttle cycles.

28.3.12.5 Sticky Shed and Tape Baking

As mentioned earlier, the goal is to attach a maximum number of perfectly stacked and oriented magnetic particles onto the surface of the backing material. Anything that interferes with this goal by displacing some of the magnetic particles, such as additives for lubrication, fungicides, and static charge reduction, degrade the performance of the tape. Most important in this category is the very binder that holds the particles in place. Every bit of binder displaces some of the useful magnetic particles.

The best choice is to use a very strong binder that can do the job with the minimum amount of glue, allowing space for more magnetic particles. The winner is the highly crosslinked thermoset polymers in use today. Starting around 1970, these binders with a high urethane content gave a big boost to tape performance. Unfortunately, long term experience with these tapes now shows that the binder can break down during storage. The symptoms are a buildup of residue on the head and guides and a tendency for the tape to stick to these residue buildups, in some cases actually dragging the tape to a stop. The popular name for this problem is sticky shed. The problem is usually discussed in terms of binder breakdown, but there appears to be a second major problem related to lubricant oozing that is also present.

Urethane Binder Breakdown. The urethane binder contains long polymer chains that provide the high strength of the binder. Water in the surrounding air enters the tape and breaks the long chains through a process known as *hydrolysis*.

As a result of the chemical breakdown of the long polymer chains, the binder is weakened enough for the surface of the tape to begin to rub off onto the stationary guides and heads. Depending on the design of the transport, this residue can clog the heads in just a few seconds. Machines with rotating guides and low tape tensions take longer to clog, but the damage to the tape is still intolerable.

Fortunately, the hydrolysis is somewhat reversible. Tapes can be *baked* at a moderate temperature to reverse the hydrolysis and restore strength to the binder. Although this may seem like a bit of witchcraft, thousands of baked rolls of archived tapes have proven the technique.

The electric oven must provide a well-controlled temperature of about 120–140°F (50–60°C). Large dehydrators or fruit dryers are popular because of their size and limited temperature range. Only an electric oven should be used. The oven should be preheated and checked for temperature stability with a high-resolution thermometer such as a candy thermometer. The tape, wound onto a metal reel, is placed into the oven horizontally with generous space above, below, and around the reel for air circulation. The tape is baked for 15–20 hours, and then allowed to cool to room temperature undisturbed in the oven.

The baking process creates a low-humidity environment that draws some of the excess water from the tape binder. The short polymer chains may recombine with their neighbors to produce a better bond, but the breakdown process is not fully reversed.

Lubricant Oozing. The second failure mechanism also involves the binder, but in this case the culprit is the oxide. A change of oxide particles also changes the chemistry needed to make a liquid binder that can:

1. Hold all the magnetic particles in suspension.
2. Be smoothly coated onto a polyester backing material.
3. Have the volatile byproducts evaporated in the drying ovens.

In the early 1970s Phizer introduced a new high-output oxide with excellent signal characteristics, but the particle required a reformulated binder with a low pH in order to meet the above requirements for a usable dispersion. This particle was utilized by 3M in the 226 family of tapes (226, 227, 806, 807, 808, 809) and by Ampex in the 456 family.

The new binder formula included a component that served primarily as a lubricant. Unfortunately, however, this lubricant would migrate to the surface of the tape and concentrate into a sticky residue.

The baking operation described in the previous section warms the concentrated lubricant enough to allow the lubricant to flow and be reabsorbed into the depths of the coating.
Since both types of sticky shed problems are treated by baking, most people who bake tapes don’t know for certain which problem they are treating, and if the sticky shed is eliminated, they probably don’t care.

How long before a baked tape begins to again exhibit sticky shed? Results will vary depending on the amount of degradation, the tape type and specific batch, the exact baking method, and the operating environment after baking. Reports vary from days to years. Certainly baking provides an adequate window for the tape to be transferred to another medium.

Is there any degradation due to the baking process? The most likely problem is print through caused by the elevated temperature. Print through is a time-dependent problem that peaks out at a maximum value after a long time. Heat accelerates the printing. However, stored tape probably has had enough time for the print through to be near the maximum value before baking. As a result, the additional print through caused by the baking may be negligible. Follow the exercise process described at the end of Section 28.3.12.4 to minimize the print through before copying the tape.

How can sticky shed be avoided? The rate of hydrolysis depends on the storage conditions. Archival storage at a temperature of 60°F (15°C) and relative humidity of 25% ± 5% is optimal, but few have the luxury of an environmental chamber, so store the tapes in a cool, dry location in the original package standing on edge.

Sticky shed may also produce layer-to-layer adhesion. If you strongly suspect sticky shed, bake the tape before trying any winding operations on a tape transport. This will avoid the total loss of recorded segments due to oxide being ripped from the tape’s plastic backing during spooling.

28.3.12.6 Squealing Tape

One of the many ingredients in the coating recipe is a small amount of lubricant. Obviously, the tape cannot be too slippery or else the capstan couldn’t maintain constant tape speed. Running the tape completely dry, on the other hand, can produce an audible squeal. The tape undergoes a “stick-slip” phenomenon on the stationary guides and head, creating a jerky motion at a high frequency. The irregular motion can even be measured with a scrape flutter meter.

The squeal results from the loss or failure of the original lubricant. The obvious solution is to replace the lubricant. A can of 10-W30 motor oil isn’t appropriate, but another common household lubricant, WD-40, is recommended by Quantegy. Quantegy claims that WD-40 is cheap, available, inert to all recorder components, and a very good lubricant. Apply the oil sparingly by lightly wetting a lintless rag or swab with the oil and holding the applicator against the oxide side of the moving tape at the first guide after the supply reel. A bit of experimenting may be required to find the proper amount of oil that is required to eliminate the squeal without causing slippage and speed irregularities. When you are finished using the tape, prepare the tape for storage by passing the tape over a dry applicator in a medium speed fast wind mode. (Use extreme caution on tape transports that have elastomer coatings on the capstan and/or timing rollers. Lightly lubricate the tape while passing the tape directly from the supply reel to the takeup reel, and then dry the tape with a second pass over a dry applicator before threading the tape over the elastomer components.)

28.4 Analog Circuits and Systems

The transport mechanism, heads, and tape should combine to determine the basic performance limitations of a tape recorder. The analog electronic circuits of the recorder, on the other hand, should exceed the capabilities of the heads and tape in all respects so that only the heads and tape limit the quality of the final signal. In practical terms, this means that the SNR, frequency response, distortion, and head room of the electronics are comfortably better than the heads and any tape, including future improved tapes.

The block diagram of the signal electronics of a typical professional audio recorder is shown in Fig. 28-36. In terms of actual hardware, approximately 75% of the audio circuits of a modern professional audio recorder are devoted to operator interfacing and controls; the remaining 25% implement the basic functions of erasing, recording, and playback. Since the variation of features and technology used to implement the interfacing and control functions is too broad to be summarized herein, the following description covers only the latter basic functions.

28.4.1 Playback Amplifiers

The amount of electrical power that can be generated by a magnetic tape passing over the face of a reproduce head is exceedingly small. The output voltage from the head for loud recorded passages will reach no more than a few millivolts, with quiet passages dropping into the microvolt region. This weak signal must be carefully boosted without the introduction of additional noise to a
higher, more usable level by the first stage of the playback amplifier. Special low-noise amplifier circuits developed for this purpose provide at least 20 dB of gain so that subsequent amplifier stages will not be required to operate near their noise limits.

Since the reproduce head produces an output voltage that is related to the rate of change of the flux on the tape, $d\phi/dt$, the output voltage will rise at a rate of 6 dB/octave. A compensating circuit with a falling 6 dB/octave response, known as an integrator, is used in the playback amplifier to correct for this rise and give a voltage that is proportional to the value of flux sensed by the head.

When the effects of playback head resonance peaking and gap length, spacing, eddy current, and thickness losses are included, the output from the low-noise amplifier and integrator would follow the falling curve in Fig. 28-37 for 15 in/s (38 cm/s) operation, see Fig. 28-12 for details. This curve must be reshaped by the combined effect of the record and playback equalizers to yield a flat response. The method of partitioning this correction between the record and playback circuits is dictated by the equalization standard chosen by the operator. Since all users of a given equalization standard will be using the same partitioning, the recorded tapes will all be interchangeable.

Fig. 28-38 shows a simplified schematic of a typical operational amplifier type of a playback amplifier capable of the necessary playback corrections. The low-frequency-cut circuit is utilized in some NAB and cassette standards to achieve a decrease in low-frequency playback noise below 100 Hz at the expense of low-frequency headroom. A typical design would include additional ancillary components for amplifier biasing and stabilization.

With one common exception, the same type of circuitry is utilized in the sync/overdub mode to condition and amplify the playback signal from the record head. The exception is in the form of an added voltage-boosting transformer that is commonly necessary to get the signal above the noise floor of the low-noise input section. This problem arises from the low inductance and few turns of wire that are typically found in a record head. The record head must pass the audio plus the high-frequency bias signal; therefore, the inductance must be kept low enough to avoid self-resonance with the head cables at the bias frequency. When fewer turns are used to reduce the inductance, the output voltage goes down proportionately. In essence, these turns are restored in the transformer by a step-up turns ratio ranging from 3:1 to as high as 10:1.

**Figure 28-36.** Tape recorder signal block diagram.
28.4.2 Record Circuits

The primary task of the amplifier that drives the record head is to convert the input audio signal voltage into a proportional amount of current flowing in the windings of the record head. To accomplish this task, the head driver must overcome the rise in head impedance with frequency that is due to the inductance of the head. A common technique to achieve flat current response, as shown in Fig. 28-39A, is to insert a resistor in series with the head so that the combined series impedance of the resistor and the head remain relatively constant throughout the audio band. If the resistance is chosen to be two to three times the reactance of the head at the upper limit of the desired audio band, the desired constant current characteristics can be closely approximated.

The primary disadvantage of the series resistor is the loss of head room due to the extra signal drop across the resistor. This problem can be overcome with an active current feedback circuit that senses the current in the head through a small sampling resistor. Fig. 28-39B shows a sampling resistor $R_s$ in series with the return leg of the head. The voltage generated across $R_s$ by the current flowing in the head is fed back to the inverting input for comparison with the incoming audio signal. The high gain of the driver amplifier necessitates only a very small feedback signal, creating a negligible loss in head room at high frequencies.

The circuits of Fig. 28-39 oversimplify the task of driving the record head since no provisions are included for adding the high-frequency bias signal to the current in the head. A common method of adding the bias and audio signals is shown in Fig. 28-40. The audio driver is isolated from the bias source by a parallel trap tuned to the bias frequency so that the bias signal does not create nonlinearities within the audio driver. The high impedance of the trap at the bias frequency also reduces the loading effect of the audio source on the bias source.

A similar isolation of the bias source is accomplished by the capacitor in series with the bias supply. Since the capacitor looks like a high impedance at audio frequencies, the loading effect of the bias supply on the audio source is minimized. At the higher frequencies of the bias signal, the reactance of the capacitor has dropped to a relatively low value that provides adequate coupling of the bias signal into the record head.

An alternate approach that eliminates some of the previously mentioned isolation requirements is shown in Fig. 28-41. In this case, the bias and the audio are added together at the input to a combination bias/audio head driver amplifier. If the amplifier has sufficient head room and very low distortion, the two signals can be amplified simultaneously by the same amplifier without any interference. The problem of coupling the
output to the head for constant current drive must still be overcome, however, by including either a complex coupling network or an active feedback network.

In addition to the head driver circuits, which correct for any response droop due to head inductance, the record amplifier must provide deliberate frequency response tailoring to match the desired equalization standards. The standards usually require an adjustable boost at 6 dB/octave beginning in the middle of the audio band, with lower tape speeds generally requiring greater boosts to overcome the increased tape thickness and self-erasure losses.

The needed boost is easily implemented by the resistance-capacitance circuit shown in Fig. 28-42A, but the use of a variable capacitor is inconvenient due to the limited range of capacitor adjustment and the awkward size and mounting of the capacitor. Newer designs, therefore, favor operational amplifier configurations that control the amount of boost with a potentiometer. One such circuit, shown in Fig. 28-42B, selectively adds the output of a differentiator circuit, which rises at 6 dB/octave, to the main signal path.

A secondary benefit of the differentiator circuit is the phase change introduced by the inverting characteristics of the differentiator amplifier. Unlike most of the loss-correction circuits of the signal path, which introduce signal delay at high frequencies, the inverted differentiator advances the high frequencies. The proper combination of advance and delay can provide less phase distortion in the signal, yielding improved transient response with less overshoot. A similar phase-correcting effect has been implemented in other designs by providing an all-pass, phase-shifting network in the reproduce amplifier.

The NAB and compact cassette equalization standards provide an additional record signal boost at low frequencies to overcome the hum and noise limitations of the reproduce heads and amplifiers. Typical circuits for this purpose are shown in Fig. 28-43. Both cases achieve a 6 dB/octave rise with decreasing frequency from 50 Hz or 100 Hz to below 20 Hz.

Abrupt changes in the bias and audio signals on the record head must be avoided whenever the record mode is entered or exited. Ramping circuits are employed for this purpose to control the buildup and decay of these signals. Typical methods include the use of analog switching elements such as bipolar-junction or field-effect transistors. The rate of switching of these elements is limited to a value that does not create abrupt transients but, at the same time, is quick enough to avoid annoying delays, overrecordings, or program holes.
28.4.3 Bias and Erase Circuits

The high-frequency signals required for biasing and erasing all tracks of the tape are derived from a single master oscillator so that no interference or beating of multiple oscillators will occur. Older designs generally employ a tuned push-pull multivibrator oscillator; newer designs favor crystal-stabilized oscillators utilizing digital circuitry. Several designs have used separate bias and erase frequencies, with the erase circuit running at one-third the bias frequency to minimize the power dissipation on the erase head.

In all cases, the primary consideration is purity of the bias and erase current waveforms. Any even-order harmonics, including dc, second harmonics, fourth harmonics, and so on, will create a detrimental rise in the background tape noise, reducing the available SNR for the recorder. Older designs, such as Fig. 28-44A, relied heavily on push-pull circuits with balancing transformers to minimize these even-order components. Newer designs, such as Fig. 28-44B, favor filtering and feedback control to reduce unwanted components. The divide-by-two flip-flop eliminates any even-order distortion in the oscillator waveform.

The erase head is typically coupled to the erase source with an adjustable series resonating capacitor to minimize the voltage required from the driver and to filter out even-order components. A current sampling resistor is frequently provided in the ground leg of the erase head circuit so that the amplitude of the erase current can be conveniently monitored.

28.4.4 Noise Reduction Systems

The SNR of an analog audio recorder is usually taken as the difference between the residual biased tape noise level and the level which produces 3% third harmonic distortion at 1 kHz. In the ideal case this ratio is limited by the tape speed, track width, and tape type. Once these parameters are set, the maximum SNR is determined.

Direct analog noise reduction systems rely on the masking effect of human hearing. If both a background noise and a louder desired signal exist within the same frequency band, the noise will be masked by the desired signal. If, on the other hand, the noise and signals are in different parts of the audio spectrum, such as a bass guitar and high-frequency tape hiss, the noise will not be masked. The perceived noise can be reduced if the SNR is compromised during masking situations so that unmasked noise can be reduced. This requires dynamic change of the gain or transfer function of the system depending on the program content.

Dolby™ and dbx™ noise reduction systems are examples of amplitude-only encode/decode systems. Both systems modify the amplitude of the signal to squeeze the dynamic range of the input signal into a smaller dynamic range that will avoid the noise and distortion limitations of the recording tape. The fidelity of these compander (compression/expander) systems is limited not only by the tracking of the encode and decode circuits, but also by the nature of the errors that are generated by noise, nonlinearities, and frequency response anomalies introduced by the record/playback cycle of the tape recorder. These parasitic errors can cause dynamic mistracking that will create distortions of dynamic signals that may not be evident during sine-wave testing.

The Dolby systems process the low-level signals by boosting them during recording and then attenuating them on playback. The original professional Dolby system (Dolby A) subdivides the audio spectrum into bands that are processed individually to optimize the masking effect.

A later development, the Dolby SR system also adds adaptive filters that change their cutoff frequencies as the signal content varies. When the program material includes information at high frequencies, the filter opens up to full bandwidth. If no high-frequency content is present, the cutoff frequency of the filter slides down to match the program material. The filter must be “intelligent” enough to distinguish between desired audio signals and unwanted noise.

The Dolby SR system was quickly embraced by the music and film markets as a method of raising analog...
recorder performance to a level that rivals digital recorders.

DBX is also a “compander” system, but instead of dividing the spectrum into bands and acting on each band differently, DBX acted on the true RMS value of the signal. This resulted in SNR improvements that were significantly better than Dolby A, but many users felt that the DBX system was more prone to audible artifacts of the process.

28.4.5 Sync Operation

Multitrack recording requires that artists be able to listen to the previously recorded tracks while simultaneously adding their new performance in synchronism with the prior tracks. Analog recorders accomplish this by using some tracks of the record head as playback sources while simultaneously recording on other tracks of the same head.

28.5 Digital Magnetic Recording

The information in this section on digital magnetic recording is presented as an attempt to document a bit of audio history. It is very likely that by the time the next edition is published, all recording will be performed in RAM or other solid state memory, and magnetic recording both analog and digital will be of historical interest only. As of this publication there is a clear trend toward digital audio workstations as being the standard recording devices, with the audio stored on hard drives. Tape-based systems are virtually gone. Currently, computers exist which utilize flash memory, and as such have no moving parts at all. At the moment these computers are expensive and have relatively low capacity compared to conventional hard-disk-based computers, but they are clearly the wave of the future.

28.5.1 Longitudinal Digital Tape Transports

Longitudinal digital tape recorders came in many varieties, the most successful were the DASH and ProDigi formats. DASH is an acronym for Digital Audio Stationary Head. The tape transports for these recorders were very similar to any high-quality analog mastering machine, but the very high density of very narrow tracks required extremely accurate tape guiding and head placement. For example, the DASH format with 52 tracks across a ½ inch tape specified head height to 0.6 mils (0.015 mm) and a guide placement to 0.2 mils (0.005 mm).

Tape speeds for multitrack DASH and ProDigi machines was 30 in/s for normal 48 kHz sampling of 16 bit data, but the DASH high resolution (HR) upgrade boosted the speed to 45 in/s for recording 24 bit data. The tape speed was servo controlled by the capstan to exactly match the sampling rate of the data recorded on the tape. The sampling rate could be varied from nominal by up to ±7% for varispeed operation.

Both formats included tape cleaning devices to remove loose debris from the surface of the tape. Loose particles were wiped from the oxide surface by passing the tape across a post covered with lintless fabric tape. A clock motor mechanism slowly advanced the fabric to refresh the wiping surface.

The DASH and ProDigi formats used conventional reels of tape that were mounted on the reeling spindle and threaded through the machine by hand. Aside from a few types of reel-to-reel digital instrumentation recorders, all other modern longitudinal digital tape formats utilize self-threading tapes that are permanently enclosed in a cartridge or cassette.

28.5.1.1 Signal Flow

A 48 channel DASH digital recorder contains more electronic circuits in one channel than all the audio electronics in an entire 24 track analog recorder, Fig. 28-45.

Some DASH recorders offered analog to digital conversion as extra cost options. Generally, digital data was fed through the Digital In port. This data was immediately routed to the output for monitoring via the Input Select selector. The data were also fed to a Crossfader that smoothly switches between the input source and tape playback for punch-ins. The data to be recorded was first spread out by the Interleave circuit to minimize the impact of a burst error. A powerful Reed-Solomon error correction encode process was applied by the RSC Coder. The data was then delayed by a variable amount.
to account for fixed and variable timing errors. A 4/6 Modulator adds bits to the data to create easily recognized data patterns that have an optimized bandwidth for recording on the tape. The patterns were then fed through the Write Amplifier to the write head.

Playback from the tape began at either of two read heads, one located before the write head for sync/overdub operations and one located after the write head for confidence monitoring. The selected data was fed to the Read Amplifier where the analog-looking pulses from the tape were converted into digital pulses by a differentiator and level detector. The patterns of digital pulses passed through the 4/6 Demodulator to strip off the extra bits added by the modulator during the write process. The Timebase Corrector removed any timing variations due to flutter in the tape transport, restoring the exact sampling rate. The RSC Decoder and Deinterleave used the Reed-Solomon data to correct any correctable errors and put the data back into the proper order. Any uncorrectable errors were concealed by the Interpolator, which made a best guess attempt to hide errors. If the errors are too large to hide, the output mutes rather than passes faulty data.

Other functions include master timing circuits, tape motion servos, extensive logic, and display functions for metering and control.

### 28.5.2 Helical Scan Digital Tape Transports

The primary limitations of longitudinal magnetic tape with a large number of narrow tracks were tape guiding and crosstalk and of course expense. Helical scan techniques greatly reduce these problems by using heads with alternating azimuth angles on the record/play heads to reduce crosstalk. Track-to-track spacing can be virtually overlapping, with dynamic tracking of the flying heads to eliminate any errors, Fig. 28-46.

The limiting factor for helical scan tape is the throughput on the single digital track that is being recorded. For example, a recorder capable of 8 channels of 16 bit or 24 bit audio requires bandwidths of approximately 8 MHz or 12 MHz, respectively. The most economical approach is to adapt a consumer format to fit this requirement. For example, the popular ADAT series manufactured by Alesis and others were based on the S-VHS format that used ½ inch tape. Similarly, the Tascam DTRS (Digital Tape Recording System) series utilizes the technology developed for 8 mm handheld video recorders. Both of these products offer 8 channels in an inexpensive package. Multiple machines can be locked together to provide up to 128 tracks of audio at about one-tenth the price of the equivalent DASH recorder.

The basic helical scan transport consists of a rapidly rotating head drum and a capstan to control the forward speed of the tape. A spooling mechanism engages the reel hubs in the cassette to provide proper winding of the tape in all modes. Auxiliary functions include auto loading mechanisms to load and eject the cassette and auto threading mechanisms to extract the tape from the cassette.

For most applications, the tape is wrapped around the head drum to cover slightly more than half the circumference of the drum. Heads are mounted in pairs 180° apart on the drum, protruding slightly from the face of the drum. The specific tape format determines the diameter of the head drum. The drum spins many revolutions per second to provide the high linear scanning speed required for the digital data stream. For example, in 16 bit mode the ADAT drum is 2.44 inches in diameter and spins at 50 rev/s to yield a linear scanning speed of 192 in/s. In comparison, the forward speed of the tape is only 3.9 in/s, about one-fiftieth of the scanning speed.

The scanning drum is tilted slightly with respect to the path of the tape, causing the spinning head to scan the tape in diagonal stripes. For the ADAT example, the angle is 7.5°, yielding a diagonal track length of slightly less than 4 inches. In comparison, the R-DAT system uses a 1.18 inch (30 mm) diameter drum inclined 6.5° spinning at 33.3 rev/s to give a scanning speed of about 120 in/s.

### 28.5.3 Rotary Digital Audio Tape

The R-DAT format shares technology with the 8 mm camcorder VCRs. By optimizing a miniaturized helical scan system using 4 mm tape for direct digital recording
of stereo audio, a very compact digital recorder, Fig. 28-47, has been made possible. New heads and metal particle tapes have been utilized to produce a long-playing cassette tape system with quality equal to the compact digital disk.

The R-DAT format operates at two tape speeds, 8.15 mm/s (0.32 in/s) for recording and 12.23 mm/s (0.48 in/s) for widetrack playback of prerecorded tapes. In spite of the very slow tape speed, very high data rates are made possible with a rotating head drum speed of 2000 rev/min and flying head velocity of 3 m/s. The resulting slant tracks are 23.5 mm (0.93 in) long and inclined at an angle of approximately 6.5° from horizontal.

The data is digitized to 16 bit resolution and recorded with double-encoded Reed-Solomon error correcting coding with interleaving between not only channels 1 and 2 but also adjacent scans of the flying heads, Figs 28-48. A 60 m (65.6 ft) tape holds 2200 Mbytes of information capable of encoding 2 hours of stereo music. Search for a desired program can be conducted at 60 times normal speed; rewind and fast forward without search is up to 180 times normal speed, allowing full rewinding in approximately 40 s.

The digital storage capacity of the audio R-DAT format has been greatly enhanced by newer technology to serve as a backup medium for computer hard disks. The fourth generation of the Digital Data Storage format (DDS4) jointly developed by Sony and Hewlett-Packard from the original R-DAT format boasts a capacity of 20 Gbytes per 150 meter tape. The drum spins at 11,480 rev/min to achieve a data throughput of 2.87 MB/s before data compression and up to 7.62 MB/s after compression.

28.5.4 Packing Density Maximization with Rotary Head Recorders

The professional analog multitrack formats are very inefficient in the use of recording tape. Nearly half of the tape width is devoted to guardbands between tracks. These guardbands are required to minimize crosstalk between channels due to fringing and crosstalk within the heads. These problems are overcome in rotary head recorders that do not require guardbands.

Several aspects of the rotary head system contribute to the elimination of guardbands, including servo positioning of the tape, azimuth shifting on alternate scans, and the elimination of low-frequency components in the recorded signal.

The servo positioning of the helical scan tape during playback is analogous to a conventional longitudinal recorder with self-aligning guides to correct for any guiding errors. Control signals recorded along the edge of the tape are used to synchronize the motion of the tape past the rotating drum to the spinning of the drum. This synchronization adjusts the position of the recorded tracks on the tape to exactly coincide with the path of the flying head. The active servo control of the tape motion duplicates any disturbances that may have occurred during recording to maintain correlation between the flying head path and the track, permitting tracks to be recorded abutting each other.

This technique can be carried one step further if the spinning head is augmented with a rapidly responding positioning actuator. Fig. 28-49 shows a scanning head mounted on a piezoelectric positioner called a bimorph. If a voltage is applied to the bimorph, the head mount deflects and moves the head.

Since the bimorph can respond much faster than the servo system, tracking errors can be continuously corrected throughout the helical scan of the tape. This
wider bandwidth, however, requires a method of actually sensing any errors when the head begins to slip off the center of the slant track. One of several techniques for this purpose is utilized in the 8 mm helical format. As shown in Fig. 28-50, low-frequency tracking signals are added to the high-frequency data. Four different frequencies are recorded on four sequential passes, with the frequencies chosen so that the difference between adjacent frequencies is either 16.5 kHz or 46.2 kHz.

Isolation of the short-wavelength encoded signals between adjacent odd and even tracks is further improved by offsetting the azimuth tilt of the heads during recording and playback as shown in Fig. 28-51. The resulting azimuth error for any signal leaking from the adjacent tracks will partially attenuate any crosstalk.

A helical scan recorder must have additional circuitry to assemble the digital data from several tracks into a serial stream that is recorded as blocks of data by the scanning head. The data must usually be replaced as an entire block, necessitating a complete rewrite of all channels if any channel is changing.

All of the digital circuitry of a helical recorder can be squeezed into just a few custom integrated circuits. The newer generations of ADAT machines, for example, adopted digital servos for controlling the transport so that all of the motor servos could be consolidated into a single chip, eliminating the need for any analog servo adjustment potentiometers. The digital signal chain is also highly integrated, resulting in an amazingly uncomplicated main circuit board with just a few ICs for the entire machine.

### 28.5.5 Heads for Digital Tape Recorders and Hard Disk Drives

The packing density of the data on hard disks in 1990 was around 100 mb/in$^2$. At the time of this publication, it is over 200 Gbits/in$^2$. Fig. 28-52 shows a thin film digital tape head.

As the areal density of the data on tapes and disks increases, each bit must shrink in size. The smaller bits contain less magnetic energy and generate smaller electrical pulses in the coil of a read head. The resulting loss in SNR eventually imposes a useful lower limit on the size of the bits.

This limit has been pushed back by read head technology called giant magnetoresistive (GMR) or spin valve heads. (The term giant differentiates these very high-output heads with giant output signals from earlier low-output magnetoresistive heads.) The GMR head is fabricated by vacuum deposition, creating a sandwich of metals that changes resistance when excited by a...
magnetic field. The rear layer of the sandwich shown in Fig. 28-53 has a fixed or pinned magnetic field that serves as a reference. The filler of the sandwich is a magnetoresistive (MR) material chosen for a large change in resistance per change in magnetic flux. The front outer layer is a magnetic probe that actually samples the magnetic flux of the bits on the disk. As the magnetic polarity of the data bits reverses, the angle of the magnetic field in the outer layer spins back and forth. Part of this field bridges through the center layer to the pinned rear layer, causing the resistance of the MR layer to change. The resulting output signal has a much better SNR than an equivalent read head.

Since the GMR effect does not work in reverse to generate a varying magnetic field when driven by an electrical signal, we still need a coiled conductor for writing the data onto the disk. The solution is a composite head that has both a GMR read element and a coil for writing. The entire head, including the GMR read element and the coil for writing, can be fabricated together using thin film techniques. A single thin film wafer may contain up to 20,000 heads.

Most digital recording schemes drive the record head hard enough to saturate the medium in one polarity or the other. If the head is tracking exactly over any prior data, the old data will be completely overwritten. Unfortunately, the tolerances of the head tracking system may cause slight alignment errors that leave a bit of the old signal unerased.

One method to remove the residue is to use a straddle erase technique that resembles the outriggers on a Hawaiian canoe. Two thin erase cores straddle the desired track and trim off any of the prior signal that wasn’t covered by the new recording.

A newer technique is to write wide and read narrow. Just as we discussed for analog recording, we can write a track that is wider than the read core. The extra width of the recorded track allows for a small tracking error. This technique is easily implemented with GMR heads since these heads have separate read and write elements. The read element is fabricated slightly narrower than the write element to create the desired overlap.

**28.5.6 Magnetic Disks**

A 2500 foot roll of 2 inch recording tape has enough surface to carpet a large living room. A 60 minute DTRS tape would only cover half of a couch. In comparison, a multigigabyte hard disk in a digital audio workstation uses a few 3½ inch (89 mm) diameter magnetic disks with a working area about the size of your footprint. Although the basic technology of all of these products is similar, the precision required in their manufacturing increases rapidly as the size shrinks and the density increases.

**28.5.6.1 Floppy Disks**

Floppy disks were close cousins to magnetic tape. Although the disks were cut from large rolls much like the jumbo rolls from which magnetic tape is slit, the coatings parameters were very different.

The diskette, which we now call the floppy disk, was developed around 1970 as a read-only device. The contents of the prerecorded diskette were loaded into a
computer or storage system to furnish startup or diagnostic information, much like a boot ROM in today’s computers. Over the next ten years the product evolved from an 8 inch diameter single-sided read-only device to a 3.5 inch double-sided read/write device with twenty times the capacity of the original diskette.

Although the original diskette operated on only one side of the disk, the media had magnetic coatings on both sides to promote flatness. The symmetric construction of the disk was eventually exploited to double the data capacity by recording on both sides.

By the end of their evolution, floppy disks utilized a very thin coating of cobalt doped gamma ferric oxide. The coating thickness was about one-fiftieth the thickness found on our analog mastering tapes, and the particle coercivity was about twice as high.

One important difference in floppy disk media is that the magnetic particles for a spinning disk must not be oriented in a single direction as on our audio tapes. Recording characteristics degrade several dB when an oriented tape is operated crosswise to the intended direction. A linearly oriented disk would therefore see large peaks and troughs in output at twice the rotational speed. To avoid these fluctuations, the floppy disk coating process is optimized to either disperse the magnetic particles in a random orientation or orient the particles circularly.

The floppy disk operated with the magnetic head in direct contact with the magnetic media, just as in a tape recorder. As a result, the floppy disk system was subject to head wear and head clogging due to dirt and debris.

Aluminum/magnesium alloys and glass are the preferred substrate materials, with glass rapidly gaining popularity as disk sizes decrease. Plastic disks, some with servo patterns pressed into the surface during the molding process, are also entering the market.

Aluminum disk substrates are cut from special aluminum sheet that is optimized for flatness and surface smoothness. The disks are polished and then plated with an undercoat of nickel phosphorus (NiP).

Glass and glass/ceramic substrates are rapidly displacing aluminum disks. Glass offers a very smooth surface and a higher stiffness than aluminum. The benefits are a lower flying height with fewer surface defects and a disk that is more robust.

The aluminum or glass disk is coated with multiple layers that include foundation layers, the active magnetic surface and protective overcoats. Although earlier disks were spin coated with a slurry resembling the coating for magnetic tape, modern disks are prepared by plating and ion bombardment. Hard diamond-like overcoats and surface lubricants protect the magnetic layer from accidental contact with the head.

28.5.7 Hard Disk Drives

Rotating disk drives offer very rapid random access to a huge array of data, Fig. 28-54. This yields two very important benefits. First, the rewind, fast forward, and autolocate functions of a tape recorder become nearly instantaneous. This speeds up operation, especially during editing sessions.

A second and much more important benefit is the ability to rearrange the output data. Assuming a fast host computer with versatile digital audio workstation (DAW) software, the user can construct a song from a multitude of track segments almost as if he or she cut each track of a reel of multitrack tape into a thin ribbon and then chopped and spliced the individual ribbons back together to arrange the song. This incredible versatility has fueled the rapid replacement of analog audio tape recorders in recording studios. Even when an analog recorder is employed for the initial capture of the music, the analog tracks will probably be digitized and loaded into a DAW for editing and mixing.

To demonstrate how data are stored on a spinning disk, consider the inner workings of a representative single-platter drive. Although this unit is only a single-platter, 15 Gb entry-level drive under $100, this drive’s areal density of 22.5 Gb/in² led the industry when the drive was introduced in early 2001. We will look at the major subsystems to rotate the disk, position
The spinning disk is an aluminum or glass disk covered with a magnetic layer. Since smaller disks are flatter and more rigid, the trend has been downward in disk size from 14 inch diameter disks in 1960 to disks ranging from 3.5 inch down to 1.8 inch diameter today. Smaller disks can spin faster and rotation rates have risen from about 3000 rpm for the 14 inch disks to targeted speeds of 22,000 rpm for high-performance small disks.

These higher rates and tighter tolerances are exceeding the capabilities of the ball bearings that support the spinning disk, requiring new types of bearings. Fluid dynamic bearings replace the rolling balls in a ball bearing with a film of oil that is less than one-tenth the thickness of a human hair. In addition to providing tighter tolerance, the fluid dynamic bearing is quieter, longer lasting, and more rugged.

The spindle assembly includes an integral motor for spinning the disk. The power required from the spindle motor due to aerodynamic drag of the spinning disks is

\[ P \propto n \times \omega^{2.8} \times r^{4.6} \]

where,
- \( n \) is the number of platters,
- \( \omega \) is the angular velocity of rotation,
- \( r \) is the disk radius.

Additional power is required to overcome the friction and viscous losses of the bearings.

The magnetic data on the disk is accessed by magnetic heads flying over the surface of the disk. The very close spacing between the head and disk is maintained by a cushion of air generated by the aerodynamic design of the head. For our example drive, the head-to-disk spacing is 0.6 \( \mu \text{in} \) (15 nm) or \( \frac{1}{40} \) the wavelength of orange light.

Since the head cannot fly when the disk rotation stops, provisions must be included to transition from flying to nonflying status. Some drives land the heads on a dedicated portion of the disk periphery appropriately known as the landing zone. Other drives move the head to an extreme position to engage a parking ramp that holds the head away from the disk. The parking ramp also provides protection from shock and vibration incurred during shipping or handling of the computer.

Some of today’s disk surfaces are so smooth that the head will literally stick to the surface after landing. To overcome this stiction, the surface of the disk may be textured with microscopic bumps. The bumps may require an increase in the flying height, thereby reducing the maximum storage density of the disk.

To avoid these problems, the example drive uses a parking ramp at the center of the disk. The resulting ability to use an untextured disk surface is a major reason for this drive’s very high packing density.

The flying head is mounted on metallic spring matrix called a gimbal that allows the head to assume the proper flying attitude parallel to the disk surface. The gimbal is at the end of a long support arm called a flexure that cantilevers the head above the disk surface. The flexure lightly presses the head onto the disk surface to overcome the aerodynamic lift generated by the head.

The flexure is attached to an actuator that moves the head to the appropriate track of magnetic data on the disk surface using either linear or rotary motion. The linear actuator is very similar to the voice coil and magnet of a loudspeaker. A current in the coil produces a magnetic field that interacts with the field of the permanent magnet to create a linear force along the axis of the coil. A sled assembly with ball bearing wheels
maintains alignment of the coil as the head moves in a straight line along a radius of the disk.

A rotary actuator is a pivoting device that moves the head in an arc across the surface of the disk. The arc causes the head to depart from absolute tangency to the disk, but the error is relatively small since only 30% of the disk’s radius contains data. The actuating force is once again generated by a coil and magnet, but in this case the components are curved to match the pivoting motion. The support bearings and structure of the rotary actuator are simpler and less expensive than the linear actuator’s sled.

The actuators are part of a closed loop control system that moves the head to the appropriate radius on the disk. The desired address comes from a translator that converts a data address into a physical radius. The feedback to the control system is the actual data that is being read from the disk. Older systems used one surface of one disk in the stack of disks for nothing but positioning information. These dedicated servo drives contained prerecorded positioning information defining the radius and the angle of rotation. The actuator would move to match the desired radius to the data being read from the servo platter.

Newer drives save the expense of a servo platter by using information written on the normal data surfaces. These embedded servo schemes have short blocks of address information scattered around each circular track at regular intervals. These systems can also sense changes in the readout pattern when the head begins to move off the centerline of the data track.

Embedded servos have allowed designers to greatly increase the track density on the surface of the disk. Any small changes due to temperature and wear are actively sensed at the exact point where the data is being written and read, not at a remote location on another disk. Our example drive uses an embedded servo to pack 40,000 tracks per inch of radius.

The current trend is to utilize digital signal processor (DSP) chips for the tracking servo and spindle motor control. Other electronics tasks include a buffered digital data interface with the host computer, error detection and correction and encode/decode of the data to optimize the read/write process.

All of the mechanisms and servos in a disk drive would be useless if any dirt gets into the system. When a head is flying at a spacing of less than 1 μinch, even a particle of cigarette smoke can cause a catastrophic collision that might destroy the head and/or disk. To avoid contamination problems, the entire head and disk assembly are enclosed in a clean environment. Any air entering the sealed head/disk assembly for cooling or atmospheric pressure balancing passes through a filter that traps all dirt.

### 28.5.8 Hard Disk Electronics

The hard disk drive also features very dense circuit packaging. A typical drive has less than 20 in² of circuit board with just a few highly integrated chips. The block diagram of Fig. 28-55 shows the basic functions that are squeezed into this small space.

![Block diagram of a hard disk drive.](image)

The spindle motor controller provides the servo loop that turns the disk at a constant speed. The controller also provides the acceleration and deceleration profiles during startup and shutdown.

The actuator servo controls the linear or rotary voice coil motor that positions the head actuator at the proper radius of the disk. This servo must provide rapid seeks to the desired data and track any eccentricities or other disturbances that might cause a tracking error. The current trend is to program custom DSP chips to serve as digital servos for both the actuator servo and spindle motor controllers.

The data path circuitry provides many of the interleaving, error correction, and modulation code functions described in conjunction with the digital tape recorder above. In addition, the interface provides data format-
checks for media defects, marking bad sectors and relo-
garding sector and block lengths. Formatting also
defines the nature of the digital data blocks
the correct physical locations. In addition, to properly and accurately move the media and heads to
user data can be recorded.

The trend is toward higher levels of integration in
disk drives, with more of the very high-speed circuitry moving closer to the read/write head to avoid delays and waveform distortions due to wire lengths and inductances. (Electricity travels about 1 foot in a nanosecond, and 1 ns is the period of one cycle of a gigahertz signal.)

The adoption of fluid dynamic bearings permits higher disk rotation speeds that reduce the latency time for a desired block of data to rotate to the head’s location. The average latency is half the rotation period for the disk. For a 15,000 rev/min (250 rev/s) disk drive, the average latency is 2 ms.

28.5.9 Formatting Media

Digital media typically require one or two stages of preparatory recordings of control information before user data can be recorded. Low-level formatting involves basic housekeeping tasks that allow the drive to properly and accurately move the media and heads to the correct physical locations. In addition, high-level formatting defines the nature of the digital data blocks regarding sector and block lengths. Formatting also checks for media defects, marking bad sectors and relocating data to good sectors.

Formatting may also include writing control tracks with synchronization and address information. To illustrate why, consider a helical scan digital audio tape recorder. We can start with a blank tape and begin a recording. The machine records the helical stripes of data with embedded address information and a control track along the edge of the tape to facilitate synchronizing the linear tape speed with the rotations of the helical drum during subsequent playbacks. If we stop the recording, we also stop the recording of all of the address and synchronizing data.

If we wish to restart the recording by punching in at our previous exit point, we must seamlessly append address and synchronization data to the ends of the previously recorded tracks. But what happens if the recorder is running at a slightly different speed, perhaps due to the recorder warming up, when we punch in? Whenever we play back the tape, the recorder must abruptly change the tape speed at the punch-in point.

A better technique is to prerecord or format the entire tape with address and synchronizing information. This will allow us to locate any address on the tape in a continuous manner, and the tape speed will be constant throughout the tape.

Formatting a tape or disk can be a very time-consuming task. Tapes typically must run through the machine at normal speed; hence a 30 minute tape would require 30 minutes for formatting. Preformatted tapes with prerecorded address and synchronization tracks are now available from the tape manufacturers for some of the digital audio formats. In addition to saving time, the preformatted tapes also reduce wear on the recorder.

Hard disk formatting may vary from minutes to many hours, depending on the operation. The lengthiest operation is repacking all of the data on a disk. After a file has been changed a number of times, the physical file may be many sections scattered widely across the surfaces of the disks, leaving unusable islands of updated and deleted data. The repacking operation relocates and reassembles the files as contiguous data, freeing up the wasted space. Repacking also checks the disk surface for defects. If a sector is contaminated with errors, the drive may try several read operations to recover the data. Some drives will also move the head off-track slightly to recover poorly written tracks. Bad sectors are marked so that they will not be reused.

Although audio tape recordings do not contain any addressing and synchronizing information embedded within the audio recording, some applications require adding a track of SMPTE/EBU timecode for synchronization or editing. For live production work, the time-code track will be recorded on all of the audio and video machines to allow later synchronization of multiple machines.

Timecode is also used during the editing process to identify segments that are to be assembled onto a master reel. Timecode is first prerecorded or striped onto the master reel to allow the editing computer to precisely locate the destination addresses of all of the edits. The computer then locates the appropriate segments in the timecodes on the source reels and copies the audio and/or video onto the designated timecode section of the master reel.

28.5.10 Long-Term Storage

A common question is “How do I store my digital data when I finish a project?” Many users have decided that
hard disk drives are cheap enough to just store the hard drive as the archival copy. This strategy is fraught with problems that could come back to bite the user. Disk drives have several failure mechanisms that can render the data unrecoverable over time.

Some systems park the head on the surface of the disk. Over time, the lubricant that is embedded in the disk’s coating can migrate to the surface and “glue” the head to the disk. This problem is avoided with drives that have parking ramps to hold the heads off the surface of the disk when the disk drive isn’t running.

Another problem is the spindle bearings. If the drive is stored for extended periods, the lubricant may degrade or migrate away from the critical bearing surfaces. This can lead to bearing failure when the drive is restarted.

The manufacturer rates a typical drive for about three years of useful life. There is no separate specification regarding storage life. Expecting a long storage life is an act of sheer faith.

The advantage of a tape or optical disk backup of the digital data is that the media and the mechanism are two separate items. The drive mechanism can be maintained and serviced without involving the media. The problem then becomes finding a working sample of the appropriate drive, or finding parts and a trained technician to fix a nonworking sample. Several digital tape formats have already reached the point at which finding a working tape deck to play the tapes is difficult or impossible. This problem will only get worse in the future.

If the data is valuable, the user should map out a backup strategy that will assure accessibility. This may require occasional copying of the digital information to newer formats. If nothing else, the user should have a schedule to verify every year or two that the original data can still be accessed without any degradation.

### 28.5.11 Data Interchange

Standards for compatibility of digitally recorded tapes have become much more difficult to achieve because of the wide range of choices open to the digital audio designer. The common problems of mechanical compatibility of tape speed and track format are still present, plus the sampling rate, data format, timing, and error-handling methods must also be compatible.

The rapid evolution of digital audio technology in these areas, which has already rendered several generations of digital audio recorders obsolete, has blunted any attempts at standardization at the media level. The point of data compatibility has moved up to the electronic interface between systems. At this level we find widely used standard protocols such as AES/EBU, SPDIF, and ADAT light pipe. Additional work, such as AES 31, to standardize file transfer protocols between hard disk systems will provide for the electronic transport of audio files throughout a facility via local area networks, and throughout the world via the Internet.

### 28.6 Tape Recorder Transport, Maintenance, and Testing

Maintenance begins with inspection and cleaning. Before starting the cleaning procedure, note the location and type of dirt and debris that has accumulated due to prior use. Excessive debris indicates that your recording tape is being slowly destroyed by the tape transport.

A deposit of very fine, silky threads indicates that the polyester base film of the tape is being scraped off by a sharp edge on a guide flange. Examine all edge guides for grooves cut into the flanges by the tape. Either reposition the guide to place an unworn surface in contact with the tape or install a new guide if the groove is severe.

Deposits of brown or black dust near the guides indicate that the edges of the tape are being scraped or deformed enough to break small chunks of coating from the edge of the tape. Check the tape tension and the height of the guides and reel hubs.

Any caked-on deposits on the surface of the guides or heads are very serious. Inspect the surface of the tape for scratch marks. If the tape surface is being scratched, continued use will destroy the tape. Correct the cause of the scratches before continuing.

Several types of cleaners are available for cleaning tape machines. Older head cleaners usually contained Xylol, a strong solvent, to aggressively dissolve tape residue. Milder isopropyl alcohol is a more popular solvent today, but avoid rubbing alcohol containing 30% water in favor of the 99% pure variety for topical antimicrobial use.

Use a soft swab moistened with cleaner to scrub the contact surfaces of the heads, guides, and capstans. Avoid drenching the swab. If the swab is too wet, solvent may run down the capstan shaft into the top bearing, washing away the bearing’s lubrication. Cotton swabs are suitable for most analog tape recorders but not for the delicate heads on a helical scan recorder. Use special lint-free swabs with more pliable sticks for cleaning rotary head machines.

When cleaning the head, always rub the swab in the direction of tape motion, never across the head sideways. Sideways scrubbing may peel away the edge laminations of the cores. Avoid scraping the face of the
head with the stick or core of the swab. Allow adequate time, typically 30 s, for the solvent to evaporate before rethreading the tape. You don’t want the leftover solvent dissolving your recording tape.

Xylene head cleaning solvents will attack some plastics including the lenses of optical sensors. Aggressive solvents may either partially dissolve or create a hard, glazed surface on some rubber rollers. If you notice a lot of residue on your swab or rag after wiping a seemingly clean roller, you are probably dissolving the roller, not cleaning it! Use general-purpose cleaners for the plastic components and rubber cleaners for the rubber rollers.

The tape must also be kept completely free of dirt. Keep the surface of the transport clean to avoid dirt being picked up during high-speed spooling. Always return the tape to its storage carton between uses. Do not stick your fingers through the windage cutouts in the flanges of the reel and touch the edges of the tape pack when handling the reel. (Skin debris from fingers is a source of tape dropouts!) In addition:

1. Avoid eating greasy foods while handling tapes.
2. Contamination due to finger oils and debris can be avoided during editing sessions by wearing lint-free editing gloves, which are available at most camera supply stores.
3. Keep cigarette ashes and other powdery materials far away from the tape.

The cooling system of the tape recorder should be cleaned periodically. Clean all air filters and cooling passageways and remove any dust buildup with a vacuum cleaner. Verify that all inlet or exhaust ports on the bottom of the machine are not obstructed by carpeting or dust and that adequate clearance for free airflow exists at the rear of the machine.

Following cleaning, diagnostic servicing should begin with verification that the tape guiding and tension at the heads is adequate to maintain good tape-to-head contact. Set aside one reel of tape, known as a shop tape because it typically comes from the maintenance shop, for testing. Run this tape in all modes while observing the tape at the heads and the guides. The tape should not run hard against either guide flange and there should never be any edge distortion. If edge distortion is noted, check for a bent guide or tension sensor arm. These components can be easily bumped out of alignment by a full reel of tape during loading or unloading.

On many machines a tape tension gauge of the type shown in Fig. 28-56 can be inserted in the tape path near the heads to measure the tension. For other machines that are too crowded in the head area, either the head assembly must be removed or a test location away from the heads must be used. Measure the tension at both the beginning and the end of the reel.

![Figure 28-56. Tension measurement. Courtesy Ampex Corp.](image)

Note that the stiffness of a piece of tape varies with the width, base film thickness, and type of tape. The tension gauge must be adjusted before use to read correctly for the specific tape sample being used on the transport. A calibration weight is included with the gauge for this purpose.

The following tape tension values indicate the range of tensions commonly encountered on studio recorders.

<table>
<thead>
<tr>
<th>Width</th>
<th>Tension Range</th>
</tr>
</thead>
<tbody>
<tr>
<td>¼ inch</td>
<td>3–4 oz</td>
</tr>
<tr>
<td>½ inch</td>
<td>4–8 oz</td>
</tr>
<tr>
<td>1 inch</td>
<td>6–12 oz</td>
</tr>
<tr>
<td>2 inch</td>
<td>10–24 oz</td>
</tr>
</tbody>
</table>

The nominal value for a given model of recorder will be found in the maintenance manual for the machine.

Some manufacturers specify tension measurements with a spring scale and a cord that is wrapped around a tape hub. Follow the recommended procedure.

Verify that the mechanical brakes or dynamic braking logic is stopping the tape smoothly from all modes and speeds without excessive force. A sticky brake solenoid or dirty brake band can quickly ruin your precious tape.

### 28.6.1 Speed

Absolute tape speed is extremely difficult to measure, even under the controlled conditions of a laboratory. One method available to maintenance personnel is to measure the frequency reproduced from a commercially available speed reference tape. The frequency read on the frequency counter must be corrected for any
difference between the tape tension on the playback machine and the tension value used by the manufacturer of the tape during the recording process. A correction table is furnished with the tape for this purpose.

A more common speed test is to check speed uniformity from beginning to end of a reel of a tape. The following procedure outlines the general technique:

1. Using an oscillator that has been operating long enough to reach stable conditions, record a reference tone in the range of 1–5 kHz at the head end of the tape.
2. Flip the reels so that the head end becomes the tail.
3. Using the console monitoring provisions of the console, mix the reproduced tone with the oscillator tone, listening for any major pitch differences. (If a significant error is detected, flip the reels again to verify that the oscillator has not shifted frequency.)

A more accurate version of this test is to use a frequency counter to measure the frequency at both ends of the reel. The speed error in percent is then calculated as

\[
\text{\% speed error} = 2 \left( \frac{\text{head} - \text{tail}}{\text{head} + \text{tail}} \right) \times 100\%. \tag{28-12}
\]

A speed error of 6\% will yield a pitch change of one half-tone step. Typical recorder specifications are in the range of 0.1–0.5\%. Machines with constant tape tension will generally have the least error.

Possible causes of speed error include excessive tension variations from beginning to end of the reel, tape slippage due to a worn capstan surface or pinch roller, inadequate pinch roller pressure, and unstable capstan speed.

Assuming that tape tension has already been determined to be correct on both sides of the capstan, the next test is to check pinch roller pressure. First, inspect the pinch roller for glazing of the roller surface or excessive wear. Fig. 28-57 shows roller wear patterns that may reduce the traction between the tape and capstan.

Next, a spring scale is coupled to the top (and the bottom, if possible) of the pinch roller yoke or arm, as shown in Fig. 28-58. The scale is pulled at right angles to the support arm with just enough force to disengage the roller from the capstan. The force reading at disengagement should be compared with the recorder manufacturer’s recommended value.

For some transports the pinch roller force is set as a fixed number of turns of a nut or screw. For this case the roller linkage is first tightened to bring the roller into light contact with the capstan, and then the recommended clamping force is applied by tightening the adjustment by the specified number of additional turns.

The surface of the capstan may become so highly polished by the abrasive action of the tape that slippage will persist for the correct values of tension and pinch roller pressure. In this case the capstan must be resurfaced by plating or sandblasting or both to restore the required traction.

In very rare cases the capstan motor may actually slow down due to excessive loading caused by bad motor bearings or high tension. Bushing bearings, which are used on many direct-drive ac synchronous capstan motors and some capstan pinch rollers are an especially noteworthy problem. Periodic lubrication of these components is essential to maintain low-friction operation. Although these components may appear to spin freely when turned by hand in an unloaded state, the friction can rise dramatically when the engagement solenoid exerts several pounds of side load on the bearings. The resulting drag and wear due to dry bearings may produce substantial speed errors. One small drop of oil can make all the difference in the world. To avoid problems, follow the manufacturer’s recommended lubrication schedule.

A simple strobe light, as shown in Fig. 28-59, can be used to check the running speed of the flywheel or fan on the shaft of the synchronous capstan motors. Package the components inside a discarded plastic pen housing with the tip of the bulb protruding. Hold the light close enough to the rotating device to observe a reflection. The reflected pattern must remain stationary.
under all conditions of tape pack and speed. Induction motors, which do not run at synchronous speed, will always yield a moving pattern.

Crystal-referenced servos may falsely appear to vary in speed when tested with a strobe light if the frequency of the ac mains driving the strobe varies. An oscilloscope and frequency counter are required to properly verify correct servo operation.

### 28.6.2 Flutter

Speed drift represents only the very lowest frequency components of the spectrum of speed errors. Measurement of the higher-frequency flutter components requires a specialized frequency demodulating instrument called a **flutter meter**. As seen in Fig. 28-60, the flutter meter may resemble the phase-lock servo of Fig. 28-4. The reference signal from the crystal clock must pass through the record/playback process of a tape recorder before being applied to one of the phase comparator inputs. The low-pass filter and voltage-controlled oscillator simulate a large flywheel that stores the average value of the playback frequency. By applying the average value to the second phase comparator input, the phase comparator output will consist of only the short-term variations from the average speed. These variations are divided into various frequency bands for further analysis. The metering circuit provides a convenient quantitative measurement of the speed variations.

Just as the sampling rate of a digital audio system determines the highest possible audio frequency that can be encoded, the frequency of the test tone determines the range of flutter components that can be measured by any frequency demodulator. The typical upper frequency is about 0.4 times the test frequency. Due to the nature of the sidebands that are required to operate the demodulator, a typical 18 kHz audio bandwidth can support a 12.5 kHz test tone and a flutter bandwidth of 5 kHz. This measurement technique, referred to as **high-band flutter measurement**, is supported by Audio Precision.

Unfortunately, most flutter meters use a low-frequency test tone of 3150 Hz and cut off all flutter components above 250 Hz, ignoring many flutter components caused by modern-day servo systems and virtually all scrape components due to the elastic vibration of the tape. To make matters worse, most flutter specifications are made through a flutter weighting filter that only measures flutter components near 4 Hz. Proper maintenance requires that a broader spectrum test be implemented to check for any possible problem.

Two methods of specifying flutter performance are commonly encountered. If a flutter-free test tape is available, the flutter reading obtained in the playback mode can be reported. Most professional recorders, however, have flutter levels that are equal to or better than any available test tapes. In this case, recording and
reproducing on the same machine is appropriate. The method of testing should be noted as part of the performance report.

Although test and diagnostic work is commonly conducted with simultaneous record/reproduce, the final testing should always be conducted in the reproduce-only mode. The tape should be started and stopped several times, with the various transport elements reoriented by hand between runs, to achieve a sampling of random combinations of the various record and playback flutter components. The arithmetic average of the maximum values of each sample throughout the reel, excluding any infrequent short-duration bursts, is the reported value.

If the flutter readings are excessive, the next step is to analyze the flutter waveform for information to help pinpoint which tape path component is defective. The following techniques are helpful in isolating the culprit:

1. The human ear and brain form a very versatile spectrum analyzer that frequently can immediately identify the defective component from the characteristics of the flutter signal being reproduced in a monitor loudspeaker. Take advantage of this free portable instrument that is always at your disposal by listening to the demodulated output from the flutter meter.
2. The various selectable filters of the flutter meter can be used to isolate the general portion of the flutter spectrum in which the offending component is generating flutter.
3. The expected rotational flutter rate from a rotating component can be calculated from the diameter of the component and the tape speed using the expression

   \[ \text{Flutter frequency} = \frac{S_T}{\pi d} \]  

   (28-13)

   where,
   
   \( S_T \) is the tape speed,
   
   \( d \) is the diameter of the component.

   These frequencies can range from approximately 0.5 Hz for the once-around of full reel of tape to 60 Hz for a small-diameter capstan shaft. Some manufacturers include a table of these flutter frequencies in their maintenance manuals. The small balls and retainer clips inside the ball bearings used in many rotating components generate additional not-so-obvious flutter components at frequencies higher than the once-around rate of the bearing.
4. If the flutter is very regular, the flutter pattern displayed on the oscilloscope can be utilized to calculate the frequency of the dominant flutter component. Any flutter components caused by ac motors or power supply ripple will remain stationary on the oscilloscope screen if the sweep triggering mode is set to line.
5. A common search technique is to deliberately create flutter by attaching a small piece of masking tape to the surface of a rotating component. The rate of the flutter blips created by the masking tape can then be compared with the unknown component to determine if the two rates are identical.
6. Note any change in the flutter spectrum when each of the auxiliary rotating components such as guides and flutter idlers is stalled. Stalling the defective component will cause the offending flutter component to cease. A notable exception to this case is the scrape flutter idler. Stalling a scrape flutter idler should usually double or triple the scrape flutter amplitude. If little or no increase is noted, the idler is not functioning properly. Check for dirty or damaged bearings that would keep the idler from spinning freely.

The following procedure describes a flutter test using a wide-bandwidth flutter meter, such as is shown in Fig. 28-61. The general technique also applies to other meters.

![Flutter meter](image)

**Figure 28-61.** Flutter meter. Courtesy MANCO.
reading is the composite value of all flutter components in the frequency band of $0.5–250\ \text{Hz}$, including flutter due to not only the rotating capstan, roller, and guides and their associated bearings but also any ac-power-related motor torque pulsations.

7. Select the Wtd. filter. The bandwidth is now reduced to $0.5–20\ \text{Hz}$, to emphasize the once-around rates due to eccentricities of the rotating components. Capstans and rollers with diameters of $\frac{1}{2}–2\ \text{in}$ (12–50 mm) are major contributions in this band.

8. Select the $250\ \text{Hz}–5\ \text{kHz}$ bandpass filter labeled $\leftrightarrow$. The dominant component in this range is scrape flutter, which typically peaks at $3–4\ \text{kHz}$ for most recorders. Instabilities or oscillations of the capstan or spooling servos, which tend to occur in the $100–500\ \text{Hz}$ range, may also be evident.

9. If the machine is equipped with a scrape flutter idler, stall the idler by pressing the point of a pencil against the top of the idler. The scrape flutter component should typically rise to two or three times the normal value. If little or no rise or even a decrease is noted, the scrape flutter idler is not functioning properly. Clean and lubricate the idler bearings according to the manufacturer’s instructions. Use the flutter meter to obtain optimum positioning of the idler after cleaning.

10. Select the $5\ \text{kHz}$ filter. This overall reading covers the entire range from $0.5\ \text{Hz}–5\ \text{kHz}$.

28.7 Tape Testing

Contrary to popular belief, not all tape that reaches the customer’s hands is fault free. Although the tape manufacturers are to be commended for the very high standards of excellence that are maintained, the customer must be prepared to deal with the bad rolls of tape that slip through the manufacturer’s quality control screening. The problems that do arise can usually be traced to one of the seven steps in the manufacturing process:

1. The basic recipe of approximately a dozen major ingredients that form the oxide mixture must be correctly formulated. Each ingredient must be pure and must be measured correctly. Errors in mixing and experimental formula modifications often lead to nondurable oxides that shed debris onto the guides and heads.

2. The mixing of the ingredients must be thorough but not excessive. Inadequate mixing leads to high modulation noise and high background noise.

Excessive mixing reduces noise but increases print through.

3. The coating process must apply a uniform coating across the width and length of the tape. The coating is applied to jumbo rolls that range from $18–36\ \text{inch}$ (0.5–1 m) in width. To monitor the entire width of one of these rolls fully would require over 400 channels of conventional record/reproduce circuits!

4. The tape is baked to remove solvents by passing the coated web through a multizone oven. Poor temperature control can lead to either brittle or soft oxides.

5. The jumbo roll is run through heated rollers that make the oxide denser to increase output and high-frequency response. This calendaring step is a major factor in determining the modulation noise content of the finished tape.

6. The tape is slit to the final width by a set of rotary shears. Poor slitting can produce ruffled edges, wavy or crooked tape, and excessive oxide and backing debris on the recording surface.

7. The tape is rewound onto reels or hubs, tested, and then packaged for sale. The tape cartons usually pass through a very large degausser so that no residual signals are left on the tape.

Mistakes during the manufacturing process create four types of problems. The most common of these is signal amplitude variations, which are due to either a nonhomogeneous magnetic dispersion or erratic tape-to-head contact due to physical distortions of the tape. Other common problems include excessive noise or distortion and high print through.

A common method of testing the signal instability and dropouts is to observe the amplitude variations of a sine-wave signal on either an oscilloscope or a VU meter. While these techniques give some insight into the performance of the tape, they do not yield a quantitative value that can be used for determining acceptable limits of performance.

A more informative method is to amplitude demodulate the test signal to remove the steady tone and magnify the fluctuations. If the output of the demodulator is properly filtered and fed to a metering circuit, quantitative values for the fluctuations in various test bandwidths can be read.

Unlike other flutter test instruments, the flutter meter shown in Fig. 28-49 contains amplitude-demodulating circuitry to be used for testing tape. The AM test configuration is identical to the previous flutter setup, except that the FM/AM selector is set for AM mode testing to connect the phase-lock loop as a synchronous amplitude demodulator. The AM meter ranges, which
are ten times larger than the flutter ranges, are labeled below the meter ranging pushbuttons.

The AM reading for 15 in/s (38 cm/s) operation is typically 0.5% rms for a good roll of tape on a professional recorder. The texture of the demodulation products coming from the audio monitor should be a low rumbling with only occasional moderate bursts. The high-pass filter should produce a uniform hiss.

Typical symptoms of bad rolls of tape include readings that are approximately three times higher than the normal readings or very large frequent bursts that drive the meter pointer hard against the upper stop. Routine studio tests of large quantities of tape stock over a period of two years has shown that these easily spotted characteristics are good indicators of defective tape.

Although amplitude variations are symptomatic of bad tape, the tape transport and heads are also possible sources. If the tape is not being held snugly against the faces of the heads due to inadequate tape tension, the tape may suffer irregular spacing loss. Other contributors are dirt on the heads or heads that have been worn so flat that the gap is no longer pressed firmly against the tape. Mechanical misalignments, such as a twisted head or improperly positioned guides or scrape flutter idlers, can also degrade the contact between the tape and head.

Misadjustments of the bias amplitude or even-order distortions of the bias or erase waveforms can also produce excessive AM levels. Always verify that the bias levels and tuning are correct before condemning the tape.

A simple method of avoiding embarrassment when a defective roll of tape is suspected is to recheck the machine with a reference roll of the same type of tape that is known to be good. If changing from the reference roll to the suspect roll causes a large increase in AM content, then the tape is the source of the problem.

Since none of the tape manufacturers supplies information that is useful for specifying the AM performance of a tape, the user must generate data by testing several rolls of tape on machines. Once this process is begun, subsequent additions to the database will provide even more insight into the expected range of values.

**28.8 Magnetic Head Troubleshooting and Maintenance**

Troubleshooting any piece of complex equipment requires a methodical search technique to isolate the source of the problem quickly. The most productive technique is to conduct a series of tests that subdivide the faulty portion of the total system into smaller and smaller parts until the fault source is finally isolated.

Applying this technique to a magnetic tape recorder would lead to partitioning questions such as:

1. Is the problem associated with the tape drive, the audio circuitry, or the control logic?
2. Does the fault occur during recording, playback, and/or input monitoring?
3. Is the problem due to the recorder or the roll of tape?
4. Is the problem similar at both tape speeds?
5. Is the problem the same throughout the reel of tape?
6. Does temperature or running time have an effect?

If the problem relates to the audio signal passing through the recorder, a fundamental question that must be answered is whether the problem is wavelength-dependent or frequency-dependent. Wavelength problems immediately isolate the problem to the interface between the moving tape and the heads. Frequency problems are often related to the audio circuits.

A very useful tool for separating wavelength problems from frequency problems is a simple device known as a flux loop shown in Fig. 28-62. The flux loop, which consists of nothing more than a few turns of fine magnet wire driven with a constant current from an audio oscillator, creates a magnetic field that simulates a perfect lossless piece of tape. When the flux loop is attached to the gap region of the playback head, the flux from the loop excites the head much like the primary winding on a transformer excites the secondary winding. This direct excitation eliminates all the wavelength effects associated with gap length, azimuth error, and thickness loss. If the reproduce electronics perform correctly when excited by the flux loop but still fail to reproduce a known-good prerecorded test tape correctly, the problem is a wavelength-dependent error at the head-to-tape interface.

The playback response from a simple flux loop is by no means flat. Since the dominant loss due to the coating thickness is not present for flux loop excitation, the high-frequency response with a flux loop will show a pronounced rise that relates to the particular reproduce equalization standard that is being utilized. NAB low-frequency equalization will also produce a roll-off below 50 Hz.

To simplify the measurement process, the oscillator signal feeding the flux loop is usually pre-equalized to accommodate these effects of the equalization standard. Fig. 28-62 includes a simple circuit for correcting the high end, with capacitor values for several common equalizations. (The 600 Ω impedance of the oscillator is
For a 50 Ω oscillator, multiply the capacitor values by 2.57.) The resulting high-frequency playback response of an equalized flux loop will be flat except for any residual high-frequency discrepancies due to eddy current losses or self-resonance of the playback head and cabling.

The flux loop can also be used in reverse as a pickup device to probe the magnetic fields generated at the gaps of the record and erase heads. If the driving network is disconnected and the loop connected directly to the inputs of an oscilloscope and meter, the relative magnitude of the bias and audio fields can be examined. Care must be exercised to correct for the 6 dB/octave rise in flux loop output voltage due to the inductive nature of the flux loop. (A resistor in series with the input and a capacitor shunted across the input can be used to create an integrating low-pass filter that will flatten out this 6 dB/octave rise.)

Details regarding the construction and use of a flux loop, along with detailed mechanical alignment procedures for azimuth, height, and tape wrap, are available from the various tape recorder manufacturers.

### 28.8.1 Head Relapping

The performance characteristics gradually change as the abrasive action of the tape wears away the faces of the heads. The resulting decreases in gap depth will reduce shunting effects, leading to an increase in efficiency for both the record and playback heads. Bias and audio levels must be gradually reduced to offset the rising efficiency. A critical point is reached, however, when the useful face of the head has been completely removed and the length of the gap begins to increase quickly with wear. The top end of the playback response will drop abruptly within a matter of only a few hours of use, rendering the recorder unusable. At this point, the head must be replaced to restore normal performance.

The heads on most recorders require attention long before this point of ultimate failure is reached. On most machines, the tape wears away the rounded apex at the gap of the head, leading to a drop in contact pressure with the tape at the gap. The tape begins to lift off the head slightly, creating erratic short-wavelength performance due to the spacing loss effect.

The common solution is to recontour the face of the head to restore the contact pressure. This process, known as *head relapping*, can be utilized two or three times during the useful life of a head to restore original performance. Although the average technician can be trained in the relapping process, the high cost of making a mistake with a 2 inch (50 mm) multitrack head assembly suggests that the more exotic relapping tasks should be handled by relapping specialists.

### 28.9 Routine Signal Alignment Procedure

A common problem arises with conventional recorders and alignment procedures—namely, that the procedures require a change in each adjustment to verify that the optimum point has been reached. This typically leads to not only the premature demise of many trimmer potentiometers (which are typically rated by the manufacturer for a life of 200 adjustment cycles) and head azimuth hardware, but also many operator errors due to the tedious nature of adjusting a multitrack machine that may have as many as 1000 adjustments.

If the operator is willing to adopt a philosophy that most of the adjustments are probably adequately close to optimum and that they need not be readjusted, then the alignment task shifts to looking for the exceptions to the norm rather than arbitrarily resetting everything. This strategy promotes better results since each iteration of the alignment procedure serves to fine-tune the results rather than to erase all past efforts and start afresh for each alignment with a high probability of error.

A few exceptions to the need for tweaking to verify proper performance are worthy of note. For example, head azimuth can be verified with a differential method that uses alternating test segments that have equal but opposite amounts of deliberate azimuth error. If the drop in level is equal for both directions of tilt, then the head must be correctly aligned to the correct vertical reference. No head adjustments are required if the test results are satisfactory.

A similar noninvasive test procedure for optimizing the bias level can be achieved if the bias system contains a master bias level trimmer that varies the level.
of bias for all tracks simultaneously. The bias level can be increased and decreased on all tracks with this single control to verify that the proper level of overbias is achieved without resorting to unnecessary adjustments on each track.

The following sequence of steps represents a comprehensive alignment procedure that would be appropriate whenever the proper performance of a recorder must be verified. Since the details of each step vary with machine type, the operator should consult the operator’s manual published by the manufacturer of the recorder:

1. Clean and inspect the tape transport. (Refer to Section 28.8).
2. Degauss the heads and guides. (Refer to Section 28.3.8). Before using a degauss, always verify that the tips of the unit are covered with a soft material such as plastic or tape that will not scratch the faces of the magnetic heads.
3. Calibrate the reproduce section of the recorder with a test tape of known accuracy. Several brands of standard alignment tapes are available for this purpose. Remember that the final results will be no better than the measurement standard that is being used as a reference.

First, verify the perpendicular alignment of the reproduce head with the short-wavelength azimuth test tone on the test tape. The azimuth and/or phase alignment of the head can be measured with an oscilloscope using either a Lissajous pattern or a dual-trace display or with a phase meter that reads phase error directly. If no specialized equipment is available, invert one channel and sum the inverted output with another channel that is not inverted. Phase alignment produces a deep null in the summed output. Since phase alignment at one frequency does not eliminate the possibility of a $360^\circ$ error, check the phase for several lower frequencies. The voice announcements on the alignment tapes provide a convenient multifrequency sample for this purpose.

Next, establish a convenient reference level for making playback frequency-response measurements. Check and adjust the high-frequency reproduce equalizer at 10 kHz to match this reference level. Once the equalizer has been set, sweep through the tones on the tape, noting the maximum deviations from the reference value. Readjust the equalizer and the reference level as necessary to obtain the desired degree of flatness.

When the results are satisfactory, write down the results for later comparison. Having a record of correct performance makes troubleshooting much easier.

Two pitfalls exist when making the previously discussed adjustments: one affects the reference level and the other affects the frequency-response and reference level. Some recorders use different track widths for the record and playback heads. For machines that have wider playback heads, the full-track test tapes used for most of the wide-tape formats will produce an enhanced output during testing. The reference level from the tape must be set above the 0 VU reference by the amount of this extra pickup due to the wider head when using the playback head. When setting the reference level for sync/overdub playback, the track width is correct, yielding a true 0 VU level that requires no correction.

If the record head has a wider track, then the normal playback level will be correct and the error will occur on the sync/overdub level.

The second problem is created by the fringing effect of long wavelengths that produces a rise in playback response at low frequencies whenever additional flux is present beyond the area being scanned by the reproduce head. Such a condition exists for playback of a full-track alignment tape and for test and alignment procedures that apply the same low-frequency signal to all tracks of the recorder simultaneously.

The fringing effect will first create a problem in establishing the correct reference level for the midband-level set tone. At 15 in/s and 30 in/s (38 cm/s and 76 cm/s) tape speeds, sufficient fringing may exist to create an error of approximately 0.5–1 dB, depending on the track format, tape speed, and geometry of the head cores and shielding. This extra fringing contribution in the reference tone also makes the high-frequency response appear to be deficient, tempting the operator to raise the equalizer adjustment. Consult the operator’s manual for the correct procedure and correction factors for a given model of recorder.

The final step in the reproduce alignment procedure is to set the level and equalization of the sync/overdub circuit. The operator may choose to defer the azimuth alignment of the record head until the following record alignment procedure if the heads have not been disturbed.

4. The record alignment begins with the verification and/or adjustment of the azimuth setting of the record head. Using the playback head as a standard, set the record head alignment while recording a
short-wavelength signal such as a 10 kHz or 15 kHz signal to give minimum azimuth or phase error using whatever method was used for the reproduce alignment procedure. This alignment should be rechecked after the bias and record equalization settings are made, since these adjustments can introduce varying amounts of phase delay.

The bias should be set by adjusting for the desired amount of overbias as recommended by the tape and machine manufacturer for the appropriate type of tape, record head gap width, and tape speed. Note that a 10 kHz signal at 30 in/s (76 cm/s) does not achieve the desired wavelength of 1.5 mils (38 μm) that is typically specified for bias adjustment. The test frequency must be changed to match the tape speed.

The bias should first be decreased to achieve deliberate underbias, and then slowly increased to the point at which a peak in the playback level is observed. Continue to increase the bias until the signal drops by the number of decibels desired. Typical overbias settings range from 2–5 dB for professional formats.

Once the bias is correctly adjusted, the input signal should be set to the frequency used as a reference during the playback alignment. The record gain control can then be set to produce the reference level when driven with the appropriate 0 VU input level.

Adjust the high-frequency record equalizer to match the record/play response as closely as possible to the alignment tape response noted previously. Smoothness in the midband frequencies is more important than trying to hold small errors at 15 kHz or 20 kHz.

Recheck the record head azimuth to verify that changes in bias and equalization have not created any phase differences. Readjust as necessary until all parameters are optimized.

Set the record gain preset and the input monitor gain calibration to achieve a 0 VU reading in all monitor modes.

5. After the record section has been aligned, a final test and alignment of the low-frequency playback equalizers can be undertaken. To eliminate all the fringing problems previously mentioned, the equalizers should be set in the record/play mode with signal being applied to every other track. Make small adjustments as required to optimize the smoothness of the response.

If any large discrepancies are noticed, rerun the alignment tape. Any failure in the low-frequency record equalizer circuits, such as a faulty switching component, will create an error that should be obvious if a large correction is required. If any doubt still exists, record a full-frequency sweep and then flip the reels over to play the tape backward. The alignment should be similar within a few tenths of a dB to the values set in the forward direction.

6. The alignment procedure is not completed until the noise level and erasure have been checked. Record a signal at +6 VU, rewind the tape, and then erase the signal. Listen on the monitor speakers to the level of the residual signal and to the subjective nature of the tape noise. The tone should be either completely eliminated or well buried in the tape noise. The noise should be a smooth hiss without large or frequent bursts or crackling. All tracks should be similar in performance. Also, check for objectional clicks and pops when changing modes.

Although these noise and erasure levels can be read from instruments, the operator should take the time to listen to the machine before issuing his or her stamp of approval. Many sessions have died aborning because the recorder was never given a final listening test after alignment.

The previous procedure does not include several steps that are more appropriately considered to be maintenance routines. Examples include tuning of the bias and erase sources, tuning of bias traps, checking meter calibration, and testing distortion levels. These tests are not required on a day-to-day basis.

As a final note on alignment, never gloss over large discrepancies. The corrections that should be required for this alignment procedure should be on the order of a small part of a dB, not several dB. Whenever a large change seems required, stop long enough to determine why such a large change is necessary. Look for faulty components and recheck your own procedure. Recheck the maintenance log to establish the proper level of performance that should be expected. Heeding the small symptoms may help you avoid a serious catastrophic failure.

28.10 Automated Alignment

The onslaught of digital technology has provided the tools to control the variable alignment adjustments of a tape recorder with a microprocessor. Multiple sets of calibration constants can be stored in nonvolatile memory, permitting rapid changes of operating speeds, equalization standards, reference flux levels, and tape types.
Once the provisions for automated adjustment are made available, three methods of alignment are possible. Under the simplest mode, the operator performs a manual alignment with the calibration constants being stored for later use. This method permits rapid changeovers, but does not simplify bias and equalization adjustments to optimize a specific roll of tape.

If the microprocessor can be provided with input information from the metering devices on the individual tracks, then calibration programs can be automatically executed without operator intervention. The program contains the “strategy” for alignment, including desired amounts of overbias, equalization adjustment frequencies, and operating levels. Beware that such systems use an inferred adjustment technique which does not actually test many of the critical parameters. For example, the recorder will set the bias level for minimum distortion based on an overbias criterion at a specified frequency. In reality, the machine doesn’t have the ability to measure distortion. The strategy only infers that overbiasing by the desired amount corresponds to minimum distortion. Unfortunately, if a malfunction exists that causes abnormal operation, the adjustment routine may not detect the symptoms.

Nearly automatic calibration can be implemented by connecting external automated test equipment such as an Audio Precision System One test set to the machine through an external intelligent controller such as an IBM-compatible computer. A remotely controlled input/output switching matrix will also be necessary for multitrack machines. An operator is still required to adjust nonautomated devices such as head azimuth and to change tape reels for calibration tapes and sample stock. The calibration program of the intelligent controller sequences through a comprehensive set of tests which rigorously exercise the machine. Parameters such as harmonic and intermodulation distortions, crosstalk, erasure, flutter, speed, noise, and phase can be tested against absolute standards of acceptance.

Hopefully, the advent of inexpensive DSP (digital signal processor) chips will allow manufacturers to include the diagnostic equipment as a part of the built-in calibration hardware.

A final word of caution is appropriate at this point. Many operators and test technicians ignore symptoms that indicate problems are developing in a tape recorder. A good example is the frequent need to boost the high-frequency equalization adjustments of a recorder. A properly operating machine should not show such trends, but a gradually deteriorating head would create just such a problem. Simply readjusting without determining the cause of the change wastes an opportunity to fix a problem at an early stage before it grows to catastrophic consequences. Try to avoid problems by fixing things before they break completely.

29.1 Introduction to MIDI

Simply stated, Musical Instrument Digital Interface (MIDI) is a digital communications language and compatible specification that allows multiple hardware and software electronic instruments, performance controllers, computers, and other related devices to communicate with each other over a connected network. MIDI is used to translate performance- or control-related events (such as playing a keyboard, selecting a patch number, varying a modulation wheel, triggering a staged visual effect, etc.) into equivalent digital messages and then transmit these messages to other MIDI devices where they can be used to control sound generators and other performance parameters. The beauty of MIDI is that its data can be easily recorded into a hardware device or software program (known as a sequencer), where it can be edited and transmitted to electronic instruments or other devices to create music or control any number of parameters.

In artistic terms, this digital language is an important medium that lets artists express themselves with a degree of flexibility and control that wasn’t possible at an individual level beforehand. Through the use of this performance language, an electronic musician can create and develop a song or composition in a practical, flexible, affordable, and fun production environment.

The word *interface* refers to the actual data communications link and software/hardware systems in a connected MIDI network. Through MIDI, it’s possible for all of the electronic instruments and devices within a network to communicate real-time performance and control-related MIDI data messages throughout a system to multiple instruments and devices via MIDI, USB, or FireWire networked data lines. Given that MIDI data can simultaneously transmit performance and control messages over multiple channels (usually in groupings of 16 channels per port), an electronic musician can record, overdub, mix, and play back their performances in a building-block fashion that resembles the multitrack recording process. In fact, the true power of MIDI lies in its ability to edit, control, alter and automate parts of a composition after the original performance has been recorded, allowing performance parameters to be easily altered in ways that are unique to the medium.

29.1.1 What MIDI Isn’t

For starters, let’s dispel one of MIDI’s greatest myths: MIDI doesn’t communicate audio it cannot create sounds! It is a digital language protocol that can only be used to trigger and/or control a device (which, in turn generates, reproduces, or controls the sound). Thus, the MIDI data and the audio routing paths are kept entirely separate from each other, Fig. 29-1. Even if they digitally share the same transmission cable (such as through USB or FireWire), the actual data paths and formats are distinct.

In short, MIDI’s control-related language can be thought of as the dots on a player-piano roll—when we put the paper roll up to our ears, we hear nothing. However, when the cutout dots pass over the sensors on a player piano, the instrument itself begins to make beautiful music. The analogy is pretty much the same with MIDI. A MIDI file or data stream is simply a set of instructions that pass through wires in a serial fashion, but when an electronic instrument interprets the data, we then hear sound.

As a performance-based control language, MIDI complements modern music production, by allowing a performance track to be edited, layered, altered, spun-dled, mutilated, and improved with relative ease under completely automated computer control and after the fact, during post-production. If you played a bad note, fix it. If you want to change the key or tempo of a piece, change it. If you want to change the expressive volume of a phrase in a song, just do it! Even its sonic character (timbre) can be changed! These capabilities merely hint at the power of this medium that widely affects the project studio, professional studio, audio or visual and film, live performance, multimedia, and even your cell phone!

29.2 The MIDI Message

From its inception in the early 80s, the MIDI 1.0 spec (which is still the adopted version to this day) must be strictly adhered to by those who design and manufacture MIDI-equipped instruments and devices. As such, users needn’t worry about whether the MIDI Out of one device will be understood by the MIDI In of a device that’s made by another manufacturer (at least the basic performance level). We need only consider the day-to-day dealings that go hand-in-hand with using electronic instruments, without having to be concerned with data compatibility between devices.

MIDI messages are communicated through a standard MIDI line in a serial fashion at a speed of 31,250 bits/s. These messages are made up of groups of 8-bit words (known as bytes), which are used to convey instructions to one or all MIDI devices within a system. Only two types of bytes are defined by the MIDI specification: the status byte and the data byte.
A status byte is used to identify what type of MIDI function is to be performed by a device or program. It's also used to encode channel data (allowing the instruction to be received by a device that's set to respond to a specific channel). A Data byte is used to associate a value to the event that's given by the accompanying status byte.

The most significant bit (MSB), the leftmost binary bit within a digital word within a MIDI byte, is used solely to identify the data's particular function. The MSB of a status byte is always 1, while the MSB of a data byte is always 0. For example, a 3 byte MIDI note-on message (which is used to signal the beginning of a MIDI note) in binary form might read as shown in Table 29-1. Thus, a 3 byte note-on message of (10010100) (01000000) (01011001) will transmit instructions that would be read as “Transmitting a note-on message over MIDI channel #5, using keynote #64, with an attack velocity (volume level of a note) of 89.”

29.2.1 MIDI Channels

Just as a public speaker might single out and communicate a message to one individual in a crowd, MIDI messages can be directed to communicate information to a specific device or series of devices within a MIDI system. This is done by imbedding a channel-related nibble (4 bits) within the status byte, allowing data to be conveyed to any of 16 channels over a single MIDI data cable line, Fig. 29-2. This makes it possible for performance or control information to be communicated to a
specific device or a sound generator within a device that’s assigned to a particular channel.

Whenever a MIDI device, sound generator, or program function is instructed to respond to a specific channel number, it will only respond to messages that are transmitted on that channel (i.e., it ignores channel messages that are transmitted on any other channel). For example, let’s assume that we’re going to create a short song using a synthesizer that has a built-in sequencer (a device or program that’s capable of recording, editing, and playing back MIDI data) and two other synths, Fig. 29-3.

1. We could start off by recording a drum track into the master synth using channel 10 (many synths are pre-assigned to output drum/percussion sounds on this channel).

2. Once recorded, the sequence will then transmit the notes and data over channel 10, allowing the synth’s percussion section to be heard.

3. Next, we could set a synth module to channel 3, and instruct the master synth to transmit on the same channel (since the synth module is set to respond to data on channel 3, its generators will sound whenever the master keyboard is played). We can now begin recording a melody line into the sequencer’s next track.

4. Playing back the sequence will then transmit data to both the master synth (percussion section) and the module (melody line) over their respective channels. At this point, our song is beginning to take shape.

5. Now, we can set a sampler (or other instrument type) to respond to channel 5, and instruct the master synth to transmit on the same channel, allowing us to further embellish the song.

6. Now that the song’s complete, the sequencer can then play the musical parts to the synths on their respective MIDI channels, all in an environment that allows us to have complete control of volume, edit, and a wide range of functions over each instrument. In short, we’ve created a true multi-channel working environment.

It goes without saying that the above example is just but one of the infinite setup and channel possibilities that can be encountered in a production environment. It’s often true, however, that even the most complex MIDI and production rooms will have a system, a basic channel and overall layout that makes the day-to-day operation of making music easier. This layout and the basic decisions in your own room are, of course, up to you. Streamlining a system to work both efficiently and easily will come over time with experience and practice.

### 29.2.2 MIDI Modes

Electronic instruments often vary in the number of sounds and/or notes that can be simultaneously produced by their internal sound-generating circuitry. For example, certain instruments can only produce one note at a single time (known as a monophonic instrument), while others can generate 16, 32, and even 64 notes at once (these are known as polyphonic instruments). The latter type is easily capable of playing chords and/or more than one musical line on a single instrument.

In addition, some instruments are only capable of producing a single generated sound patch (often referred to a voice) at any one time. Its generating cir-
cuits could be polyphonic, allowing the player to lay down chords and bass/melody lines), but it can only produce these notes using a single, characteristic sound at any one time (e.g., an electric piano, or a synth bass, or a string patch). However, the vast majority of newer synths differs from this in that they’re multi-timbral in nature, meaning that they can generate numerous sound patches at any one time (e.g., an electric piano, and a synth bass, and a string patch). That is it’s common to run across electronic instruments that can simultaneously generate a number of voices, each offering its own control over parameters (such as volume, panning, modulation, etc.) and—best of all—it’s also common for different sounds to be assigned to their own MIDI channels, allowing multiple patches to be internally mixed within the device (often top a stereo output bus), or to independent outputs.

As a result of these differences between instruments and devices, a defined set of guidelines (known as MIDI reception modes) has been specified that allows a MIDI instrument to transmit or respond to MIDI channel messages in several ways. For example, one instrument might be programmed to respond to all 16 MIDI channels at one time, while another might be polyphonic in nature, with each voice being programmed to respond to only a single MIDI channel.

47.2.2.1 Poly/Mono

An instrument or device can be set to respond to MIDI data in either the poly mode or the mono mode. Stated simply, an instrument that’s set to respond to MIDI data polyphonically will be able to play more than one note at a time. Conversely, an instrument that’s set to respond to MIDI data monophonically will only be able to play a single note at any one time.

47.2.2.2 Omni On/Off

Omni on/off refers to how a MIDI instrument will respond to MIDI data at its input. When Omni is turned on, the MIDI device will respond to all channel messages that are being received regardless of its MIDI channel assignment. When Omni is turned off, the device will only respond to a single MIDI channel or set of assigned channels (in the case of a multitimbral instrument).

The following list and figures explain the four modes that are supported by the MIDI spec in more detail.

- **Mode 1—Omni On/Poly:** In this mode, an instrument will respond to data that’s being received on any MIDI channel, and then redirect this data to the instrument’s base channel, Fig. 29-2A. In essence, the device will play back everything that’s presented at its input in a polyphonic fashion... regardless of the incoming channel designations. As you might guess, this mode is rarely used.

- **Mode 2—Omni On/Mono:** As in Mode 1, an instrument will respond to all data that’s being received at its input, without regard to channel designations. However, this device will only be able to play one note at a time, Fig. 29-2B. Mode 2 is used even more rarely than Mode 1, as the device can’t discriminate channel designations and can only play one note at a time.

- **Mode 3—Omni Off/Poly:** In this mode, an instrument will only respond to data that matches its assigned base channel in a polyphonic fashion, Fig. 29-2C). Data that is assigned to any other channel will be ignored. This mode is by far the most commonly used because as it allows the voices within a multi-timbral instrument to be individually controlled by messages that are being received on different MIDI channels. For example, each of the 16 channels in a MIDI line could be used to independently play each of the parts in a 16-voice, multitimbral synth.

- **Mode 4—Omni Off/Mono:** As with Mode 3, an instrument will be able to respond to performance data that’s transmitted over a single, dedicated channel; however, each voice will only be able to generate one MIDI note at a time, Fig. 29-2D. A practical example of this mode is often used in MIDI guitar systems, where MIDI data is monophonically transmitted over six consecutive channels (one channel/voice per string).

29.2.3 Channel Messages

Channel-voice messages are used to transmit real-time performance data throughout a connected MIDI system. They’re generated whenever a MIDI instrument’s controller is played, selected, or varied by the performer. Examples of such control changes could be the playing of a keyboard, pressing of program selection buttons, or movement of modulation or pitch wheels. Each channel-voice message contains a MIDI channel number within its status byte, meaning that only devices that are assigned to the same channel number will respond to these commands. There are seven channel-voice message types: note-on, note-off, polyphonic-key pressure, channel pressure, program change, pitch-bend change and control change.
Note-On Messages. A note-on message is used to indicate the beginning of a MIDI note. It is generated each time a note is triggered on a keyboard, controller, or other MIDI instrument (i.e., by pressing a key, hitting a drum pad, or by playing a sequence).

A Note-On message consists of 3 bytes of information, Fig. 29-4.

Note-on status/MIDI channel number, MIDI pitch number and Attack velocity value.

<table>
<thead>
<tr>
<th>Status/Ch#</th>
<th>Note #</th>
<th>Attack velocity</th>
</tr>
</thead>
<tbody>
<tr>
<td>(1–16)</td>
<td>(0–127)</td>
<td>(0–127)</td>
</tr>
</tbody>
</table>

Figure 29-4. Byte structure of a MIDI note-on message.

The first byte in the message specifies a note-on event and a MIDI channel (1–16). The second byte is used to specify which of the possible 128 notes (numbered 0–127) will be sounded by an instrument. In general, MIDI note number 0 is assigned to the middle C key of an equally tempered keyboard, while notes 21 to 108 correspond to the 88 keys of an extended keyboard controller. The final byte is used to indicate the velocity or speed at which the key was pressed (over a value range that varies from 0 to 127). Velocity is used to denote the loudness of a sounding note, which increases in volume with higher velocity values (although velocity can also be programmed to work in conjunction with other parameters such as expression, control over timbre, sample voice assignments, etc).

Note-Off Messages. A note-off message is used as a command to stop playing a specific MIDI note. Each note-on message will continue to play until a corresponding note-off message for that note has been received. In this way, the bare basics of a musical composition can be encoded as a series of MIDI note-on and note-off events. It should also be pointed out that a note-off message wouldn’t cut off a sound; it’ll merely stop playing it. If the patch being played has a release (or final decay) slope, it will begin this stage upon receiving the message.

A note-off message consists of three bytes of information, Fig. 29-5. Note-off status/MIDI channel number, MIDI pitch number and Attack velocity value.

<table>
<thead>
<tr>
<th>Status/Ch#</th>
<th>Note #</th>
<th>Attack velocity</th>
</tr>
</thead>
<tbody>
<tr>
<td>(1–16)</td>
<td>(0–127)</td>
<td>(0–127)</td>
</tr>
</tbody>
</table>

Figure 29-5. Byte structure of a MIDI note-off message.

A note-off message that contains an attack velocity of 0 (zero) is generally equivalent to the transmission of a note-off message. This common implementation tells the device to silence a currently sounding note by playing it with a velocity (volume) level of 0.

All Notes Off. On the odd occasion (often when you least expect it), a MIDI note can get stuck! This can happen when data drops out or a cable gets disconnected, creating a situation where a note receives a note-on message, but not a note-off message, resulting in a note that continues to playyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyyy
example, if six notes are played on a keyboard and additional aftertouch pressure is applied to just one key, the assigned parameter would be applied to all six notes.

A channel-pressure message consists of 3 bytes of information, Fig. 29-6: Channel-pressure status/MIDI channel number, MIDI note number, and pressure value.

Polyphonic-key pressure messages respond to pressure changes that are applied to the individual keys of a keyboard. That’s to say that a suitably equipped instrument can transmit or respond to individual pressure messages for each key that’s depressed.

How a device responds to these messages will often vary from manufacturer to manufacturer (or can be assigned by the user). However, pressure values are commonly assigned to such performance parameters as vibrato, loudness, timbre, and pitch. Although controllers that are capable of producing polyphonic pressure are generally more expensive, it’s not uncommon for an instrument to respond to these messages.

A polyphonic-key pressure message consists of 3 bytes of information, Fig. 29-7. Polyphonic-key pressure status/MIDI channel number, MIDI note number, and pressure value.

Program-Change Messages. Program-change messages are used to change a MIDI instrument or device’s active program or preset number. A preset is a user- or factory-defined number that actively selects a specific sound patch or system setup. Using this extremely handy message, up to 128 presets can be remotely selected from another device or controller. For example:

- A program-change message can be transmitted from a remote keyboard or controller to an instrument, allowing sound patches to be remotely switched, Figs. 29-8 and 29-9.
- Program-change messages could be programmed at the beginning of a sequence, so as to instruct the various instruments or voice generators to set to the correct sound patch before playing.
- It could be used to alter patches on an effects device, either in the studio or on stage. The list goes on.

A program-change message, Fig. 29-8, consists of 2 bytes of information: program-change status/ MIDI channel number and program ID number.

Pitch-bend Messages. Pitch-bend sensitivity refers to the response sensitivity (in semitones) of a pitch-bend wheel or other pitch-bend controller, which, as you’d expect, is used to bend the pitch of a note upward or downward. Since the ear can be extremely sensitive to changes in pitch, this control parameter is encoded using 2 data bytes, yielding a total of 16,384 steps. Since this parameter is most commonly affected by varying a pitch wheel, Fig. 29-9, the control values range from $-8,192$ to $+8,191$, with 0 being the instrument’s or part’s unaltered pitch.

Control-Change Messages. Control-change messages are used to transmit information to a device (either internally or through a MIDI line/network) that relates to real-time control over its performance parameters.
Three types of control-change messages can be transmitted via MIDI:

1. Continuous controllers: Controllers that relay a full range of variable control settings (often ranging in value between 0–127 although, in certain cases, two controller messages can be combined in tandem to achieve a greater resolution).
2. Switch controllers: Controllers that have either an off or an on state with no intermediate settings.
3. Channel-mode message controllers: The final set of control change messages ranges between controller numbers 120 through 127, and are used to set the note sounding status, instrument reset, local control on/off, all notes off, and MIDI mode status of a device or instrument.

A single control-change message or a stream of such messages is transmitted whenever controllers (such as foot switches, foot pedals, pitch-bend wheels, modulation wheels, breath controllers, etc.) are varied in real time. Newer controllers and software editors often offer up a wide range of switched and variable controllers, allowing for extensive, user-programmable control over any number of device, voice, and mixing parameters in real-time, Fig. 29-10.

A control-change message, Fig. 29-11, consists of 3 bytes of information: control-change status/MIDI channel number, controller ID number, and corresponding controller value.

As you can see, the second byte of the control-change message is used to denote the controller ID number. This all-important value is used to specify which of the device’s program or performance parameters are to be addressed.

Table 29-2 details the general categories and conventions for assigning controller numbers to an associated parameter (as specified by the 1995 update of the MMA (MIDI Manufacturers Association, www.midi.org). This is definitely an important section to earmark, as these numbers will be an important guide towards knowing and/or finding the right ID number that can help you on your path towards finding that perfect variable for making it sound right.

The third byte of the control-change message is used to denote the controller’s actual data value. This value is used to specify the position, depth, or level of a parameter. Here are a few examples as to how these values can be implemented to vary control and mix parameters.

In certain cases, greater resolutions than can be given by a single 7-bit course message (128 steps) might be available to increase a controller’s resolution. This is simply accomplished by adding an additional fine controller value message to the data stream, resulting in an overall resolution that yields an overall total of 16,384 discrete steps!

**Reserved for Channel Mode Messages**

128–129 Reserved  

The third byte of the control-change message is used to denote the controller’s actual data value. This value is used to specify the position, depth, or level of a parameter. Here are a few examples as to how these values can be implemented to vary control and mix parameters.

In certain cases, greater resolutions than can be given by a single 7-bit course message (128 steps) might be available to increase a controller’s resolution. This is simply accomplished by adding an additional fine controller value message to the data stream, resulting in an overall resolution that yields an overall total of 16,384 discrete steps!

**29.2.4 System Messages**

**System Messages.** As the name implies, system messages are globally transmitted to every MIDI device in
the MIDI chain. This is accomplished because MIDI channel numbers aren’t addressed within the byte structure of a system message. Thus, any device will respond to these messages, regardless of its MIDI channel assignment. The three system message types are system-common messages, system real-time messages, and system-exclusive messages.

**System-Common Messages.** System-common messages are used to transmit MIDI time code, song position pointer, song select, tune request, and end-of-exclusive data messages throughout the MIDI system or 16 channels of a specified MIDI port.

**MTC Quarter-Frame Messages.** MIDI time code (MTC) provides a cost effective and easily implemented way to translate SMPTE (a standardized synchronization time code) into an equivalent code that conforms to the MIDI 1.0 spec. It allows time-based codes and commands to be distributed throughout the MIDI chain in a cheap, stable, and easy-to-implement way. MTC quarter-frame messages are transmitted and recognized by MIDI devices that can understand and execute MTC commands.

A grouping of eight quarter frames is used to denote a complete time code address (in hours, minutes, seconds, and frames), allowing the SMPTE address to be updated every two frames. Each quarter-frame message contains 2 bytes. The first is a quarter-frame common header, while the second byte contains a 4-bit nibble that represents the message number (0–7). A final nibble is used to encode the time field (in hours, minutes, seconds, or frames).

**Song Position Pointer Messages.** As with MIDI time code, song position pointer (SPP) lets you synchronize a sequencer, tape recorder, or drum machine to an external source from any measure position within a song. The SPP message is used to reference a location point in a MIDI sequence (in measures) to a matching location within an external device. This message provides a timing reference that increments once for every six MIDI clock messages (with respect to the beginning of a composition).

Unlike MTC (which provides the system with a universal address location point), SPP’s timing reference can change with tempo variations, often requiring that a special tempo map be calculated in order to maintain synchronization. Because of this fact, SPP is used far less often than MIDI time code.

**Song Select Messages.** Song select messages are used to request a specific song from a drum machine or sequencer (as identified by its song ID number). Once selected, the song will thereafter respond to MIDI start, stop, and continue messages.

**Tune Request Messages.** The tune request message is used to request that a MIDI instrument initiate its internal tuning routine (if so equipped).

**End-of-Exclusive Messages.** The transmission of an end-of-exclusive (EOX) message is used to indicate the end of a system-exclusive message. In-depth coverage of system-exclusive messages will be discussed later in this chapter.

**System Real-Time Messages.** Single-byte system real-time messages provide the all-important timing element required to synchronize all of the MIDI devices in a connected system. To avoid timing delays, the MIDI specification allows system real-time messages to be inserted at any point in the data stream, even between other MIDI messages.

**Timing-Clock Messages.** The MIDI timing-clock message is transmitted within the MIDI data stream at various resolution rates. It is used to synchronize the internal timing clocks of each MIDI device within the system and is transmitted in both the start and stop modes at the currently defined tempo rate.

In the early days of MIDI, these rates (which are measured in pulses per quarter note, ppq) ranged from 24 to 128 ppq. However, continued advances in technology have brought these rates up to 240, 480, or even 960 ppq.

**Start Messages.** Upon receipt of a timing-clock message, the MIDI start command instructs all connected MIDI devices to begin playing from their internal sequences initial start point. Should a program be in midsequence, the start command will reposition the sequence back to its beginning, at which point it will begin to play.

**Stop Messages.** Upon receipt of a MIDI stop command, all devices within the system will stop playing at their current position point.

**Continue Messages.** After receiving a MIDI stop command, a MIDI continue message will instruct all connected devices to resume playing their internal sequences from the precise point at which it was stopped.

**Active-Sensing Messages.** When in the stop mode, an optional active-sensing message can be transmitted throughout the MIDI data stream every 300 milliseconds. This instructs devices that can recognize this mes-
System-Reset Messages. A system-reset message is manually transmitted in order to reset a MIDI device or instrument back to its initial power-up default settings (commonly mode 1, local control on, and all notes off).

System-Exclusive Messages. The system-exclusive (SysEx) message allows MIDI manufacturers, programmers and designers to communicate customized MIDI messages between MIDI devices. It’s the purpose of these messages to give manufacturers, programmers, and designers the freedom to communicate any device-specific data of an unrestricted length, as they see fit. In practice, SysEx data is commonly used to communicate real-time controller information (i.e., a remote controller surface will commonly use SysEx to communicate data to/from a MIDI-capable hard- or software device. SysEx can also be used to transmit and receive device-specific program, patch parameter and sample data from one instrument or device to another. For example, SysEx can be used to transmit patch and overall setup data between identical make and (most-often) model of synthesizer. Let’s say that you have a Brand X Model Z synthesizer and it turns out that you have a buddy across town who also has a Brand X Model Z. That’s cool, except your buddy’s synth has a completely different set of sound patches that was loaded into her instrument and you want them! SysEx to the rescue! All you need to do is go over and transfer your buddy’s patch data into your synth, or into a MIDI sequencer as a SysEx data dump. In order to make life easier, make sure you take your instruction manual along, (just in case you run into a snag), and follow these simple guidelines. I’ll caution you that you’re taking on these tasks at your own risk. Take your time; be patient and be careful during these procedures:

1. Back up your present patch data! This can be done by transmitting a SysEx dump of your synthesizer’s entire patch and setup data to your sequencer’s SysEx dump utility, or SysEx track on your sequencer (of course, you should get out both the device’s manual and your sequencer’s manual and follow their SysEx dump instructions very carefully during the process). This is so important that I’ll say it again: Back up your present patch data before attempting a SysEx dump! If you forget and download a new SysEx dump, your previous settings could easily be lost.

2. Save the data, according to your sequencer’s manual.

3. Check that the dump was successful by reloading it back into the device in question. Did it reload properly? If so, your current patch data is now saved.

4. Next, connect your buddy’s device to your sequencer. Dump this data to your sequencer. Save the new patch data (using a new and easily identifiable file-name), according to your sequencer’s manual and then safely back this data up.

5. Reconnect the sequencer to your synth and load the new data dump into it. Does your synth have a bunch of new sounds? Now reload your original SysEx dump back into your device. Are the original sounds restored?

The transmission format of a SysEx message, Fig. 29-12, as defined by the MIDI standard includes a SysEx status header, manufacturer’s ID number, any number of SysEx data bytes, and an EOX byte. On receiving a SysEx message, the identification number is read by a MIDI device to determine whether or not the following messages are relevant. This is easily accomplished, because a unique 1- or 3-byte ID number is assigned to each registered MIDI manufacturer. If this number doesn’t match the receiving MIDI device, the ensuing data bytes will be ignored. Once a valid stream of SysEx data is transmitted, a final EOX message is sent, after which the device will again begin responding to incoming MIDI performance messages. A detailed practical explanation of the many uses (and wonders) of SysEx can be found in the synthesizer section of Chapter 4, as well as in the patch editor section of Chapter 6. I definitely recommend that you check these out, because SysEx is one of the most cost-effective and powerful tools that an electronic musician can have. It’s definitely well worth the reading!

![Figure 29-12. System-exclusive data (one ID byte format).](image)

29.3 Hardware Systems within MIDI Production

As a data transmission medium, MIDI is relatively unique in the world of sound production in that it’s able to pack 16 discrete channels of performance, controller, and timing information and transmit it in one direction, using data densities that are economically small and...
easy to manage. In this way, it’s possible for MIDI messages to be communicated from a specific source (such as a keyboard or MIDI sequencer) to any number of devices within a connected network over a single MIDI data chain. In addition, MIDI is flexible enough that multiple MIDI data lines can be used to interconnect devices in a wide range of possible system configurations (for example, multiple MIDI lines can be used to transmit data to instruments and devices over 32, 48, 128, or more discrete MIDI channels!

**The MIDI Cable.** A MIDI cable, Fig. 29-13, consists of a shielded, twisted pair of conductor wires that has a male 5-pin DIN plug located at each of its ends. The MIDI specification currently uses only 3 of the 5 pins, with pins 4 and 5 being used as conductors for MIDI data, while pin 2 is used to connect the cable’s shield to equipment ground. Pins 1 and 3 are currently not in use, although the next section describes an ingenious system for power devices through these pins, using a system that’s known as MIDI phantom power. The cables themselves use twisted cable and metal shield groundings to reduce outside interference, such as radio-frequency interference (RFI) or electrostatic interference, both of which can serve to distort or disrupt the transmission of MIDI messages.

MIDI cables come prefabricated in lengths of 2, 6, 10, 20, and 50 feet, and can commonly be obtained from music stores that specialize in MIDI equipment. To reduce signal degradations and external interference that tends to occur over extended cable runs, 50 feet is the maximum length specified by the MIDI specification. (As an insider tip, I found that Radio Shack is also a great source for picking up 3 and 6 feet MIDI cables at a fraction of what you’d sometimes spend at a music store).

**MIDI Phantom Power.** In December 1989, Craig Anderton wrote an article in *Electronic Musician* about a proposed idea for allowing a source to provide a standardized 12 Vdc power supply to instruments and MIDI devices directly through pins 1 and 3 of a basic MIDI cable. Although pins 1 and 3 are technically reserved for possible changes in future MIDI applications, over the years several forward-thinking manufacturers (and project enthusiasts) have begun to implement MIDI phantom power directly into their studio and on-stage systems.

**Wireless MIDI.** In recent times, a number of companies have begun to manufacturer wireless MIDI transmitters that can allow a battery-operated MIDI guitar, wind controller, etc. to be footloose and fancy free on-stage and in the studio. Working at distances of up to 500 feet, these battery-powered transmitter/receiver systems introduce very low delay latencies and can be switched over a number of radio channel frequencies.

**MIDI Jacks.** MIDI is distributed from device to device using three types of MIDI jacks: MIDI In, MIDI Out, and MIDI Thru, Fig. 29-14. These three connectors use 5-pin DIN jacks as a way to connect MIDI Instruments, devices, and computers into a music and/or production network system. As a side note, it’s nice to know that these ports (as strictly defined by MIDI 1.0 Spec.) are optically isolated to eliminate possible ground loops that might occur when connecting numerous devices together.
• **MIDI In**—The MIDI In jack receives messages from an external source and communicates this performance, control, and/or timing data to the device’s internal microprocessor, allowing an instrument to be played and/or a device to be controlled. More than one MIDI In jack can be designed into a system to provide for MIDI merging functions or for devices that can support more than 16 channels (such as a MIDI Interface). Other devices (such as a controller) might not have a MIDI In jack at all.

• **MIDI Out**—The MIDI Out jack is used to transmit MIDI performance, control messages or SysEx from one device to another MIDI instrument or device. More than one MIDI Out jack can be designed into a system, giving it the advantage of controlling and distributing data over multiple MIDI paths using more than just 16 channels (i.e., 16 channels × N MIDI port paths).

• **MIDI Thru**—The MIDI Thru jack retransmits an exact copy of the data that’s being received at the MIDI In jack. This process is important, because it allows data to pass directly through an instrument or device to the next device in the MIDI chain. Keep in mind that this jack is used to relay an exact copy of the MIDI In data stream and isn’t merged with data being transmitted from the MIDI Out jack.

• **MIDI Echo**—Certain MIDI devices may not include a MIDI Thru jack, at all. Certain of these devices, however, may give the option of switching the MIDI Out between being an actual MIDI Out jack and a MIDI Echo jack, Fig. 29-15. As with the MIDI Thru jack, a MIDI echo option can be used to retransmit an exact copy of any information that’s received at the MIDI In port and route this data to the MIDI Out/Echo jack. Unlike a dedicated MIDI Out jack, the MIDI Echo function can often be selected to merge incoming data with performance data that’s being generated by the device itself. In this way, more than one controller can be placed in a MIDI system at one time. It should be noted that although performance and timing data can be echoed to a MIDI Out/Echo jack, not all devices can echo SysEx data.

**Typical Configurations.** Although electronic studio production equipment and setups are rarely alike (or even similar), there are a number of general rules that make it easy for MIDI devices to be connected into a functional network. These common configurations allow MIDI data to be distributed in the most efficient and understandable manner possible.

As a primary rule, there are only two valid ways to connect one MIDI device to another within a MIDI chain, Fig. 29-16:

1. Connecting the MIDI Out jack of a source device (controller or sequencer/computer) to the MIDI In of a second device in the chain.

2. Connecting the MIDI Thru jack of the second device to the MIDI In jack of the third device in the chain and following this same Thru-to-In convention until the end of the chain is reached.

**The Daisy Chain.** One of the simplest and most common ways to distribute data throughout a MIDI system is the daisy chain. This method relays MIDI data from a source device (controller or sequencer/computer) to the MIDI In jack of the next device in the chain (which receives and acts upon this data). In turn, this device relays an exact copy of this incoming data out to its MIDI Thru jack, which is then relayed to the next device in the chain. This device can then relay an exact copy of this incoming data out to its MIDI Thru jack, which is then relayed to the next device in the chain… etc. In this way, up to 16 channels of MIDI data can be chained from one device to the next within a connected data network—and it’s precisely this concept of transmitting multiple channels through a single MIDI line
that makes this concept work! Let’s try to understand this concept better by looking at a few examples.

Fig. 29-17A shows a simple (and common) example of a MIDI daisy chain, whereby data flows from a controller (MIDI Out jack of the source device) to a synth module (MIDI In jack of the second device in the chain), where an exact copy of this data is relayed from its MIDI Thru jack to another synth (MIDI In jack of the third device in the chain). From the section on MIDI channels in Chapter 2, it shouldn’t be hard to understand that if our controller is transmitting on MIDI channel 2, the second synth in the chain (which is set to channel 2) will ignore the messages and not play while the 3rd synth (which is set to channel 3) will be playing its heart out. The moral of this story is that although there’s only one connected data line, a wide range of instruments and channel voices can be played in a surprisingly large number of combinations, all by using individual channel assignments along a daisy chain.

Another example, Fig. 29-17B, shows how a computer can easily be designated as the master source within a daisy chain, so that a sequencing program could be used to control the entire playback and channel routing functions of a daisy-chained system. In this situation, the MIDI data flows from a master controller/synth to the MIDI In jack of a computer’s MIDI interface—where the data can be played into, processed, and rechanneled through a MIDI sequencer. The MIDI Out of the interface is then routed back to the MIDI In jack of the master controller/synth (which receives and acts on this data). In turn, the controller relays an exact copy of this incoming data out to its MIDI Thru jack, which is then relayed to the next device in the chain. This device can then relay an exact copy of this incoming data out to its MIDI Thru jack, which is then relayed to the next device in the chain etc. When we stop to think about this second example, the controller is used to perform into the MIDI sequencer, which then is used to communicate this edited and processed performance data out to the various instruments throughout the connected MIDI chain.

The Multiport Network. Another common approach to routing MIDI throughout a production system involves distributing MIDI data through the multiple 2, 4 and 8 In/Out ports that are available on a newer multiport MIDI interfaces or through the use of multiple MIDI interfaces (typically these are USB devices).

In larger, more complex MIDI systems, a multiport MIDI network, Fig. 29-17, offers several advantages over a single daisy chain path. One of the most important is its ability to address devices within a complex setup that requires more than 16 MIDI channels. For example, a 2 × 2 MIDI interface that offers up two-independent In/Out paths is capable of addressing up to 32 channels simultaneously (i.e., port A 1–16 and port B 1–16), whereas an 8 × 8 port interface is capable of addressing up to 128 individual MIDI channels.

29.3.1 The MIDI Interface

Although computers and electronic instruments both communicate using the digital language of 1s and 0s, computers simply can’t understand the language of MIDI without the use of a device that translates the serial messages into a data structure that computers can comprehend. Such a device is known as the MIDI interface.

A wide range of MIDI interfaces currently exist that can be used with most computer systems and OS platforms. For the casual and professional musician, interfacing MIDI into a production system can be done in a number of ways. Probably the most common way to access MIDI In, Out, and Thru jacks is on a modern-day USB or FireWire audio interface or instrument/DAW controller surface. It’s become a common matter for portable devices to offer 16 channels of I/O (on one port), while multi-channel interfaces often include multiple MIDI I/O ports that can give you access to 32 or more channels.

Another additional option is to choose a USB MIDI interface that can range from devices that include a single I/O port (16 channels) to a multiport system that can easily handle up to 128 channels over eight I/O
ports. The multiport MIDI interface, Fig. 29-18, is often the device of choice for most professional electronic musicians who require added routing and synchronization capabilities. These rack-mountable USB devices can be used to provide eight independent MIDI Ins and Outs to easily distribute MIDI and time code data through separate lines over a connected network.

29.3.2 Hardware and Software Electronic Instruments

Since its inception in the early 80s, MIDI-based electronic musical instruments have helped to shape the face and sounds of our modern music culture. These devices (along with digital audio and advances in recording equipment technology) have altered music production, through the creation of one of the most cost-effective and powerful tools in the development of music history—the personal project studio.

The following is a sample listing of the many hardware MIDI instrument types that are currently available on the market.

The Synth. A synthesizer, Fig. 29-19, is an electronic instrument that uses multiple sound generators to create complex waveforms that can be combined (using various waveform synthesis techniques) into countless sonic variations. These synthesized sounds have become a basic staple of modern music and vary from sounding cheesy, to those that closely mimic traditional instruments all the way to those that generate rich, otherworldly sounds that literally defy classification.

Synthesizers (also known as synths) generate sounds and percussion sets using a number of different technologies or program algorithms. The earliest synths were analog in nature and generated sounds using additive or subtractive FM (frequency modulation) synthesis. This process generally involves the use of at least two signal generators (commonly referred to as operators) to create and modify a voice. Often, this is done through the analog or digital generation of a signal that modulates or changes the tonal and amplitude characteristics of a base carrier signal. More sophisticated FM synths can use up to 4 or 6 operators per voice and also often use filters and variable amplifier types to alter the signal’s characteristics into a sonic voice that either roughly imitates acoustic instruments or creates sounds that are totally unique.

Another technique that’s used to create sounds is wavetable synthesis. This technique works by storing small segments of digitally sampled sound into a read-only memory chip. Various sample-based synthesis techniques use sample looping, mathematical interpolation, pitch shifting, and digital filtering to create extended and richly textured sounds that use a very small amount of sample memory.

Synthesizers are also commonly designed into rack- or half-rack-mountable modules, Fig. 29-20, that contain all of the features of a standard synthesizer, except that they don’t incorporate a keyboard controller. This space-saving feature means that more synths can be placed into your system and can be controlled from a master keyboard controller or sequencer, without cluttering up the studio with redundant keyboards.

Software Synthesis and Sample Resynthesis. Since wavetable synthesizers derive their sounds from prerecorded samples that are stored in a digital memory medium, it logically follows that these sounds can also be stored on hard disk (or any other medium) and loaded into the RAM memory of a personal computer. This process of downloading wavetable samples into a computer and then manipulating these samples is used to create what is known as a virtual or software synthesizer, Fig. 29-21.
In recent years, software synths have grown from being novel and obscure programs that were primarily used by the academic community to their present state of being widely accepted in the production community as a cost-effective musical instrument. These software modules can be used in conjunction with a digital audio workstation to offer up a wide range of complex sounds that can mimic traditional instruments, as well as create sonic textures that are both new and interesting.

Sample resynthesis software systems are able to take software synthesis to a new level, by allowing the user to build, save, and recall sonic patches that can be built from traditional synthesis building blocks (such as oscillators, voltage-controlled amplifiers, voltage-controlled filters, and mixers). In addition to sound generation, digital audio samples can be imported and re-synthesized in a way that can create sounds of almost any texture or type that you can possibly imagine. All of these software blocks can be combined in a graphic environment that allows these instruments, textures, and soundscapes to be easily saved to disk for later recall.

Using various internal software data communications protocols, it’s possible to communicate MIDI, audio, timing sync and control data between an instrument (or effect plug-in) and a host DAW program/CPU processor. These plug-in protocols make it possible for much or all of the audio and timing data to be routed through the host audio application, allowing the instrument or application to either integrate into the DAW or application or to work in tandem so as to route the audio and performance/control data through the host application with relative ease. A few of these protocols include:

- Steinberg’s VST (Virtual Studio Technology).
- MOTU’s MAS (MOTU Audio System).
- Propellerheads ReWire.

**Samplers.** A sampler, Fig. 29-22, is a device that can convert audio into a digital form and/or manipulate pre-recorded sampled data, using the system’s own random access memory (RAM). Once loaded into RAM, the sampled audio can be edited, transposed, processed, and played in a polyphonic musical fashion.

![Figure 29-21. Steinberg xphrase VSTi software synth. Courtesy of Steinberg Media Technologies GmbH, a division of Yamaha Corporation, www.steinberg.net.](image1)

![Figure 29-22. Akai MPC-1000 Music Production Center. Courtesy of Akai Professional, www.akaipro.com.](image2)

Basically, a sampler can be thought of as a wavetable synth that lets you record, load, and edit samples into RAM memory. Once loaded, these sounds (whose length and complexity are often limited only by memory size and your imagination) can be looped, modulated, filtered, and amplified (according to user or factory setup parameters), in a way that allows the waveshapes and envelopes to be modified. Signal processing capabilities, such as basic editing, looping, gain changing, reverse, sample-rate conversion, pitch change, and digital mixing capabilities can also be altered and/or varied.

A hardware sampler’s design will often include a keyboard or set of trigger pads that let you polyphonically play samples as musical chords, sustain pads, triggered percussion sounds, or sound effect events. These samples can be played according to the standard Western musical scale (or any other scale, for that matter) by altering the playback sample rate over the controller’s note range. For example, pressing a low-pitched key on the keyboard will cause the sample to be played back at a lower sample rate, while pressing a high-pitched one will cause the sample to be played back at rates that would put Mickey Mouse to shame. By choosing the proper sample rate ratios, sounds can be polyphonically played (whereby multiple notes are sounded at once) at pitches that correspond to standard musical chords and intervals.

A sampler (or synth) with a specific number of voices (i.e., 64 voices) simply means that up to 64 notes...
can be simultaneously played on a keyboard at any one time. Each sample in a multiple-voice system can be assigned across a performance keyboard, using a process known as *splitting* or *mapping*. In this way, a sound can be assigned to play across the performance surface of a controller over a range of notes, known as a *zone*, Fig. 29-23. In addition to grouping samples into various zones, velocity can enter into the equation by allowing multiple samples to be layered across the same keys of a controller, according to how soft or hard they are played. For example, a single key might be layered so that pressing the key lightly would reproduce a softly recorded sample, while pressing it harder would produce a louder sample with a sharp, percussive attack. In this way, mapping can be used to create a more realistic instrument or wild set of soundscapes that change not only with the played keys, but with velocity ranges as well.

![Figure 29-23. Samples can be mapped to various zones on a keyboard.](image)

In addition to hardware sampling systems, a growing number of virtual or software samplers exist that use a computer’s existing memory, processing, and signal routing capabilities in order to polyphonically reproduce samples in real time.

Offering much of the same functionality as their hardware counterparts, these software-based systems, Fig. 29-24, are capable of editing, mapping, and splitting sounds across a MIDI keyboard, using on-screen graphic controls and DAW integration that has improved to the point of equaling or surpassing their hardware counterparts in cost-effectiveness, power, and ease of use.

As with a software synth, software samplers derive their sounds from recorded and/or imported audio data that is stored as digital audio data within a personal computer. Using the DSP capabilities of today’s computers (as well as the recording, sequencing, processing, mixing, and signal routing capabilities of most digital audio workstations), most software samplers are able to store and access samples within the internal memory of a laptop or desktop computer. Using a graphic interface, these sampling systems often allow the user to:

- Import previously recorded soundfiles (often in WAV, AIF, and other common formats)
- Edit and loop sounds into a usable form
- Vary envelope parameters (i.e., dynamics over time)
- Vary processing parameters
- Save the edited sample performance setup as a file for later recall

Software sampler systems are also often able to communicate MIDI, audio, timing sync and control data between a hard- or software instrument and a host DAW program/CPU processor, allowing for a wide range of control and setup recall.

**The Drum Machine.** The drum machine is most commonly a sample-based digital audio device that can’t record audio into its internal memory (although this has changed in recent years, allowing it to import, record, and manipulate sampled audio much like a sampler). Traditionally, these hardware or software systems use ROM-based, prerecorded samples to reproduce high-quality drum sounds. These factory-loaded sounds often include a wide assortment of drum sets, percussion sets, rare and wacky percussion hits, and effected drum sounds (i.e., reverberated, gated, etc.). Who knows, you might even encounter “Hit me!” screams from the venerable King of Soul—James Brown.

Most hardware drum machines allow prerecorded samples to be assigned to a series of playable keypads that are often located on the machine’s top face. This provides a straightforward controller surface that usually includes velocity and aftertouch dynamics. Drum voices can be assigned to each pad and edited using...
such control parameters as tuning, level, output assignment, and panning position. Multiple outputs are often provided, enabling individual or groups of voices to be routed to a specific output on a mixer or console.

Although a number of hardware drum machine designs include a built-in sequencer, it’s more likely that these workhorses will be triggered from a MIDI sequencer. This lets us take full advantage of the real-time performance and editing capabilities that a sequencer has to offer. For example, sequenced patterns can easily be created in step time (where notes are entered and assembled into a rhythmic pattern one note at a time) and can then link together into a song that’s composed of several rhythmic patterns. Alternately, performing into a sequencer on-the-fly can help create a live feel or you can combine step- and real-time tracks to create a human-sounding composite rhythm track. In the final analysis, the style and approach to composition is entirely up to you.

In addition to their hardware counterparts, an increasing number of software drum and groove instrument plug-ins have come onto the market that allow for drum patterns to be added to a production in a wide range of pattern and playing styles, Fig. 29-25.

### 29.3.3 Performance and Parameter Controllers

MIDI performance controllers are used to translate the voicings and expressiveness of a musical performance into MIDI data, while a parameter controller surface is used to alter the control variables of a workstation, device or instrument.

It should be noted that a MIDI controller is expressly designed to control other devices (be they for sound, light or mechanical control) within a connected system. It contains no internal tone generators or sound-producing elements. Instead, it offers a wide range of controls for handling control, trigger and device switching events. In short, controllers have become an integral part of music production, and are available in many incarnations to control and emulate many types of musical instruments.

**Keyboard Controller.** The MIDI keyboard controller, Fig. 29-26, is a keyboard device that’s expressly designed to control hard/software synths, samplers, modules and other devices within a connected MIDI system. It contains no internal tone generators or sound-producing elements. Instead, its design includes a performance keyboard and controls for handling MIDI performance, control, and device switching events.

**Percussion Controllers.** MIDI percussion controllers are used to translate the voicings and expressiveness of a percussion performance into MIDI data. These devices are great for capturing the feel of a live performance, while giving you the flexibility of recording and automating a performance within a DAW/sequencer environment. These controllers vary over a wide range from being a simple and cost-effective setup (i.e., using the pads on a drum machine, keys on a keyboard surface, or pads on an intro-level drum controller) to a full-blown drum kit that mimics its acoustic cousin, Figs. 29-27 and 29-28.

**Wind Controllers.** MIDI wind controllers are expressly designed to bring the breath and key articulation of a woodwind or brass instrument to a MIDI performance. These controller types are used because many of the dynamic- and pitch-related expressions (such as breath and controlled pitch glide) simply can’t be commun-
cated from a standard music keyboard. In these situations, wind controllers can often help create a dynamic feel that’s more in keeping with their acoustic counterparts by using an interface that provides special touch-sensitive keys, glide- and pitch-slider controls, and real-time breath sensors for controlling dynamics.

MIDI Guitars. Guitar players often work at stretching the vocabulary of their instruments beyond the traditional norm. They love doing nontraditional gymnastics using such tools of the trade as distortion, phasing, echo, feedback, etc. Due to advances in guitar pickup and microprocessor technology, it’s also possible for the notes and minute inflections of guitar strings to be accurately translated into MIDI data. With this innovation, many of the capabilities that MIDI has to offer are available to the electric (and electronic) guitarist. For example, a guitar’s natural sound can be layered with a synth pad that’s been transposed down, giving it a rich, thick sound that just might shake your boots. Alternately, recording a sequenced guitar track into a session would give a producer the option of changing and shaping the sound later in mixdown! On-stage program changes are also a big plus for the MIDI guitar, allowing the player to radically switch between guitar voices from the guitar or sequencer or by stomping on a MIDI foot controller.

29.4 Sequencers

Apart from electronic musical instruments, one of the most important tools that can be found in the modern-day project studio is the MIDI sequencer. Basically, a sequencer is a digital device that’s used to record, edit, reproduce, and distribute MIDI messages in a sequential fashion. Most sequencers function using a traditional track-based interface, separating different instruments, voices, beats, etc. in a way that makes it easier for us humans to view MIDI data as though they were linear tracks on a DAW or tape machine.

These virtual tracks contain MIDI-related performance and control events that are made up of such channel and system messages as note on/off, velocity, modulation, aftertouch, and program/continuous-controller messages. Once a performance has been recorded into a sequencer’s memory, these events can be graphically (or audibly) edited into a musical performance, played back and saved to a digital storage media for recall at any time.

Integrated Sequencers. Some of the newer and more expensive keyboard synth and sampler designs include a built-in sequencer. These portable keyboard workstations have the advantage of letting you take both the instrument and sequencer on the road without having to drag a computer along.

Integrated sequencers are designed into an instrument for the sole purpose of sequencing MIDI data, and include integrated controls for performing sequence-specific functions. Ease of use and portability are often the advantages of a hardware sequencer, most of which are designed to emulate the basic functions of a tape transport (record, play, start/stop, fast forward, and rewind).

These devices generally offer a moderate amount of editing features, including note editing, velocity and
other controller messages, program change, cut and paste and track merging capabilities, tempo changes, etc. Programming, track, and edit information is commonly viewed on a liquid crystal display (LCD) that’s often limited in size and resolution and generally limits information to a single parameter or track at a time.

These sequencers often don’t offer a wide range of editing tools beyond standard transport functions; punch-in/out commands and other basic edit tools. However, they’re often more than adequate for capturing and reproducing a performance and can be integrated with other instruments that are connected in a MIDI chain.

Software Sequencers. By far, the most common sequencer type is the software MIDI sequencer. These programs or integrated components of a digital audio workstation take advantage of the versatility that a computer can offer in the way of speed, flexibility, digital signal processing, memory management, and signal routing.

Computer-based sequencers offer numerous functional advantages over their hardware counterparts. Among these are increased graphic capabilities (which often offers extensive control over track- and transport-related functions), standard computer cut and paste techniques, an on-screen graphic environment (allowing easy manipulation of program and edit-related data), routing of MIDI to multiple ports in a connected system, and the graphic assignment of instrument voices via program change messages (not to mention the ability to save and recall files using standard computer memory media). Now, let’s take a look into how these devices function.

29.4.1 A Basic Introduction to Sequencers

When dealing with any type of sequencer, one of the most important concepts to grasp is the fact that these devices don’t store sound directly—instead, they encode MIDI messages that instruct an instrument to play a particular note, over a certain channel, at a specific velocity and with any optional controller values. In other words, a sequencer stores music-related data commands that follow in a sequential order, which then tells instruments and/or devices how their voices are to be played and/or controlled. This simple (but important) fact means that the amount of encoded data is far less memory intensive than its hard disk audio or video recording counterparts and that the data overhead that’s required by MIDI is very small. In short, a computer-based sequencer can simultaneously operate in a digital audio, digital video, processing environment without placing an additional significant load on a computer’s CPU.

As you might expect, many sequencer types are currently on the market, with each offering its own set of advantages and disadvantages. It’s also true that each sequencer has its own basic operating feel, and thus, choosing the best tool and toy for the job or studio is totally up to you.

Recording. From a functional standpoint, a sequencer is used as a digital workspace for creating personal compositions in environments that range from the bedroom to more elaborate project studios. Whether they’re hardware or software-based, most sequencers use a working interface that’s designed to emulate the traditional multitrack recording environment. A tapelike transport lets you move from one location to the next using standard Play, Stop, FF, REW and Rec command buttons. Beyond using traditional record-enable button(s) to arm selected recording track(s), all you need to do is select the MIDI input (source) and outputs (destination) ports, instrument/voice MIDI channel, instrument patch and other setup information, press the record button, and start playing.

Once you’ve finished laying down a track, you can jump back to any point in the sequence and listen to your original track while continuing to lay down additional MIDI tracks until the song begins to form.

Almost all sequencers are capable of punching in and out of record while playing a sequence. This common function lets you drop in and out of record on a track (or tracks) in real time. Although punch-in/out points can often be manually performed on-the-fly, most sequencers can perform a punch automatically, once the in/out measure numbers have been graphically or numerically entered. The sequence can then be rolled back a few measures and the artist can play along, while the sequencer automatically performs the necessary switching functions (usually with multiple take and full undo capabilities).

In addition to recording a performance in a track-based environment, most sequencers let you enter note values into sequence one note at a time. This feature (known as step time) lets you give the sequencer a basic tempo and note length (i.e., quarter note, sixteenth note, etc.) and then manually enter the notes from a keyboard or other controller. This data entry style is often (but not always) used with fast, high-tech and dance styles, where a real-time performance just isn’t possible or accurate enough for the song.

Whether you’re recording a track in real time or in step time, it’s almost always best to select the proper
song tempo before recording a sequence. I bring this up because most sequencers are able to output a click track that can be used as an accurate, audible guide for keeping in time with the song’s selected tempo. It’s also critical that the tempo be accurate when trying to sync groove loops and rhythms to a sequence via plug-ins or external instruments.

**Editing.** One of the more important features that a sequencer (or sequenced MIDI track within a DAW) has to offer is its ability to edit tracks or blocks within a track. Of course, these editing functions and capabilities often vary between hardware and software sequencers.

The main track window of a sequencer or MIDI track on a DAW is used to display such track information as the existence of track data, track names, MIDI port assignments for each track, program change assignments, volume controller values, etc.

Depending on the sequencer, the existence of MIDI data on a particular track at a particular measure point (or over a range of measures) is often indicated by the visual display of MIDI data in a piano-roll fashion (showing the general vertical and length placements of the notes as they progress through the musical passage... as shown in Fig. 29-29.

By navigating around the various data display and parameter boxes, it’s possible to use cut and paste and/or direct edit techniques to vary note, length and controller parameters for almost every facet of a section or musical composition. For example, let’s say that we really screwed up a few notes when laying down an otherwise killer bass riff. With MIDI, fixing the problem is totally a no-brainer. Simply highlight each fudged note and drag it to its proper note location. We can even change the beginning and end points in the process. In addition, tons of other parameters can be changed including velocity, modulation and pitch bend, note and song transposition, quantization, and humanizing (factors that eliminate or introduce human timing errors that are generally present in a live performance), as well as full control over program and continuous controller messages. The list goes on.

**Playback.** Once a composition is complete, all of the MIDI tracks in a project can be transmitted through the various MIDI ports and channels to plug-ins, instruments, or devices for playback. Since the data exists as encoded real-time control commands, you can listen to the sequence and make changes at any time. For example, you could change instrument settings (by changing or editing patch voices), alter volume and other mix changes, or experiment with such controllers as pitch bend, modulation or aftertouch, even change the tempo and key signature. In short, this medium is infinitely flexible how a performance and/or set of parameters can be created, saved, folded, spindled, and mutilated until you’ve arrived at the sound and feel that you want.

Another of the greatest beauties of MIDI production is its ability to be altered at any later point in time. For example, let’s say that 5 years ago you laid down a killer synth riff in a song that made it onto the charts. A couple of weeks ago a producer came to you in hopes of collaborating on a remix. Of course, technology marches on and your studio has improved over time. First off, even though a lot of the setup parameters have been saved with the original sequence, let’s assume that you were smart enough to keep really good setup notes. One big change, however, is that you have a new software synth that has a patch that sounds better than the original patch. Since the remix is to be used in an upcoming film track, MIDI can be used to tweak things up a bit by splitting the riff into two parts: one that contains the lower notes and another the highs. By sending the lows to one patch on the synth and the highs to another, not only have you improved the overall sound, you’ve filled it out by expanding the soundfield into surround. Without MIDI, you’d have to arrange for a new session and hope that it all goes well, with MIDI, the performance is exactly the same and improvements are made in a no-brainer environment. This is what MIDI’s all about—performance, repeatability, easy editing, and cost-effective power!

I now have to take time out to give you a few pointers that will make your life easier when dealing with MIDI production.

1. Remember to set the session to the proper tempo at the beginning of the session. Although tempo can
be changed at a later time, attention to tempo
details can help you to avoid later pitfalls.

2. Always name your track before you go into record
(this goes for both audio and MIDI tracks). Prop-
erly naming your tracks (i.e., with its instrument,
patch name) is the first step toward good
documentation.

3. You can never overdocument a session. Keeping
good instrument, patch, settings, musician, studio,
and other notes might not only come in handy—it
can save your butt if you need to revisit the tracks
in the future.

4. Never delete a final take MIDI track from a DAW
session. Even though you’ve transferred the instru-
ment to an audio track, it is always wise to archive
the original MIDI track with session. Trust me,
both you and the producer will be glad you did,
should any changes need to be made to the track in
the future.

29.4.2 Other Software Sequencing Applications

In addition to DAW and sequencing packages that are
designed to handle most of the day-to-day production
needs of the musician, other types of software tools and
applications exist that can help to carry out specialized
tasks. A few of these packages include drum pattern
editors, algorithmic composition programs, patch edi-
tors and music printing programs.

Drum-Pattern Editor/Sequencers. At any one time,
there are a handful of companies that have software or
hardware devices, that are specifically designed to
create and edit, drum patterns. In addition, most of the
higher-end DAW audio production systems also include
a drum pattern editor that relies on user input and quan-
tization to construct and chain together any number of
user-created percussion grooves. More often than not,
these editors use a grid pattern that displays
drum-related MIDI notes or subpatterns along the ver-
tical axis, while time is represented in metric divisions
along the horizontal axis, Fig. 29-30. By clicking on
each grid point with a mouse or other input system,
individual drum or effect sounds can be built into
rhythmic patterns.

Once created, these and other patterns can be linked
together to create a partial or complete rhythm section
within a song. These editors commonly offer such fea-
tures as the ability to change MIDI note values (thereby
changing drum voices), note length, quantization and
humanization, as well as adjustments to note and pattern
velocities. Once completed, the sequenced drum track
(or chained patterns) can be imported into a sequence,
saved, and/or exported.

Groove Tools. Getting into the groove of a piece of
music often refers to a feeling that’s derived from the
underlying foundation of the piece: rhythm. With the
introduction and maturation of MIDI and digital audio,
new and wondrous tools have made their way into the
mainstream of music production that can help us to use
these technologies to forge, fold, mutilate and create
compositions that make direct use of rhythm and other
building blocks of music through the use of looping
technology.

Of course, the cyclic nature of loops can be— repeat
repeat—repetitive in nature, but new toys and tech-
niques in looping have injected the notion of flexibility,
real-time control, real-time processing, and mixing to
new heights that can be used by an artist as a won-
drously expressive tool.

Loop-based audio editors are groove-driven music
programs, Figs. 29-31 and 29-32, that are designed to
let you drag and drop prerecorded or user-created loops
and audio tracks into a graphic multitrack production
interface. At their basic level, these programs differ
conceptually from their traditional DAW counterpart, in
that the pitch- and time-shift architecture is so variable
and dynamic that even after the basic rhythmic, percus-
sive and melodic grooves have been created, their
tempo, track patterns, pitch, session key, etc. can be
quickly and easily changed at any time. With the help of
custom, royalty-free loops (available from the manufac-
turer and/or third-party companies), users can quickly
and easily experiment with setting up grooves, backing
tracks, and creating a sonic ambience by simply drag-
ing the loops into the program’s main soundfile view where they can be arranged, edited, processed, saved, and exported.

One of the most interesting aspects of a loop-based editor is its ability to match the tempo of a specially programmed loop soundfile to the tempo of the current session. Amazingly enough, this process isn’t that difficult to perform, as the program extracts the length, native tempo, and pitch information from the imported file’s header and (using various digital time and/or pitch change techniques) adjusts the loop to fit the native time/pitch parameters of the current session. This means that loops of various tempos and musical keys can be automatically adjusted in length and pitch so as to fit in time with previously existing loops. These shifts in time to match a loop to the session’s native tempo can actually be performed in a number of ways. For example, using basic DSP techniques to time-stretch and pitch-shift a recorded loop will often work well over a given plus-or-minus percentage range (which is often dependent on the quality of the program algorithms). Beyond this range, the loop will often begin to distort and become jittery. At such extremes, other playback algorithms and beat slice detection techniques can be used to make the loop sound more natural. For example, drums or percussion can be stretched in time by adding additional silence between the various hit points within the loop at precisely calculated intervals. In this way, the pitch will remain the same while the length is altered. Of course, such a loop would sound choppy and broken up when played on its own; however, when buried within a mix, it might work just fine. It’s all up to you and the current musical context.

The software world doesn’t actually hold the total patent on looping tools and toys; there are a number of groove keyboards and module boxes that are on the market. These systems, which range widely in sounds, functionality, and price, can offer up a wide range of unique sounds that can be quite useful laying a foundation under your production. In the past, getting a hardware groove tool to sync into a session could be time-consuming, frustrating, and problematic, taking time and tons of manual reading. However, with the advent of powerful time and pitch shift processing within most DAWs, the sounds from these hardware devices can be pulled into a session without too much trouble. For example, a single groove loop (or multiple loops) could be recorded into a DAW (at a bpm that’s near to the session’s tempo), edited, and then imported into the session, at which time the loop could be easily stretched into time sync, allowing it to be looped to your heart’s content. Just remember, necessity is the mother
of invention. Patience and creativity are probably your most important tools in the looping process.

If there’s a software package that has gripped the hearts and minds of electronic musicians in the 21st century, it would have to be Reason from the folks at Propellerheads, Fig. 29-33. Reason defies specific classification in that it’s an overall music production environment that has many facets. For example, it includes a MIDI sequencer, as well as a wide range of software instrument modules that can be played, mixed, and combined in a comprehensive environment that can be controlled from any external keyboard and/or MIDI controller. Reason also includes a large number of signal processors that can be applied to any instrument or instrument group under full and easily controlled automation.

In essence, Reason is a combination of modeled representations of vintage analog synthesis gear, mixed with the latest digital synthesis and sampling technology. Combine these with a modular approach to signal and effects processing; add a generous amount of internal and remote mix and controller management (via an external MIDI controller); top this off with a quirky but powerful sequencer; and you have a software package that’s powerful enough for top-flight production and convenient enough that you can build tracks from your laptop from your seat in a crowded plane. I know that it sounds like I read this from a sales brochure, but these are the basic facts of this program. When asked to explain Reason to others, I’m often at a loss as the basic structure is so open-ended and flexible that the program can be approached in as many ways as there are people who produce on it. That’s not to say that Reason doesn’t have a signature sound—it often does. However, it’s a tool that can be either used on its own or in combination with other production instruments and tools.

Algorithmic Composition Programs. Algorithmic composition programs are interactive sequencers that directly interface with MIDI controllers or imported files to generate a performance in real time, according to user-programmed computer parameters. In short, once you give it a few basic musical guidelines, it can act as a compositional robot to generate performances or musical parts on its own in order to help you gain new ideas for a song, create an automatic accompaniment, make improvisational exercises, create special performances, or just plain have fun.

This type of sequencer can be programmed to control the performance according to musical key, generated notes, basic order, chords, tempo, velocity, note density, rhythms, accents, etc. Alternatively, an existing standard MIDI file can be imported and further manipulated in real time, according to new parameters that can be varied from a computer keyboard, mouse, or controller. Often such interactive sequencers will accept input from multiple players, allowing it to be performed as a collective jam. Once a composition has been satisfactorily generated, a standard MIDI file can be created and imported into any sequencer.

Patch Editors. The vast majority of MIDI instruments and devices store their internal patch data within RAM memory. Synths, samplers, or other devices contain information on how to configure oscillators, amplifiers, filters, tuning, and other presets in order to create a particular sound timbre or effect. In addition to controlling sound patch parameters, a unit’s internal memory can also store such setup information as effects processor settings, keyboard splits, MIDI channel routing, controller assignments, etc.

Although these settings can be manually accessed from the device’s panel controls, another (and sometimes more straightforward) way to gain real-time control over the parameters of an instrument or devices is through the use of a patch editor, Fig. 29-34. A patch editor is a software package that’s used to provide on-screen controls and graphic windows for emulating and varying an instrument’s parameter controls in real time.
Direct communication between a patch editor and the device’s microprocessor commonly occurs through the use of MIDI SysEx messages. Almost all popular voice and setup editing packages include provisions for receiving and transmitting bulk patch data in this way. This makes it possible to save and organize large numbers of patch-data files, vary settings in real time, and print out patch parameter settings.

In addition to software editing packages, there are also hardware solutions for gaining quick and easy access to device parameters via SysEx. In recent years, MIDI data controllers, Fig. 29-35, have sprung onto the market that can control a wide range of instruments and devices using data faders and soft buttons to vary patch, system, and performance parameters, in real time. In many situations, these controllers can also be used to directly control the volume and mix parameters of a DAW.

Music-Printing Programs. In recent years, the field of transcribing musical scores onto paper has been strongly affected by computer, DAW, and MIDI technology. This process has been enhanced through the use of newer generations of software that make it possible for music notation data to be entered into a computer either manually (by placing the notes onto the screen via keyboard and/or by mouse movements) or via direct MIDI input. Once entered, these notes can be edited in an on-screen environment using a music printing program (or notation app within a DAW) that lets you change and configure a musical score or lead sheet using standard cut-and-paste edit techniques. In addition, most printing programs can play the various instruments in a MIDI system directly from the score. A final and important program feature is their ability to print out hard copies of a score or lead sheets in a wide number of print formats and styles.

These programs or DAW program apps, Fig. 29-36, allow musical data to be entered into a computerized score in a number of manual and automated ways (often with varying degrees of complexity and ease). Although scores can be manually entered, most music-transcription programs will generally accept direct MIDI input, allowing a part to be played directly into a sequence. This can be done in real time (by playing a MIDI instrument or finished sequence into the program), in step time (entering the notes of a score one note at a time from a MIDI controller), or from an existing standard or program-specific MIDI file.

Another way to enter music into a score is through the use of an optical recognition program. These programs let you place sheet music or a printed score onto a standard flatbed scanner, scan the music into a pro-
gram and then save the notes and general layout as a NIFF (notation interchange file format) file.

One of the biggest drawbacks to automatically entering a score via MIDI (either as a real-time performance or from a MIDI file) is the fact that music notation is a very interpretive art. "To err is human," and it’s commonly this human feel that gives music its full range of expression. It is very difficult, however, for a program to properly interpret these minute yet important imperfections and place the notes into the score exactly as you want them. (For example, it might interpret a held quarter-note as either a dotted quarter-note or one that’s tied to a thirty-second note.) Even though these computer algorithms are getting better at interpreting musical data and quantization can be used to tell a computer to round a note value to a specified length, i.e., a score will still often need to be manually edited to correct for misinterpretations.

29.5 Multimedia and the Web

It’s no secret that modern-day computers have gotten faster, sleeker, and sexier in their overall design. In addition to its ability to act as a multifunctional production workhorse, one of the crowning achievements of the modern computer is the degree of media and networking integration that has worked its way into our collective consciousness and become known as multimedia.

The combination of working and/or playing with multimedia has found its way into modern computer culture through the use of various hardware and software systems that work in a multitasking environment and combine to bring you a unified experience that seamlessly involves such media types as:

- Text.
- Graphics.
- Video.
- Audio and music.
- Computer animation.
- MIDI.

The obvious reason for integrating and creating these media types is the human desire to create content with the intention of sharing and communicating one’s experiences with others. This has been done for centuries in the form of books and more recently by movies and television. In the here and now, the Web has been added to the communications list, in that it has created a vehicle that allows individuals (and corporate entities alike) to communicate a multimedia experience to millions and then allows each individual to manipulate that experience, learn from it, and even respond in an interactive fashion. The Web has indeed unlocked the potential for experiencing multimedia events and information in a way that makes each of us a participant, not just a passive spectator.

One of the unique advantages of MIDI, as it applies to multimedia, is the rich diversity of musical instruments and program styles that can be played back in real time while requiring almost no overhead processing from the computer’s CPU. This makes MIDI a perfect candidate for playing back soundtracks from multimedia games or over the Internet. It’s interesting to note that MIDI has taken a back seat to digital audio as a serious music playback format for multimedia. Most likely, this is due to several factors, including:

1. A basic misunderstanding of the medium.
2. The fact that producing MIDI content requires a basic knowledge of music.
3. The frequent difficulty of synchronizing digital audio to MIDI in a multimedia environment.
4. The fact that soundcards often include poorly designed FM synthesizers (although most operating systems now include a higher-quality software synth).

Fortunately, an increasing number of software companies have taken up the banner of embedding MIDI within their media projects and have helped push MIDI a bit more into the Web and gaming mainstream. As a result, it’s becoming more common for your PC to begin playing back a MIDI score on its own or perhaps in conjunction with a more data-intensive program or game.

29.5.1 Standard MIDI Files

The accepted format for transmitting files or real-time MIDI information in multimedia (or between sequencers from different manufacturers) is the standard MIDI file. This file type (which is stored with a .mid or .smf extension) is used to distribute MIDI data, song, track, time signature, and tempo information to the general masses. Standard MIDI files can support both single and multichannel sequence data and can be loaded into, edited, and then directly saved from almost any sequencer package. When exporting a standard MIDI file, keep in mind that they come in two basic flavors: type 0 and type 1.

- Type 0 is used whenever all of the tracks in a sequence need to be compressed into a single MIDI track. All of the original channel messages still reside within that track; however, the data will have no
definitive track assignments. This type might be the best choice when creating a MIDI sequence for the Internet (where the sequencer or MIDI player application might not know or care about dealing with multiple tracks).

- Type 1, on the other hand, will retain its original track information structure and can be imported into another sequencer type with its basic track information and assignments left intact.

### 29.5.2 General MIDI

One of the most interesting aspects of MIDI production is the absolute setup and patch uniqueness of each professional and even semiproject studio. In fact, no two studios will be alike (unless they’ve been specifically designed to be the same or there’s some unlikely coincidence). Each artist will be unique in having his or her own favorite equipment, supporting hardware, favorite way of routing channels and tracks, and assigning patches. The fact that each system setup is unique and personal has placed MIDI at odds with the need for systems compatibility in the world of multimedia. For example, after importing a standard MIDI file over the Net and loading it into a sequencer, you might hear a song that’s being played with a totally irrelevant set of sound patches (it might sound interesting, but it won’t sound anything like it was originally intended). If the MIDI file is loaded into a new computer, the sequence will again sound completely different, with patches that are so irrelevant that the guitar track might sound like a bunch of machine-gun shots from the planet Gloob.

In order to eliminate (or at best reduce) the basic differences that exist between systems, a patch and settings standard known as General MIDI (GM) was created. In short, GM assigns a specific instrument patch to each of the 128 available program change numbers. Since all electronic instruments that conform to the GM format must use these patch assignments, placing GM program change commands at the header of each track will automatically configure the sequence to play with its originally intended sound. As such, no matter what sequencer is used to play the file back, as long as the receiving instrument conforms to the GM spec the sequence will be heard using its intended instrumentation. Tables 29-3 and 29-4 detail the program numbers and patch names that conform to the GM format (Table 29-3 for percussion and Table 29-4 for nonpercussion instruments). These patches include sounds that imitate synthesizers, ethnic instruments, and/or sound effects that have been derived from early Roland synth patch maps. Although the GM spec states that a synth must respond to all 16 MIDI channels, the first nine channels are reserved for instruments, while GM restricts the percussion track to MIDI channel 10.

### 29.6 MIDI-Based Synchronization

Just as synchronization is routinely used in audio and video production, the wide acceptance of MIDI and digital audio within the various media has created the need for synchronization in project studio and midsized production environments. Devices such as MIDI sequencers, digital audio editors, effects devices, and digital mixing consoles make extensive use of synchronization and time code. However, advances in design have fashioned this technology into one that’s much more cost-effective and easy-to-use—all through the use of MIDI. The following sections outline the various forms of synchronization that are often encountered in a MIDI-based production environment.

Simply stated, most current forms of synchronization use the MIDI protocol itself for the transmission of sync messages. These messages are transmitted along with other MIDI data over standard MIDI cables, with no need for additional or special connections.
Although no time code–based reference is implemented, it’s important to know that MIDI has a built-in (and often transparent) protocol for synchronizing all of the tempo and timing elements of each MIDI device in a system to a master clock. This protocol operates by transmitting real-time messages to the various instruments and devices throughout the system. Although these relationships are usually automatically defined within a system setup, one MIDI device must be designated as the master device in order to provide the timing information to which all other slaved devices are locked. MIDI real-time messages consist of four basic types that are each 1 byte in length:

- **Timing clock**—A clock timing that’s transmitted to all devices in the MIDI system at a rate of 24 pulses per quarter note (ppq). This method is used to improve the system’s timing resolution and simplify timing when working in nonstandard meters (e.g., \( \frac{3}{8}, \frac{5}{16}, \frac{5}{32} \)).

- **Start**—Upon receipt of a timing clock message, the start command instructs all connected devices to begin playing from the beginning of their internal sequences. Should a program be in midsequence, the
start command repositions the sequence back to its beginning, at which point it begins to play.

- **Stop**—Upon the transmission of a MIDI stop command, all devices in the system stop at their current positions and wait for a message to follow.

- **Continue**—Following the receipt of a MIDI stop command, a MIDI continue message instructs all instruments and devices to resume playing from the precise point at which the sequence was stopped. Certain older MIDI devices (most notably drum machines) aren’t capable of sending or responding to continue commands. In such a case, the user must either restart the sequence from its beginning or manually position the device to the correct measure.

### 29.6.2 Song Position Pointer

In addition to MIDI real-time messages, the Song Position Pointer (SPP) is a MIDI system common message that isn’t commonly used in current-day production. Essentially, SPP keeps track of the current position in the song by noting how many measures have passed since the beginning of a sequence. Each pointer is expressed as multiples of six timing-clock messages and is equal to the value of a 16th note.

The song position pointer can synchronize a compatible sequencer or drum machine to an external source from any position within a song containing 1024 or fewer measures. Thus, when using SPP, it is possible for a sequencer to chase and lock to a multitrack tape from any measure point in a song.

Using such a MIDI/tape setup, a specialized sync tone is transmitted that encodes the sequencer’s SPP messages and timing data directly onto tape as a modulated signal. Unlike SMPTE time code, the encoding method wasn’t standardized between manufacturers. This lack of standardization prevents SPP data written by one device from being decoded by another device that uses an incompatible proprietary sync format.

Unlike SMPTE, where tempos can be easily varied by inserting a tempo change at a specific SMPTE time, once the SPP control track is committed to tape, the tape and sequence are locked into this predetermined tempo or tempo change map. SPP messages are usually transmitted only while the MIDI system is in the stop mode, in advance of other timing and MIDI continue messages. This is due to the relatively short time period that’s needed to locate the slaved device to the correct measure position.

### 29.6.3 MIDI Time Code

MIDI time code (MTC) was developed to allow electronic musicians, project studios, video facilities, and virtually all other production environments to cost-effectively and easily translate time code into time-stamped messages that can be transmitted via MIDI. Created by Chris Meyer and Evan Brooks, MTC enables SMPTE-based time code to be distributed throughout the MIDI chain to devices or instruments that are capable of synchronizing to and executing MTC commands. MTC is an extension of MIDI 1.0, which makes use of existing message types that were either previously undefined or were being used for other non-conflicting purposes. Since most modern recording devices include MIDI in their design, there’s often no need for external hardware when making direct connections. Simply chain the MIDI cables from the master to the appropriate slaves within the system (via physical cables, USB, or virtual internal routing). Although MTC uses a reasonably small percentage of MIDI’s available bandwidth (about 7.68% at 30 fr/s), it’s customary (but not necessary) to separate these lines from those that are communicating performance data when using MIDI cables. As with conventional SMPTE, only one master can exist within an MTC system, while any number of slaves can be assigned to follow, locate, and chase to the master’s speed and position. Because MTC is easy to use and is often included free in many system and program designs, this technology has grown to become the most common and most straightforward way to lock together such devices as DAWs, modular digital multitracks, and MIDI sequencers, as well as analog and videotape machines (by using a MIDI interface that includes a SMPTE-to-MTC converter).

The MTC format can be divided into two parts:

- **Time code.**
- **MIDI cueing.**

The time code capabilities of MTC are relatively straightforward and allow devices to be synchronously locked or triggered to SMPTE time code. MIDI cueing is a format that informs a MIDI device of an upcoming event that’s to be performed at a specific time (such as load, play, stop, punch in/out, reset). This protocol envisions the use of intelligent MIDI devices that can prepare for a specific event in advance and then execute the command on cue.

MTC is made up of three message types: quarter-frame messages, full messages, and MIDI cueing messages.
• **Quarter-frame messages**—These are transmitted only while the system is running in real or variable speed time, in either forward or reverse direction. True to its name, four quarter-frame messages are generated for each time code frame. Since 8 quarter-frame messages are required to encode a full SMPTE address (in hours, minutes, seconds, and frames—00:00:00:00), the complete SMPTE address time is updated once every two frames. In other words, at 30 fps, 120 quarter-frame messages would be transmitted per second, while the full time code address would be updated 15 times in the same period. Each quarter frame message contains 2 bytes. The first byte is F1, the quarter-frame common header, while the second byte contains a nibble (four hits) that represents the message number (0 through 7) and a nibble for encoding the time field digit.

• **Full messages**—Quarter-frame messages are not sent in the fast-forward, rewind, or locate modes, as this would unnecessarily clog a MIDI data line. When the system is in any of these shuttle modes, a full message is used to encode a complete time code address within a single message. After a fast shuttle mode is entered, the system generates a full message and then places itself in a pause mode until the time-encoded slaves have located to the correct position. Once playback has resumed, MTC will again begin sending quarter-frame messages.

• **MIDI cueing messages**—MIDI cueing messages are designed to address individual devices or programs within a system. These 13 bit messages can be used to compile a cue or edit decision list, which in turn instructs one or more devices to play, punch in, load, stop, and so on at a specific time. Each instruction within a cueing message contains a unique number, time, name, type, and space for additional information. At the present time, only a small percentage of the possible 128 cueing event types has been defined.

**SMPTE/MTC Conversion.** Although MTC is commonly implemented within a software or hardware system itself (that’s the functional and economic beauty of it), whenever a hardware device that doesn’t talk MTC (but only a flavor of the SMPTE protocol), a SMPTE-to-MIDI converter must be used, Fig. 29-37. These conversion systems are available as stand-alone devices or as an integrated part of a multiport MIDI interface/patch bay/synchronizer system. Certain analog and digital multitrack systems include a built-in MTC port within their design, meaning that the machine can be synchronized to a DAW/sequencing system without the need for any additional hardware, beyond a MIDI interface.

![Figure 29-37.](image.png) SMPTE time code can be easily converted to MTC (and vice versa) for distribution throughout a production system.

30.1 Introduction

The digital storage of audio signals presents a technical challenge. A 60 minute stereo musical selection, with a sampling rate of 44.1 kHz and 16 bit pulse code modulation, generates over 5 billion bits. To store this data successfully, error correction, synchronization, and modulation may push the total required capacity to over 15 billion bits. Recordings with a higher sampling frequency, longer word-length, and additional channels require correspondingly greater storage capacity. In addition, commercial music storage media must provide random access, small size, convenience, durability, low cost, and ease of replication. Still other applications call for write-once or recordable/erasable storage. Clearly, digital audio’s storage requirements are formidable.

The CD was the first format able to meet these demands. A CD can hold over an hour of high-fidelity music on a robust and economically manufactured disc. CD player hardware specifications have evolved to surpass most listeners’ ability to audibly distinguish between players. In short, the format is well suited to the storage demands of stereo music. In addition, the CD format is suitable for many extended applications. As a result, a number of alternative CD formats were developed. A CD-ROM disc may hold several hours of music, along with video and text information. Write-once and recordable/erasable formats (CD-R and CD-RW) are widely used in both professional and consumer applications.

The desire for higher performance specifications and multichannel sound stimulated development of the super audio CD (SACD) format; it uses direct stream digital coding in place of PCM coding to store either stereo or multichannel audio signals on a multilayer disc. The need for increased storage capacity, particularly for the storage of high-quality digital video, encouraged development of the DVD format. A DVD disc may store from 4.7 to 17 Gbytes of data, using one or multiple data layers. As with the CD, DVD comes in many guises. The DVD-Video format is used to store motion pictures, DVD-Audio is used for high-quality stereo and multichannel music, DVD-ROM is used for computer applications, and a variety of DVD formats have been devised for recording applications. The HD DVD and Blu-ray disc formats use shorter wavelength lasers and higher resolution optics to dramatically increase storage density, allowing storage of high-definition video and audio. Disc formats such as these will further extend the opportunities of optical disc storage for professional and consumer applications.

30.2 CD Specifications

The compact disc digital audio (CD-DA) format is sometimes known as the Red Book standard and is codified in the ISO/IEC 908 standard. The diameter of a CD is 120 millimeters (mm) (4.7 in), its center hole diameter is 15 mm (0.59 in), and its thickness is 1.2 mm (0.047 in). The innermost diameter does not hold data; it provides a clamping area for the player to secure the disc to the spindle motor shaft. Data is recorded on a 35.5 mm (1.4 in) wide area. A lead-in area occupies the innermost data radius, and a lead-out area occupies the outermost radius; they contain nonaudio data used to control the player’s operation.

A transparent polycarbonate plastic substrate forms most of a disc’s 1.2 mm thickness, as shown in Fig. 30-1. Data is physically contained in pits that are impressed on the top surface of the substrate. The pit surface is covered with a very thin 50 nm to 100 nm (nanometer) metal (e.g., aluminum or gold) layer and another thin 10 μm to 30 μm (micrometer) protective plastic layer, with the 5 μm identifying label printed on top. A laser beam is used to read the data. It is applied from below, passes through the transparent substrate, reflects from the metallized pit surface, and passes back through the substrate. The laser beam is focused on the metallized surface embedded inside the disc. Since data on a disc is read by a light beam, playing a CD does not cause wear to the data surface, or pickup.

Figure 30-1. CD construction showing substrate, metallized surface, protective layer, and label.

30.2.1 Pit Track

Data is arranged as a pit track in a continuous spiral running from the inner circumference to the outer. A pit is
about 0.6 μm wide. A photograph of a pit surface, taken with a scanning electron microscope, is shown in Fig. 30-2. The track pitch, the distance between successive tracks, is 1.6 μm; the track pitch acts as a diffraction grating, producing a rainbow of colors. There is a maximum of 20,188 revolutions across the disc’s standard data surface width of 35.5 mm.

![Figure 30-2. Scanning electron microscope photograph of the CD data surface. Courtesy University of Miami.](image)

The linear dimensions of a track are the same at the beginning of a spiral as at the end. This means that a CD rotates with a constant linear velocity (CLV), a condition in which a uniform relative velocity is maintained between the data spiral and the pickup. To accomplish this, the rotation speed of a disc varies depending on the radial position of the pickup. Because each outer track revolution contains more pits than each inner track revolution, the disc must be slowed as it plays outward to maintain a constant rate of data. In particular, the disc rotates at a speed of about 500 rpm when the pickup is reading the inner circumference, and as the pickup moves outward, the rotational speed gradually decreases to about 200 rpm. A constant linear velocity is maintained through a CLV servo system; the player reads frame synchronization from the stored data and varies the disc speed to maintain a constant data rate. The CD standard permits a maximum of 74 minutes, 33 seconds of audio playing time on a disc. However, by reducing parameters such as track pitch and linear velocity, it is possible to manufacture discs with over 80 minutes of music.

The fact that the disc data surface is physically separated from the reading side of the substrate provides a significant asset. Damage and dust on the outer surface do not lie in the focal plane of the reading laser beam and hence their effect is minimized.

The polycarbonate substrate has refractive index of 1.55; the velocity of light slows from 3 \times 10^5 kilometers/second (km/s), to 1.9 \times 10^5 km/s. Because of the bending from the refractive index and thickness of the substrate, and the numerical aperture (NA) of 0.45 of the laser pickup’s lens, the diameter of the laser spot is reduced from approximately 800 μm on the disc surface to approximately 1 μm at the pit surface. The laser beam is thus focused to a point larger than a pit width.

The reflective data pit surface, known as land, causes almost 90% of the laser light to be reflected back into the optical pickup. When viewed from the laser’s underside perspective, the pits appear as bumps. The height of each bump is between 0.11 and 0.13 μm (110 and 130 nm.) This dimension is slightly smaller than the laser beam’s wavelength in air of 780 nm (some players use 790 nm). Inside the polycarbonate substrate, the laser’s wavelength is about 500 m. The height of the bumps is thus approximately one-quarter of the laser’s wavelength in the substrate.

There is a phase difference between the part of the beam reflected from the bump, and the part reflected from the surrounding land. The phase difference causes destructive interference in the reflected beam. In theory, when the beam strikes an area between pits virtually all of its light is reflected, and when it strikes a pit virtually all of the light returning to the pickup is canceled, hence virtually none is reflected. In practice, the laser spot is larger than required for complete cancellation between pit and land reflections, and pits are made slightly shallower than a quarter wavelength; this yields a better tracking signal, among other things. Typically the presence of a bump reduces reflective power by about 25%. In any case, the data surface varies the intensity of the reflected laser beam. Thus the data physically encoded on the disc can be recovered by the laser, and converted to an electrical signal using a photodiode.

### 30.2.2 Data Encoding

The audio program played from a CD is the culmination of a data transformation that takes place during master encoding and that undergoes decoding each time the disc is played. Various media are used to hold master recordings. Originally, many CDs were mastered from data recorded on ¾ inch U-matic videotape cassettes using a digital audio processor. In many cases, Exabyte 8 mm data tapes are used to hold the master recording. For audio mastering, the DDP (Disk Description Protocol) file format may be used to hold Red Book and PQ
subcode data. Both DDP 1.0 and DDP 2.0 are used; the 2.0 specification writes the TOC to the end of the tape. It is generally recommended to supply a replication plant with an Exabyte tape with DDP files (including PQ and ISRC data). With Exabyte tapes, glass masters may be created at faster than real time speeds. In some cases, audio data is written to a master CD-ROM (CD read-only memory) disc as 24-bit WAV or AIFF files. DAT tapes and CD-R discs can be used as masters, but their relatively higher error rates and susceptibility to damage make them nonideal. An analog tape can also be used as the master. Digital recordings made at a different sampling rate must be passed through a sample rate converter.

CD encoding is the process of placing audio data in a format suitable for storage on the disc. A frame structure provides a means to distinguish the data types. The information contained in a CD frame (prior to modulation) contains a 27-bit sync word, 8-bit subcode, 192 data bits, and 64 parity bits.

Encoding begins with the audio data. Six 32-bit PCM audio sampling periods (alternating from 16-bit left and right channels) are grouped in a frame, left channel preceding right. Each 32-bit sampling period is divided to yield four 8-bit audio symbols. Subsequent signal processing prepares the audio data for storage on the disc surface. In particular, error correction encoding must be accomplished.

The raw error rate from a CD is around $10^{-5}$ to $10^{-6}$, or about one error for every 0.1 to 1.0 million channel (stored) bits. This is impressive storage capability, but considering that a disc outputs 4.3218 million channel bits per second, the need for error correction is obvious. With error correction, 220 errors per second can be completed corrected; interleaving distributes errors, and parity corrects them.

The Cross Interleave Reed-Solomon Code (CIRC) algorithm is used for error correction in the CD system. The CIRC algorithm uses two correction codes for correcting capability, and three interleaving stages to encode data before it is placed on a disc and to decode the data during playback. Because of cross interleaving, the separation of two error correction codes by an interleaving stage, one Reed-Solomon code can check the validity of the other code. The Reed-Solomon code used in CIRC is well suited for the CD system because its decoding requirements are relatively simple. The complete CIRC encoding scheme is shown in Fig. 30-3. With this encoding algorithm, data (twenty-four 8-bit symbols) from the audio signal are cross-interleaved, and two encoding stages generate 8-bits of parity.

### 30.2.3 Subcode

Following CIRC encoding, an 8-bit CD subcode symbol is added to each frame. The eight subcode bits are designated as P, Q, R, S, T, U, V, and W. Only the P or Q bits are required in the audio format. The CD player collects subcode symbols from 98 consecutive frames to form a subcode block, with eight 98-bit words. Thus the eight subcode bits (P through W) are used as eight different channels with each CD frame containing 1 P bit, 1 Q bit, etc. A subcode block is complete with a synchronization word, instruction and data, commands, and parity. The start of each subcode block is denoted by sync patterns in the first symbol positions of two successive blocks.

The P channel contains a flag bit originally designed for use by simple players to access disc information. In practice, players ignore the P bit and use information in the more comprehensive Q channel. The Q subcode channel is vital for reading audio data on the disc. The Q channel contains four kinds of information: control, address, Q data, and cyclic redundancy check code (CRCC). Each subcode block contains 72-bits of Q data and 16-bits for CRCC, used for error detection on the control, address, and Q data information. The control information flag bits handle several player functions:

1. The number of audio channels (two or four) is indicated; this distinguishes between a two- and four-channel CD recording (the latter not implemented).
2. Preemphasis (on/off) is indicated; a CD track may be encoded with preemphasis, a noise suppression method (this is rarely employed).
3. Digital copy prohibited (yes/no) is indicated.
4. Audio or data content is indicated.

The address information consists of four bits designating the three modes for the Q data bits. Primarily, Mode 1 contains the number and start times of tracks, Mode 2 contains a catalog number, and Mode 3 contains other product codes. Mode 1 stores information in the disc lead-in area, program area, and lead-out area; the data format in the lead-in area differs from that in the other areas. Mode 1 lead-in information is contained in the CD table of contents (TOC). The TOC stores data indicating the number of music selections (up to 99) as a track number and the starting points of the tracks in disc running time. The TOC is read during disc initialization, before the disc begins playing audio data.

In the program and lead-out areas, Mode 1 contains track numbers, indices (subdivision numbers) within a track, time within a track, and absolute time. A time count is set to zero at the beginning of each track and increases to the end of the track. At the beginning of a
pause, a time count decreases ending with zero at the end of the pause. The absolute time is set to zero at the beginning of the program area and increases to the start of the lead-out area. Time and absolute time are expressed in minutes, seconds, and frames (75 frames per second). Modes 2 and 3 are optional in the subcode.

The other six channels (R, S, T, U, V, and W,) which account for about 20 megabytes of 8-bit storage, are available for other data storage. In some discs, this capacity is used to hold CD-Text, a feature that was appended to the original Red Book specification. With CD-Text, album title, song titles, artist names, and other text information are coded prior to manufacture. Compatible players can read and display CD Text information and also search for particular album titles in a changer. CD-Text supports color bitmaps and JPEG

Figure 30-3. CIRC encoding algorithm.
30.2.4 EFM Encoding

After the audio, parity, and subcode data is assembled, the bit stream is modulated using EFM (eight-to-fourteen modulation). Blocks of 8 data bits are translated into blocks of 14 channel bits, assigning an arbitrary and unambiguous word of 14-bits to each 8-bit word. By choosing select 14-bit words with a low number (and known rate) of 1/0 transitions, greater data density can be achieved. It would be inefficient to store the 8-bit symbols directly on the disc; the large number of 1/0 transitions would demand many pits. In addition, 8-bit symbols have many similar patterns. With 14-bit words, more unique patterns can be selected. EFM thus expedites error correction.

Blocks of 14-bits are linked by three merging bits; two merging bits (always 0s) are required to prevent the possibility of successive 1s between serial words (a violation of the EFM coding scheme). The additional merging bit (either a 1 or a 0, depending on the preceding and succeeding patterns) is added to each code pattern to aid in clock synchronization and to suppress the signal’s low-frequency component. The latter is accomplished by selecting merging bits that maintain the signal’s average digital sum value at zero. The ratio of bits before and after modulation is 8:17. During demodulation, only 14-bits will be processed, the 3 merging bits are discarded.

The 8 data bits require $2^8$ or 256 different code patterns. However the 14-bit channel word can offer 16,384 combinations. To achieve pits of controlled length, only those combinations are selected in which more than two but less than ten 0s appear continuously. In addition, unique patterns are sought. Only 267 combinations satisfy these criteria. Because only 256 patterns are needed, 11 of the 267 patterns are discarded (two of them are used for subcode synchronization words).

The resultant channel stream produces pits and lands that comprise at least two (3T) but no more than ten (11T) successive 0s in length. It is the combination of these varying dimensions that physically encodes the data. The selection of EFM bit patterns defines the physical relationship of the pit dimensions. The pits and intervening reflective land on the CD surface do not directly designate 1s and 0s. Rather, each pit edge whether leading or trailing, is a 1 and all increments in between, whether inside or outside a pit, are 0s, as shown in Fig. 30-4.

With EFM there are more bits to accommodate, but with modulation the highest frequency in the output signal is decreased. Therefore a lower track velocity can be utilized and longer playing time is achieved. This is an efficient encoding method because the number of bits transmitted divided by the number of transitions needed on the medium to convey them is high.

30.3 CD Player Design

A CD player hardware architecture may be considered as five functional elements each working in concert with the other: Optical readout, servo system, spindle motor, control and display, and decoding circuits. The data path directs the modulated light from the pickup through a series of processing circuits, ultimately yielding a stereo analog signal. The data path typically consists of elements such as data separator, deinterleaving RAM, error detection, correction and concealment circuits, oversampling filters, D/A converters, and analog output filters. The servo, control, and display system must direct mechanical operation of the disc, including spindle drive, auto-tracking, and auto-focusing, and handle user interface with the player’s controls and displays. A block diagram of the data path is shown in Fig. 30-5.

30.3.1 Optical Pickup

The CD optical pickup must focus, track, and read the data spiral. The entire lens assembly, a combination of the laser source and the reader, must be small enough to
glide laterally beneath the disc, moving in response to tracking information and user access demands. Furthermore, the pickup must maintain focusing and tracking even under adverse playing conditions such as a dirty disc or impact and vibration.

To achieve sharp focus on the data surface and intensity modulation, a laser is used as the light source. CD pickups use an AlGaAs semiconductor laser irradiating a coherent-phase laser beam with a 780 nm wavelength (some manufacturers use 790 nm).

CD players can employ either single-beam or three-beam pickups; three-beam designs are more prevalent. A three-beam pickup uses a center beam for reading data and focusing, and two secondary beams for tracking. The design of a three-beam pickup is shown in Fig. 30-6. To generate additional beams, the laser light passes through a diffraction grating, a screen with slits spaced only a few laser wavelengths apart. As the beam passes through the grating, the light diffracts; when the resulting collection is again focused, it will appear as a single bright centered beam with a series of successively less intense beams on either side. Three beams from this diffraction pattern usefully strike the disc. As discussed, when a laser spot strikes land, the smooth interval between two pits, the light is almost totally reflected; when it strikes a pit (seen as a bump by the laser), destructive interference and diffraction causes less light to be reflected into the pickup. The intensity-modulated light is collected by the objective lens and passes through the reading portion of the pickup.

In many three-beam designs, the property of astigmatism is used to achieve auto-focusing. A cylindrical lens is used to detect an out-of-focus condition. As the distance between the objective lens and disc reflective surface varies, the focal point of the optical system also changes, and the image projected by the cylindrical lens changes its shape, as shown in Fig. 30-7. That change in the image on a four-quadrant photodiode generates the focus correction signal. For example, if the disc were too near to the pickup’s objective lens, the focal length...
would be shortened and astigmatism from the cylindrical lens would cause the reflected laser spot to be flattened and rotated to one side. This would cause more light to fall on two (opposite) pairs of photodiodes than on the other pairs. This generates a voltage interpreted by the servo system as a command to pull the lens down from the disc. This provides the correct focal path length where astigmatism would not affect the beam. Hence, it would have a round shape, and an equal amount of light would fall on each part of the four-quadrant photodiode, providing a neutral signal to the servo system. When the disc is too far from the lens, the laser spot rotates in the opposite direction, generating a voltage that pushes the lens upward. In practice, the process in this servo loop is a dynamic one, with the objective lens moving in constant accord with disc deviations to provide a correct focal path length.

In three-beam pickups, the two secondary beams are used for auto-tracking. The central beam spot covers the pit track while the two tracking beams are aligned above and below and to either side of the center beam. When the beam is tracking the disc properly, part of each tracking beam is aligned on the pit edge; the other part covers the mirrored land between pit tracks. The main beam strikes a four-quadrant photodiode, and the two tracking beams strike two separate photodiodes mounted on either side of the main photodiode.

If the three spots drift to either side of the pit track, the amount of light reflected from the tracking beams varies. There is less average light intensity reflected by the tracking beam that encounters more pit area and greater reflected light intensity from the tracking beam that encounters less pit area. The relative output voltages from the two tracking photodiodes thus form a tracking correction signal, as shown in Fig. 30-8. Operating similarly to the signal used in the auto-focus servo loop, this tracking signal forms a control voltage for the auto-tracking servo mechanism. For example, when the pickup’s objective lens drifts to the right of the pit track, the right tracking beam encounters more reflective land and its reflected intensity is greater. When this brighter spot strikes the right tracking photodiode, a voltage greater than that on the left photodiode is generated. This voltage shift causes the servo system to move the pickup to the left, toward the pit track center. Likewise, the opposite occurs when the pickup drifts to the left. In this dynamic process the servo system continually moves the pickup to compensate for track deviations.

In addition to auto-focus and auto-tracking, a CD pickup uses other motor systems to move the pickup across the disc surface in response to user commands. For example, the pickup must search rapidly across the disc as it reads data, or jump from one track to another. These functions are handled using control signals derived from the auto-tracking and auto-focus circuits; however, separate motors are used to move the pickup itself. Three beam pickups are mounted on a sled that moves across the disc surface. In many designs, linear motors move the pickup and position it to within capture range of the auto-tracking circuit, which takes control when the selected disc location is found. A spindle motor is used to rotate the disc with constant linear velocity. Thus the player must vary the disc speed.
depending on where the pickup is located on the disc surface—faster on inner diameters, and slower on outer diameters. This is accomplished with yet another servo loop; information from the data stream recovered by the laser pickup is used to determine correct rotating speed, and the spindle motor is regulated accordingly.

30.3.2 Data Decoding

The photodiode array and its processing circuits produce a signal resembling a series of high-frequency sinusoids called the *EFM signal*. A collection of EFM waveforms (called an *eye pattern*) is shown in Fig. 30-9. The digital data can be recovered from the EFM signal if it can be determined when the signal crosses the zero axis, relative to the timing constraints created by the EFM encoding rules.

CD data decoding follows a procedure that essentially duplicates, in reverse order, the encoding process. The first data to be extracted from the signal is synchronization words. This information is used to synchronize the thirty three symbols of channel information in each frame, and a synchronization pulse is generated to aid in locating the zero crossing of the EFM pattern and to generate a transition at those points to produce a binary signal.

The EFM signal is demodulated so that every 17-bit EFM word is reconverted to 8-bits. Demodulation can be accomplished by logic circuitry or a look-up table. A buffer is used to remove the effect of disc rotational irregularities; data input to the buffer may be irregular in time but clocking ensures that the buffer output is precise. To guarantee that the buffer neither overflows nor underflows, a correction signal is generated and used to control the disc rotating speed.

Following demodulation, data is sent to a CIRC decoder for deinterleaving, error detection, and correction. The CIRC decoding process reverses the processing steps accomplished during encoding. The CIRC decoder accepts one frame of thirty-two 8-bit symbols; twenty four are audio symbols, and eight are parity symbols. One frame of twenty-four 8-bit symbols is output. The decoder utilizes parity from two Reed-Solomon decoders and deinterleaving. The first error correction decoder is designed to correct random errors, and to detect burst errors. It flags all burst errors, to alert the second error correction decoder.

Error concealment algorithms, employing interpolation and muting circuits, follow the CIRC decoder. Uncorrected words are detected through flags and dealt with, while valid data passes through unprocessed. Using error flags, the player’s signal-processing circuits determine whether to output the data directly, to interpolate it, or to mute the sound.

For continuous errors, muting is employed as a last resort; invalid data passed on to the D/A converter could result in an audible click. Muting is accomplished by beginning attenuation many samples before the invalid data, smoothly muting the invalid data, and then smoothly restoring the signal level. This method of muting is often largely inaudible.

30.3.3 Signal Reconstruction

At the output stage, the digital data is converted to a stereo analog audio signal. This reconstruction requires low-pass filtering to suppress high-frequency image components and D/A conversion. An oversampling digital filter uses samples from the disc as input and then computes interpolation samples, digitally implementing the response of a low-pass filter. A transversal filter can be used to oversample (perhaps at an eight-times rate); image components appear at multiples of the new sampling rate. Because the separation between the baseband and sidebands is greater, a low-order analog filter can be used to remove the images. The type of oversampling filter found in CD players is an example of a wider class of FIR (finite impulse response) digital filters used in many applications. These kinds of filters use addition, multiplication, and delay elements to perform their tasks, and fall under a wider category of technology known as DSP (digital signal processing). The transversal filter used in CD players resamples and filters through interpolation. Resampling acts to increase the sampling rate; for example, in an eight-times oversampling filter, seven zero values are inserted for every data value output from the disc. This increases the sampling rate from 44.1 kHz to 352.8 kHz.

Interpolation is used to generate the values of intermediate sample points—for example, seven intermediate samples for each original sample. These samples are
computed using coefficients derived from a low-pass filter response. In this way, when these samples are summed with other such samples, the output data stream corresponds to the \( \sin (x)/x \) impulse response processing of an ideal low-pass filter. Following this processing, the data is converted into a format appropriate for the type of D/A converter used in the player. In most CD players, sigma-delta D/A converters are used, employing techniques such as short word lengths, very high oversampling rates and noise shaping.

Also present in the audio output stage of every player is an audio deemphasis circuit. Some CDs are encoded with audio preemphasis characteristic. On playback, this is detected and deemphasis is automatically carried out, resulting in an improvement in signal-to-noise ratio.

### 30.4 Other CD Formats

The CD’s small size, economy, robustness, and capacity make it an excellent music carrier. However, its utility is not limited to music playback. Other formats, including computer-based storage and recordable formats, have been derived from the original Red Book standard. In particular, the CD-ROM, CD-R, and CD-RW formats are widely used in computer applications as well as stand alone audio applications.

#### 30.4.1 CD-ROM

The CD read-only memory (CD-ROM) standard, sometimes called the Yellow Book standard, is codified as the ISO/IEC 10149 standard. It is derived from the CD audio standard but defines a format for general data storage and is not tied to any specific application. Ninety-eight CD frames are summed to form a data block of 2352 bytes (24 bytes \( \times 98 \) frames). Each disc holds 330,000 blocks. The first 12 bytes of a block form a synchronization pattern, and the next 4 bytes form a header field for time and address flags. The header contains three address bytes, represented as disc times, storing minutes, seconds, and block numbers within the second. The header also contains a mode byte; depending on the mode selected, the remaining 2336 bytes can store user data, or 2048 bytes of user data with extended error correction.

The mode byte identifies three modes and is used for two different data types, shown in Fig. 30-10. Mode 1 permits 2048 bytes of user data in each block. Each block contains 2 Kbytes \((2 \times 1024)\) of user data; 280 bytes are given to extended error detection and correction (EDC/ECC). A Mode 1 CD-ROM holds 682 million bytes of user information \((333,000 \times 2048\) bytes\). Mode 2 gives the full 2336 bytes to user data. A CD-ROM bit stream is applied to conventional CD encoding so that CIRC, EFM, and other processing is applied. Mode 1 thus has two independent layers of error correction (EDC/ECC and CIRC) whereas Mode 2 uses only CIRC error correction.

Because of its extended error correction, EDC/ECC data independently supplements the CIRC error correction code applied to the frame structure, improving the error rate over that of audio CD. Mode 1 is employed for numerical data storage, which is more critical than audio data. In EDC/ECC encoding, a GF(2\(^8\)) Reed-Solomon product code (RS-PC) codes each block. It produces P and Q parity bytes with \((26,24)\) and \((45,43)\) code words respectively.

The CD-ROM/XA format is an extension to the Mode 2 standard and defines an XA data track that can contain diverse data such as computer, and compressed audio and video. However, CD-ROM/XA differs from CD-ROM Mode 2; XA provides a subheader that

---

**Figure 30-10.** CD-ROM Mode 1 contains 2048 bytes of user data with extended error correction, and Mode 2 contains 2336 bytes of user data.
defines two types of blocks: Form 1 for computer data and Form 2 for compressed audio/video data. The former provides a 2048-byte user area, and the latter provides 2324 bytes. An XA track can interleave Form 1 and 2 blocks, but Red Book data cannot be placed in an XA track. Some products are dedicated to specific types of CD-ROM/XA discs; the Video CD is an example of this.

Hybrid audio/data CD formats such as CD Extra and Mixed Mode CD combine different format types (such as CD audio and CD-ROM/XA) on one disc. A CD Extra disc contains CD audio data in the first session, and CD-ROM-XA mode 2 data in the second session. In Mixed Mode CDs, ROM data is placed in track 1, and CD audio data is placed in subsequent tracks. To make sure an audio player does not access the ROM track, a pregap may be used so that ROM data is placed after the disc table of contents (TOC), but before the first music track. CD-ROM data is placed between Index 0 and Index 1 of Track 1, while the music starts at Track 1, Index 1. An audio player thus skips the data, starting playback at the first music track. However, the pregap area is not accessible to all drive software.

Unlike the CD audio standard, the CD-ROM standard does not stipulate how content is defined. Subsequently the ISO/DIS 9660 standard was devised; it specifies how computer data is placed on a CD-ROM; to read the data, the computer operating system must read the ISO 9660 file structure. Content on CD-ROM discs can be authored for multiple platforms; however, executable files can only run on the appropriate platform. For example, hybrid CD-ROM titles can be played on IBM and Macintosh platforms. The different data types are physically partitioned on the disc surface.

30.4.2 CD-R

The CD recordable (CD-R) format allows users to permanently record audio or other data to a CD. The format is technically named CD-WO (Write Once), as codified in the Orange Book Part II. CD-R discs that carry audio and nonaudio data prior to CD replication can be written with the PMCD (premastered CD) format; the disc contains index and other information. CD-R discs with up to 80 minutes of playing time (about 700 Mbytes) are available.

CD-R discs are physically different from Red Book CDs. CD-R discs are manufactured with a pregrooved spiral track with 0.6 μm width and 1.6 μm pitch; it guides the recording laser along the track. The pregroove is physically modulated with a ±0.03 μm sinusoidal wobble with a frequency of 22.05 kHz. Recorders use the wobble to control the disc CLV rotation speed. The 22.05 kHz groove wobble is also frequency modulated with a ±1 kHz signal; this creates an ATIP (absolute time in pregroove) clocking signal.

CD-R discs are manufactured on a polycarbonate substrate, and contain a metal (e.g., gold or silver) reflective layer, an organic dye recording layer, and a top protective layer. The recording layer is placed between the substrate and reflective layer as shown in Fig. 30-11. Together with the reflective layer it provides a reflectivity of about 73%. A writing laser with wavelength of 775 nm to 795 nm passes through the polycarbonate substrate and heats the recording layer to approximately 250°C, causing it to melt and/or chemically decompose to form a depression or mark in the recording layer. Simultaneously, the reflective layer is deformed. These depressions or marks have a decreased reflectivity. During readout, the same laser, reduced in power, is reflected from the data surface and its changing intensity is monitored.

Either cyanine or phthalocyanine organic dye polymers are often used for the recording layer. They are designed to absorb light at about 780 nm. Cyanine dye has a relatively broad range of sensitivity to light and is generally reliable in a wide range of recorders and laser powers and writing speeds. Phthalocyanine-based media are generally said to have greater longevity because it is less sensitive to ordinary light and stable. However, this lower sensitivity may result in a small power margin for the writing laser. Thus the writing speed and laser power must be more carefully controlled. In some cases, metallized azo dye is used as the recording layer in CD-R media. Organic dye layers are affected by aging. The dye layer will deteriorate over time because of oxidation, material impurities, or exposure to ultraviolet light. CD-R discs will play back on most CD audio players, but the reduced data layer reflectivity can cause playback incompatibility.

Two areas are written to the inner radius (22.35–23 mm) of CD-R discs, both inside the Red Book lead-in radius. The PMA (program memory area)
contains data describing the recorded tracks, a temporary table of contents, and track skip information. When the disc is finalized, this data is transferred to the TOC. On the innermost radius, the PCA (power calibration area) is used by the recording laser to make an optimal power calibration test recording to determine proper laser recording power. A recording is complete when a lead-in area (with TOC), user data, and lead-out area are written. A maximum of 99 tracks can be recorded on a disc. Because the PMA and PCA areas are inside the normal lead-in radius, conventional CD players do not read them.

The CD-R standard defines both single-session and multisession recording (a session is a recording with lead-in, data, and lead-out areas). In single-session recording, sometimes called disc-at-once recording, an entire disc program is recorded without interruption. Track-at-once recording allows single or multiple tracks to be written in a session. Recorders using track-at-once can also write a single-session CD-R. In multisession recording, sessions can be recorded one or a few at a time. Tracks can be written singly and recording can be stopped after each track. Separate recording sessions are allowed, each with its own lead-in TOC, data, and lead-out areas. Track-at-once recorders allow both multisession and single-session recording. In track-at-once recording, multiple tracks can be written to a session, adding data one track at a time; no lead-in or lead-out is written until the session is closed. CD audio players can read only the first session on a multi-session disc. A partially recorded disc can be played on the CD-R recorder but cannot be played on a CD audio player until the session ends when the final TOC and lead-out areas are recorded. Using the CD portion of the universal disk format (CD-UDF), CD-R recorders can perform packet writing; this allows small amounts of data to be written efficiently without high overhead. Data in a file can be appended and updated without rewriting the entire file.

30.4.3 CD-RW

The CD Rewritable (CD-RW) format allows data to be written and read, and erased and rewritten. The format is technically named CD-E and is described in the Orange Book Part III standard. A CD-RW drive can read, write, and erase CD-RW media, read and write CD-R media, and read CD-ROM and CD audio media. Thousands of rewrite cycles are possible. Any data can be written, including computer programs, text, pictures, video, audio, or other files. A CD-RW disc has five layers built on a polycarbonate substrate: a dielectric layer, another dielectric layer, a reflective aluminum layer, and a top acrylic protective layer, as shown in Fig. 30-12. As in CD-R, the writing and reading laser follows a pregroove spiral track. However, the CD-RW format employs a phase-change recording method, using materials that exhibit a reversible crystalline/amorphous phase change when recorded at one temperature and erased at another. In most cases, a high-reflectivity (crystalline) to low-reflectivity (amorphous) phase change is used to record data, and the reverse to erase. Data is recorded by heating an area of the crystalline layer to a temperature slightly above its melting point and cooled rapidly. The area is amorphous when it solidifies, and the decreased reflectivity is detected by a low power reading laser. Because the crystalline form is more stable, the material will tend to change back to this form. Thus when the area is heated to just below its melting temperature and cooled slowly, it returns to a crystalline state, erasing the data. In some cases, the recording layer comprises gallium antimonide and indium antimonide; other systems use tellurium alloyed with elements such as germanium and indium. The dielectric layers comprise silicon, oxygen, zinc, and sulfur; they control the optical response of the media and increase the efficiency of the laser by containing the heat in the recording layer. The dielectric layers also thermally insulate and protect the pregroove, substrate, and reflective layer.

The reflectivity of CD-RW discs is only about 15% (amorphous state) and 25% (crystalline). Discs will not play in most CD audio players or CD-ROM drives; however, many DVD players do play CD-RW discs. Multi-read drives are capable of reading lower reflectivity CD-RW discs. They use an AGC (automatic gain control) circuit to boost the gain of the signal output from the photodiodes and compensate for the lower reflectivity and decreased signal modulation. CD-RW discs carry a code that identifies them as CD-RW discs to the player. CD-RW drives are commonly found as
computer peripherals. Software supports track-at-once, disc-at-once, and multisession recording. When CD-RW discs are appropriately formatted, the CD-Universal Device Format (CD-UDF) specification permits easy file-by-file rewriting; for example, users can write to CD-RW discs with dragging and dropping.

30.5 Super Audio CD

The super audio CD (SACD) standard provides high-density storage to support two-channel CD and two-channel and multichannel SACD audio recordings. SACD recordings use 1-bit direct stream digital (DSD) coding with a high sampling frequency to achieve a frequency response to 100 kHz and a dynamic range of 120 dB in the 0 to 20 kHz band. Hybrid SACD discs can hold both a high-density DSD data layer (containing both a 5.1-channel mix and a stereo mix) as well as a Red Book compatible (44.1 kHz/16-bit) data layer. SACD players play back both SACD and CD discs. To achieve this, dual laser pickups operate at both the SACD 650 nm wavelength and the CD 780 nm wavelength. The SACD format also specifies a lossless coding algorithm known as direct stream transfer (DST); it uses an adaptive prediction filter and arithmetic coding to effectively double disc capacity. The SACD standard is described in the Scarlet Book.

30.5.1 SACD Specifications

SACD discs have a 12 cm diameter and 1.2 mm thickness, the same as a CD. Other specifications allow greater density; the laser wavelength is 650 nm, the lens numerical aperture (NA) is 0.60, the minimum pit/land length is 0.40 μm, and the track pitch is 0.74 μm. A single-layer SACD disc holds 4.7 Gbytes of data; this provides about 110 minutes of playing time for a two-channel stereo DSD recording. Several disc types are specified in the SACD format including single-layer, dual-layer, and hybrid disc constructions. The single-layer disc contains one layer of DSD content (4.7 Gbytes); the dual layer contains one or two layers of DSD content (8.5 Gbytes with two layers); and the hybrid disc is a dual layer disc that contains one inner layer of DSD content (4.7 Gbytes) and one outer layer of Red Book CD content (780 Mbytes) that can be played in ordinary CD players. In dual-layer discs, two 0.6 mm substrates are bonded together. There is only one data side in all implementations. A semireflective layer (20–40% reflective) covers the embedded inner data layer, and a fully reflective top metal layer (at least 70% reflective) covers the outer data surface. The outer data surface is protected by an acrylic layer and a printed label. Fig. 30-13 shows a hybrid disc and a dual pickup (650 and 780 nm) reading SACD and CD layers.

SACD players can play both SACD and CD discs (and hybrid SACD discs). CD data is passed to the digital filter and SACD data is applied to the DSD decoder. DSD data is output as a 1-bit signal and applied to a pulse density modulation processor. The data signal is converted to a complementary signal; each logical 1 creates a wide pulse and each logical 0 creates a narrow pulse. A current pulse D/A converter converts the voltage pulse output into a current pulse. This signal is applied to an analog low-pass filter to create the analog audio waveform. SACD recordings with DSD coding are not compatible with the DVD-Audio standard and its PCM coding. Some players may include decoders to accommodate both disc formats.

30.5.2 Direct Stream Digital Coding

SACD recordings employ direct stream digital (DSD) coding which uses 1-bit pulse density representation and sigma-delta modulation to code audio signals. Many A/D converters use sigma-delta techniques to sample the input signal at a high sampling frequency. The signal is applied to a decimation filter and quantized for output as a PCM signal at a nominal sampling frequency of 44.1 kHz (for CD) and up to 192 kHz (for

30.6 DVD Disc Format

In its early development, DVD was envisioned as a consumer video disc playback system. Subsequent development expanded the scope of the standard. The resulting family of DVD optical disc formats encompasses video, audio, and computer applications, with both playback-only and recordable technologies. Because the scope of these applications far exceeded digital video, the original name of digital video disc was changed to digital versatile disc, but that name was never accepted. Instead, the format is simply called DVD.

Whereas the CD was originally designed exclusively for audio storage, and subsequently adapted to other applications, the DVD family was designed as a universal storage platform. The CD was designed to work with or without microcontrollers in the player. In contrast, DVD employs sophisticated microcontroller functions to read its file structure and interact with the disc and its contents. The CD was designed to play back a continuous stream of data. Thus, addressing was not provided; addressing capability was only subsequently developed for CD-ROM. In DVD, all data is addressable and randomly accessible; all DVD contents are essentially viewed as software data. Although its outer physical dimensions are identical, one DVD data layer provides about seven times the storage capacity of a CD. This increase is due to the shorter wavelength laser, higher numerical aperture, smaller track pitch, and other aspects.

The DVD family contains six DVD books: Book A is DVD-ROM (read only), Book B is DVD-Video, Book C is DVD-Audio, Book D is DVD-R (write-once), Book E is DVD-RAM (random access memory), and Book F is DVD-RW (rewritable). In each book, Part 1 defines the physical specifications, Part 2 defines the file system specifications, and subsequent parts define specific applications and extensions. For example, Part 3 defines the video application, Part 4 defines the audio application, and Part 5 defines the VAN extension. DVD-ROM video and audio discs use the same disc specifications and physical format as well as file system. DVD-R, DVD-RAM, and DVD-RW discs are more unique. The DVD format employs other specifications. For example, the DVD file system uses elements of the UDF, ISO 9660 and ISO 13346 specifications, and DVD-Video uses MPEG video coding and Dolby Digital (AC-3) audio coding.

The physical specifications for the DVD-ROM, DVD-Video, and DVD-Audio discs are identical and these read-only formats share disc construction, modulation code, error correction, etc. Discs are 120 mm or 80 mm in diameter and 1.2 mm in thickness, and have two bonded substrates with single or dual data layer per substrate. DVD discs use a pit/land structure to store data. The DVD track pitch is 0.74 μm. The track constant linear velocity (CLV) is 3.49 m/s on a single layer and 3.84 m/s on a dual layer. Minimum/maximum pit length is 0.40/1.87 μm (single layer) and 0.44/2.05 μm (dual layer). The laser beam used to read DVDs uses a wavelength of 635 nm or 650 nm. The objective lens has a numerical aperture of 0.6. A DVD layer can store 4.37 Gbytes (measured in 8-bit bytes) of data and multiple data layers provide greater capacity.
30.6.1 DVD Disc Manufacturing

A DVD thickness of 1.2 mm comprises two 0.6 mm substrates, bonded together with the data layers placed near the internal interface for greater protection. Thinner substrates are optically more resistant to tracking errors that result when a disc is slightly tilted relative to the laser pickup. The dual substrate construction allows manufacturing variants, yielding five types of playback-only discs: DVD-5 (single side, single layer), DVD-9 (single side, dual layer), DVD-10 (dual side, single layer), DVD-14 (dual side, mixed layers with single layer on one side and dual layer on the other side), and DVD-18 (dual side, dual layer). As the nomenclature loosely suggests, five disc capacities are supported: 4.37, 7.95, 8.75, 12.33, and 15.91 Gbytes (expressed in 8-bit bytes). When the average data output bit rate is 4.8 Mbps, the approximate playing times are DVD-5 (133 min), DVD-9 (241 min), DVD-10 (266 min), DVD-14 (375 min), and DVD-18 (482 min).

DVD manufacturing is similar to CD manufacturing. Following authoring, disc content is typically imaged on a hard drive disk, transferred to another medium such as Digital Linear Tape (DLT), and delivered to the disc mastering facility. A DLT Type III tape cartridge can hold up to 10 Gbytes of uncompressed data; with a transfer rate of 1.25 Mbytes/s, a 135 min program can be transferred in about 1 hour. A separate DLT is used for each physical disc layer. Alternatively, other media such as DVD-R or Exabyte may be used.

A single-layer, single-sided DVD-5 disc uses one substrate with a data surface and one blank substrate. Two substrates with data surfaces can be bonded together to form a single-layer, dual-sided DVD-10 disc; the disc is turned over to access the opposite layer. The DVD standard allows data to be placed on two layers in a substrate to create a dual-layer disc that is read from one side comprising a DVD-9 disc. The layers are separated by a clear resin and a very thin semitransparent (semireflective from 25% to 40%) sputtered layer of gold or silicon. Both layers are read from one disc side by moving the objective lens and focusing the reading laser on either layer. The beam either reflects from the lower semireflective layer or passes through it and reflects from the top reflective layer. Because the SNR and reflectivity of the interior layer are slightly reduced, the layer uses a faster linear velocity (3.84 m/s versus 3.49 m/s). Thus the pit length is longer (e.g., the minimum pit length is 0.44 μm versus 0.4 μm). The interior layer thus has less capacity than the top data layer.

In the manufacture of dual-sided discs, two polycarbonate substrates are independently formed and then bonded together using a hot-melt adhesive or UV-cureable bonding. Dual-layer discs can be formed from two 0.6 mm substrates; one layer is fully metallized and the other is semireflectively metallized. The two substrates are then bonded together with a layer of UV-cured optically clear photopolymer. This technique can be used to manufacture single-sided discs (such as some DVD-9 discs). Alternatively, a single-layer substrate can be coated with a semitransparent layer followed by a layer of liquid photopolymer that is molded by a second stamper and hardened by exposure to ultraviolet light. After the layer is hardened, a fully reflective metal layer is applied and the substrate is bonded to a second substrate. This technique is used for some DVD-9 and DVD-18 discs. Construction of a dual-layer/dual-side DVD-18 disc is shown in Fig. 30-14.

![Figure 30-14. Construction of a dual-layer/dual-side DVD-18 disc.](image)

30.6.2 DVD File Format and Coding

The DVD format is fundamentally computer-based with a file format defined for its applications. In particular, the DVD specification describes Universal Disc Format (UDF) Bridge, a file format specifically designed for optical disc storage. Read-only DVDs (DVD-ROM, DVD-Video, and DVD-Audio) use UDF for volume structure and file format, and UDF applies to the write-once and recordable disc formats. However, application-specific parameters are unique to both DVD-Video and DVD-Audio. UDF Bridge is a simplified version based on Part 4 of ISO/IEC 13346 and conforms to both UDF and ISO 9660 (the file format used in CD-ROM). UDF Bridge defines data structures such as volumes, files, blocks, sectors, CRCs, paths, records, allocation tables, partitions, and character sets, as well as methods for reading, writing, and other operations. It is a flexible, multiplatform, multiapplication, multilanguage, multisuser oriented format that has been adapted to DVD and is backward compatible to existing ISO-9660 operat-
ing system software. However, a DVD-Video or -Audio player supports only UDF and not ISO-9660.

In read-only DVD formats, data is stored in files within directories. DVD data is placed on a disc in physical sectors that run continuously without gap from the lead-in to the lead-out area. A DVD data sector comprises 2064 bytes, with 2048 bytes of main data and 16 header bytes; the latter comprises 4 bytes of identification (ID), 8 bytes of other data, and 4 bytes of error-detection code (EDC) data. The 4 bytes of identification data (ID) contain 1 byte of sector information and 3 bytes of sector number. A sync code is added to the head of every 91 bytes in the recording sector. This forms a physical sector. In all, 52 bytes of sync code is added. The 2048 bytes of user data is thus increased to 2418 bytes.

A Reed-Solomon Product Code (RS-PC) uses a combination of two Reed-Solomon codes (C1 and C2) as a product code. It differs from the CD’s CIRC code. The two C1 and C2 product codes are (208,192) and (182,172) in length. Error correction is more challenging on a DVD because the pit size is smaller. In addition, because of the thin substrates, surface defects can more readily obscure the data surface. However, RS-PC is more powerful than the double error correction used in the CD-ROM format and provides improved error protection. RS-PC is also more efficient than CIRC in terms of overhead. In the DVD format, all disc types use the same level of error correction.

Read-only DVDs use EFMPlus modulation. It is an 8/16 RLL code and is similar to the EFM code used in CDs; for example, it uses the same minimum (2) and maximum (10) run length and represents logical 1 channel bits as pit/land or land/pit transitions and logical 0 channel bits as no transition. EFMPlus provides a 6% increase in user storage capacity compared to EFM because its coding is more efficient than EFM. Whereas EFM uses merging bits and a single lookup table and simple concatenation rules to suppress low-frequency content, EFMPlus does not require merging bits and uses a more sophisticated look-up method. The EFMPlus encoder defines four look-up tables each with 351 possible source words. In practice, the source codebook size is 344; seven possible words are discarded to allow for a unique 26-bit sync word. Of these, 256 words are used to code input data. The 88 surplus words are used as alternative channel representations to minimize the running digital sum value (DSV) and thus control low-frequency content.

In a DVD player, data passes through a buffer and is evaluated by a navigator/splitter that separates the bit stream into video, subpicture, audio, and navigational information. The video, subpicture, and audio data is decoded; for example, MPEG-2 video data is decoded as is Dolby Digital audio data. This can occur in a dedicated hardware chip or with software via a computer CPU. Navigational information is used by a controller for the user interface, while audio and video data is sent to the appropriate outputs.

### 30.7 DVD-Video

The DVD-Video format provides storage and playback of motion pictures or concert videos with multichannel soundtracks. The format was designed to provide the following: at least 133 minutes of digital video, approaching D1 broadcast picture quality, stereo or multichannel digital audio, multiple aspect ratios, up to 8 language soundtracks, up to 32 subtitles, parental control options, and copy protection.

In the DVD-Video format, data in a video disc is organized using the UDF Bridge file format. A DVD-Video zone and DVD-Other zone are defined under a root directory. In the DVD-Video zone, the VIDEO_TS directory (folder) contains menu and presentation data (video, audio, etc.). A Video Manager defines file types and organization of both video and audio data, and Video Title Set (VTS) subdirectories contain video and audio data files (such as MPEG-2 video and Dolby Digital audio). One Video Manager can contain up to 99 VTS subdirectories. Other computer data may be contained in the DVD-Other zone; this data may be used by DVD-ROM drives, and is ignored by DVD-Video players.

A DVD-Video VAN disc contains video-audio navigation data in a hybrid video-audio disc. VAN discs are video discs but they contain audio information that can be played on DVD-Audio players. Audio data is contained in an Audio Title Set, and video data in a Video Title Set. The Audio Manager and Video manager define file types and organize both audio and video data; both menu and program data is included. Using Link Info, a DVD-Audio player can play audio components of video contents.

The DVD-Video standard uses the MPEG-2 data compression algorithm to encode its video program. It employs the MPEG-2 Main Profile at Main Level protocol, also known as MP@ML. This is an intermediate level and below the high level sometimes used for DTV. However, MP@ML yields a high-quality picture that equals that of the professional CCIR-601 standard. The MPEG-2 video compression algorithm analyzes the video signal. Image data that is deemed redundant, not perceived, or marginally perceived is not coded or
coarsely quantized. Analysis is carried out for both individual video frames (spatial reduction) and series of frames (temporal reduction). The video bit rate can be considerably reduced without significant degradation of the picture.

The video program is stored as 4:2:0 component video (Y, R-Y, B-Y) with progressive scan and picture resolution of 720 × 480 pixels. The picture quality of a particular DVD-Video title is primarily determined by the expertise of the picture encoding. The average output bit rate of a DVD-Video player is about 4.7 Mbps.

30.7.1 Audio Contents

Both stereo and multichannel soundtracks are accommodated in the audio portion of the DVD-Video standard. There can be 1 to 8 independent channels of linear PCM (LPCM), 1 to 6 channels of 5.1-channel Dolby Digital (AC-3), or 1 to 8 channels (5.1 or 7.1) of MPEG-2 AAC audio. A disc can also optionally employ DTS, SDDS, or other audio coding. Dolby Digital is the coding standard used for multichannel soundtracks in the United States (Region 1). The Dolby Digital sampling frequency is 48 kHz, the nominal output bit rate is 384 kbps, and the maximum bit rate is 448 kbps. Optionally, DTS codes multichannel audio data at a nominal bit rate of 1.4 Mbps. DTS can optionally be used to code 1 to 8 channels of audio, at sampling frequencies ranging from 8 kHz to 192 kHz. One DTS layer at a sampling frequency of 44.1 kHz can hold up to 74 min of 5.1-channel audio. MPEG-1 stereo audio is sampled at 48 kHz with a maximum bit rate of 384 kbps. MPEG-2 multichannel audio (up to eight channels) is also coded at 48 kHz; its maximum bit rate is 912 kbps. NTSC titles nominally use Dolby Digital, and PAL titles use MPEG-2 audio coding; however, PAL titles can optionally use Dolby Digital coding.

DVD-Video titles carry a redundant LPCM soundtrack employing sampling rates of either 48 or 96 kHz and word lengths of 16, 20, or 24 bits. These LPCM configurations are supported: 16/48 (up to eight channels), 20/48 (up to six channels), 24/48 (up to five channels), 16/96 (up to four channels), 20/96 (up to three channels), and 24/96 (up to two channels). The maximum LPCM bit rate is 6.144 Mbps on a DVD-Video. Various contents must be accommodated on a DVD-Video. For example, with an average video bit rate of 3.5 Mbps, there might be three audio soundtracks each at 0.384 Mbps, and 4 subtitles each at 0.01 Mbps, yielding a total bit rate of 4.692 Mbps. Thus, in this example, a DVD-5 would hold a 133 minute program.

Discs contain regional coding flags so players will only play certain regional discs. For example, a Region 2 (Europe and Japan) player will not play discs coded for the North American (Region 1) market. In this way, movie studios can control release of titles to different global markets. Regional coding of discs is optional; discs can carry multiple codes or no codes. Decoding circuitry is mandatory on all players.

DVD-Video optionally employ the Content Scrambling System (CSS) copy protection system. CSS-encoded content cannot be digitally copied because software keys needed to decrypt the data are missing in any copy. Macrovision copy protection, similar to that used in set-top boxes, can be employed to prevent digital-to-analog copying of DVD-Video titles.

30.8 DVD-Audio

The DVD-Audio specification describes a high-fidelity audio storage medium supporting flexibility in the numbers of channels, sampling frequencies, word lengths, and other features such as video elements. DVD-Audio is principally used to code high-fidelity stereo and multichannel music programs using linear PCM (LPCM) data. Development of DVD-Audio was influenced by the International Steering Committee (ISC) representing the interests of the major record labels.

DVD-Audio was designed for compatibility with other DVD formats, some backward compatibility with the CD format, and to achieve improved sound quality and multichannel playback. Although the DVD-Video format can provide high-quality audio (such as six channels at 48 kHz/20-bit audio), its maximum audio bit rate of 6.144 Mbps cannot support the highest audio quality levels. Thus DVD-Audio’s maximum bit rate was increased to 9.6 Mbps. However, six channels of 96 kHz/24-bit audio exceeds the maximum bit rate and high bit rates reduce playing time. Thus the Meridian Lossless Packing (MLP) lossless compression algorithm can be optionally employed to reduce bit rate, providing high fidelity and long playing time. This option allows storage of over 74 minutes of multichannel music on a single data layer. All DVD-Audio must contain an uncompressed or MLP-compressed LPCM version of the DVD-Audio portion of the program. For added compatibility with DVD-Video players, DVD-Audio may also include video programs with Dolby Digital, DTS, and/or LPCM tracks.
30.8.1 File Organization

Two types of DVD-Audio are defined. An Audio-Only disc contains primarily LPCM music content; it can optionally include still pictures (one per track), text information, and a visual menu. In an Audio-Only disc, data is contained in the DVD-Audio zone. The AUDIO_TS directory (folder) contains menu and presentation data. An Audio Manager defines file types and organizes audio and video data. Audio data, such as linear PCM, is contained in an Audio Title Set (ATS.)

An Audio with Video (AV) disc can contain motion video content formatted as a subset of the DVD-Video format. DVD-Audio players without video capability can play back the audio contents and audio components of video contents of DVD-Audio AV. They can play selected audio components on DVD-Video V AN. In an AV disc, audio data is contained in an Audio Title Set and video data in a Video Title Set. The Audio Manager and Video Manager define file types and organize audio and video data. Both menu and program data is included. The Audio Manager can control a subset of the DVD-Video data. Using Link Info a DVD-Audio player can play audio components of video contents. A DVD-Audio disc can be partially compatible with a DVD-Video player if the disc contains a stereo LPCM or Dolby Digital version of the album in the Video Title Set subdirectory of the disc. Universal DVD players can play all DVD-Audio and DVD-Video.

The presentation data for audio tracks is contained in AOB (Audio Object) files. Each AOB contains PCM data as well as optional audio data such as Dolby Digital. Optional nonaudio data such as still images are contained in ASV (Audio Still Video) files. The presentation data for video tracks is contained in VOB (Video Object) files. VOB files contain interleaved MPEG-2 data as well as audio data. Files needed to play back an audio track are located in the AUDIO_TS folder; files for video tracks are in the VIDEO_TS folder (also containing a VMG).

On many DVD-Audio, a track comprises one song. A disc can also contain up to nine groups per album (an album comprises one disc side). A group is essentially a playlist that contains up to 99 different tracks (each with up to 99 indices). A track may be included in more than one group. Users select a group and tracks within that group. This navigation is supported by the AMG (Audio Manager). The SAMG (Simple Audio Manager) is similar to a CD’s TOC and contains a list of tracks (up to 314). Every disc includes a SAMG for track-based navigation. Simple players only recognize the SAMG and cannot recognize the AMG; these players have only two channel audio output and no video output. AMG players with video outputs read the AMG/AVTT (audio with video) section of the AMG. AMG players without video output read the AMG/AOTT (audio only) section. In this way, discs are compatible with players with widely different features. Fig. 30-15 summarizes the principal data elements found on a DVD-Audio.

Figure 30-15. Data elements found in a DVD-Audio.

30.8.2 Contents and Features

The DVD-Audio format supports a variety of coding methods and recording parameters. Optional audio coding methods include Dolby Digital, MPEG-1, MPEG-2 with/without extension bit stream, DTS, DSD, SDDS, and MLP. Linear PCM (LPCM) tracks are mandatory on all discs; all DVD-Audio players must support MLP decoding. Unlike some 5.1 channel systems (Dolby Digital, MPEG) the LPCM coding used in DVD-Audio does not band-limit the LFE channel; it is a full-bandwidth channel. DVD-Audio is a scalable format and gives flexibility to content providers. When LPCM coding is used, the number of channels (1 to 6), the word length (16, 20, 24 bit), and the sampling frequency (44.1, 48, 88.2, 96, 176.4, or 192 kHz) are all allowed. At the highest sampling frequencies of 176.4 kHz and 192 kHz, only two channel playback is possible. The audio coding options and the number of disc layers create a range of playback times. For example, a stereo LPCM program on a data layer might play for 258 minutes or 64 minutes, depending on its recording parameters. Similarly, different configurations of multichannel recordings will yield a range of playing times, as shown in Fig. 30-16. Use of MLP lossless compression, or lossy compression, increases playing times as well.

Audio channels are placed in two Channel Groups (CG). Examples of channel assignments are shown in Fig. 30-17. The grouping hierarchically lists mixes that
use the front L and R channels, front L, R and C channels, and the corner L, R, Ls, and Rs channels. The sampling frequency and word length of CG1 is greater than or equal to those of CG2. Generally, CG1 assignments are for front channels, and CG2 assignments are for rear channels. Channels can be assigned as groups of mono to six channels, and different word lengths and front and rear channels can use different sampling frequencies. For example, to reduce storage requirements, front channels could be coded at 24/96 and the rear channels coded at 16/48. The sampling frequencies must be related by a simple integer such as 48/96/192 kHz or 44.1/88.2/176.4 kHz.

Audio content can vary considerably. For example, a disc might use stereo LPCM audio for its selections. Another disc might contain one selection coded as multichannel LPCM and another coded as stereo LPCM. Another disc might contain one selection coded as stereo LPCM and another coded in an optional format such as Dolby Digital; advantageously, Dolby Digital tracks can be played in a DVD-Video player. Still another disc may include a DVD-Audio selection of up to six channels at 24/96 (possibly compressed with MLP), a stereo LPCM selection, and a Dolby Digital 5.1 channel selection on the DVD-Video portion.

DVD-Audio can employ the SMART (System Managed Audio Resource Technique) feature with LPCM tracks. Using SMART, a player can mix down a multichannel audio program to two channels for playback over a stereo system. The content provider controls the down-mixing by selecting one of sixteen coefficient tables. Each coefficient table defines level (0 to −60 dB), pan position, and phase; different tables can be used for each track in an Audio Title Set. With SMART, a separate stereo mix is not necessary on a multichannel disc, not wasting disc space. Use of SMART is optional on discs, but its support is mandatory in players.

The DVD-Audio format uses optional content protection employing encryption and embedded watermark technology. The Content Protection for Pre-Recorded Media (CPPM) encryption code is stronger than that used in the DVD-Video format and has the capability to revoke, expire, or recover encryption keys. An optional CPPM watermark identifies content through unencrypted digital (and analog) links. It is not used in high-speed encrypted links and instead verifies copy status of unencrypted signals. The watermark is contained in the audio signal and is robust over analog and data-compressed transmission links.
30.8.3 Meridian Lossless Packing (MLP)

Meridian lossless packing (MLP) is an audio coding algorithm used to achieve lossless data compression. It reduces average and peak audio data rates and hence reduces storage capacity requirements. MLP packs audio data more efficiently, reducing file size without altering the contents. MLP offers other specific enhancements over PCM; whereas a PCM signal can be subtly altered by generation loss, transmission errors and other causes as it passes through a production chain, MLP can ensure that the output signal is exactly the same as the input signal by checking the MLP-coded file and confirming its bit accuracy. The compression achieved by MLP depends on the music being coded. Very approximately, it gives a 1.85:1 compression ratio; thus reducing the bit rate by almost 50%, doubling playing time with no loss of audio quality. For example, without compression, 96 kHz/24 bit audio requires 2.304 Mbps per channel. Thus a six channel recording would require 13.824 Mbps, exceeding DVD-Audio’s 9.6 MHz maximum bit rate; thus LPCM cannot be used in the configuration. In contrast, MLP allows six-channel 96 kHz/24-bit recordings; it may achieve bandwidth reduction of 38% to 52%, reducing bandwidth to 6.6 to 8.6 Mbps, allowing a playing time of 73 to 80 minutes on a DVD-5 disc. In the two-channel stereo mode of 192 kHz/24-bit, MLP provides a playing time of about 117 minutes, versus a playing time of 74 minutes for LPCM coding.

Unlike lossy perceptual coding methods, MLP preserves bit-for-bit content of the audio signal. MLP provides less compression than lossy methods, the degree of compression depends on the audio signal content, and the output bit rate can continually vary according to signal conditions; however, a fixed data rate mode is provided. MLP is a mandatory coding option. Thus, all DVD-Audio players must support MLP decoding, but use of MLP on discs is optional for content providers. MLP may be used on a track-by-track basis. All of the DVD-Audio sampling frequencies are supported by MLP and quantization may be selected for 16 to 24 bits in 1-bit steps. MLP can code both stereo and multichannel signals simultaneously.

30.9 Other DVD Formats

The DVD-Video format is defined in Book B and DVD-Audio is defined in Book C. However, the DVD family also includes DVD-ROM (Book A), DVD-R (Book D), DVD-RAM (Book E), and DVD-RW (Book F). Books A, B, and C use the UDF Bridge file format while Books D, E, and F use the UDF format. The DVD-ROM, DVD-R, DVD-RAM, and DVD-RW formats are used primarily as computer peripherals or in professional authoring environments.

All DVDs are essentially DVD-ROMs, and all DVDs use the basic UDF format. Some DVD applications, such as DVD-Video, place specialized material in a specific place such as the DVD-Video zone. Content contained in the DVD-Other zone may be quite varied. DVD-ROM uses that provision for nonspecific storage, acting as a large capacity bit bucket formatted with UDF. DVD-ROM are playback-only media used to store data, software, games, etc. With appropriate software, DVD-ROM drives can play DVD-Video and DVD-Audio.

The DVD-R format offers write-once capability to permanently record data. DVD-Rs use a CLV wobbled pregroove to generate a carrier signal used for motor control, tracking and focus. DVD-Rs use pits and lands (known as land prepits) molded into land areas between grooves to encode the time address and other prerecorded signals. A cyanine organic dye recording layer may be used, with a 635 or 650 nm laser. The reading laser tracks the pregroove, but the light shines on the prepits peripherally to create a secondary signal that is extracted from the main signal. Discs can use the same reference velocity and track pitch as molded discs to achieve the same unformatted storage capacity. There are two parts to the DVD-R specification: DVD-R General and DVD-R Authoring; both yield discs playable on DVD-Video players.

DVD-R recorders perform an optimum power calibration (OPC) procedure to determine the correct laser writing power for particular discs, using a power calibration area (PCA) on discs to test laser writing power. A recording management area (RMA) saves calibration information, disc contents, and recording locations and remaining capacity information, recorder and disc identifiers for copy protection. The remainder of the disc comprises the information area containing the lead-in, data recordable area, and lead-out. The lead-in contains information on disc format, specification version, physical size and structure, minimum readout rate, recording density, and pointers to the location of the data recordable area where user data is recorded. The lead-out marks the end of the recording area. Both sequential (disc-at-once) and incremental writing can be performed. Once recorded, discs can potentially be played in DVD-ROM, DVD-Video, and DVD-Audio players. DVD+R is another write-once format using a dye recording layer and CLV rotation. Capacities of 4.7 and 8.5 (DL) Gbytes are available. DVD+Rs are gener-
ally compatible and can be played in many DVD-ROM, DVD-Video and DVD-Audio players.

The DVD-RW format allows data rewriting; the specification is an extension to the DVD-R format. Discs use a phase-change recording mechanism and a multilayer disc structure with dielectric layers above and below the recording layer. Data is recorded into a wobbled pregroove with CLV; relatively large data blocks are written. The recording layer may use a silver, indium, antimony, and tellurium compounded layer and allows perhaps 1000 writing cycles. Unlike dye-polymer technologies, phase-change recording is not wavelength-specific.

The DVD-RAM (random access memory) is a true random-access, nonsequential storage format. It uses a phase-change recording mechanism and a wobbled land and groove disc design. Data may be recorded on both planar surfaces of the groove and land; a wider track pitch is employed. This technique doubles disc capacity; deep grooves with steep walls are used to avoid crosstalk interference between adjacent data. Servos are used to switch the pickup’s focus between the groove and land area on each revolution, and the tracking signal is inverted when the switch occurs. Discs contain preembossed pit areas (for every 2k sector) containing addressing header information and zoned constant linear velocity rotational control. DVD-RAM provides advanced error correction and defect management features. A disc allows perhaps 100,000 rewrite cycles and offers a high degree of stability for archiving integrity.

DVD+RW is a rewritable format that uses phase-change media, a wobbled pregroove, and CAV or CLV rotation, for either raw data transfer or faster data access. Data is recorded in the pregroove, not on the land. Data addresses are represented by modulation of the pregroove; this necessitates somewhat larger writing blocks. Over 100,000 rewrite cycles are possible. Both sequential and random access recording are supported.

30.10 HD DVD Format

New high-density disc formats are under continual development. HD DVD (high definition DVD) is one such format that can carry motion pictures in high-definition form, with picture quality greater than that of standard-definition DVD, and providing broadcast DTV high-definition quality. In addition, HD DVDs employ content protection that is more robust than that currently used in DVD.

The HD DVD format uses a 405 nm blue-violet laser and numerical aperture (NA) of 0.65. As with the DVD format, 12 cm diameter discs are formed from 0.6 mm substrates bonded together; data can be placed on one or both interface layers. Track pitch is 0.40 μm. A HD DVD-ROM holds 15 Gbytes on a single-layer disc, 30 Gbytes on a dual-layer disc, and 51 Gbytes on a triple-layer disc. A dual-side, single-layer disc holds 30 Gbytes and a dual-side, double-layer disc holds 60 GB. The structure of the HD disc is shown in Fig. 30-18. The single-speed transfer bit rate is 36 Mbps, and the double-speed bit rate is 72 Mbps. HD DVD movies have a maximum data bit rate of 36.55 Mbps (1×); maximum video bit rate is 28.0 Mbps. HD DVD supports the ISO 9660 and UDF optical disc file formats. HD DVD players can also play CDs and DVDs. HD DVD drives are available for the Xbox 360 and computer applications.

The mandatory video codecs for HD DVD players are VC-1 (SMPTE 421M), MPEG-4 H.264 Advanced Video Codec (AVC), and MPEG-2. In practice, the majority of movie titles are coded with VC-1 at 1080p, with a minority coded with AVC. The HD DVD format supports a range of video resolutions, from low-resolution formats such as CIF and SDTV, to high-resolution formats such as HDTV at 720p, 1080i, and 1080p.

The mandatory audio codecs for players are Dolby Digital, Dolby Digital Plus, Dolby Digital EX, Dolby TrueHD (using MLP), DTS, and linear uncompressed PCM. Optional audio codecs include DTS-HD Master Audio and DTS-HD High Resolution Audio. Using these codecs, HD DVDs can contain up to eight channels of 24-bit/96 kHz audio, or two channels of 24-bit/192 kHz audio.

HD DVD optionally allows use of the Advanced Access Content System (AACS) for digital rights management, copy protection and content distribution control. AACS uses the Advanced Encryption Standard
(AES) to encrypt contents using one or more title keys. Content providers can revoke the decryption keys in individual players. Region coding is not used in the HD DVD format; any title can be played in any player. HD DVD uses the Microsoft HDi Interactive Format platform for interactive content on discs. HDi is based on existing protocols such as HTML, XML, CSS, SMIL, and JavaScript.

Alternative formats have been developed. The 3× DVD format uses a red laser; it yields approximately three times the storage capacity of DVD-Video; this format can hold high-definition content, but with shorter playing times. The HD REC format also stores high-definition content using a red laser and H.264/MPEG-4 AVC compression. The Combo hybrid disc is a dual-side disc (with up to two layers each) with a HD DVD layer and a DVD layer. A twin hybrid disc is a single-side disc with up to three layers, with either HD DVD or DVD content. Single-layer HD DVD-R and HD DVD-RW hold 15 Gbytes and dual-layer discs hold 30 GB. A single-layer HD DVD-RAM holds 20 GB. An experimental ten-layer disc would increase HD DVD storage capacity to 150 GB.

30.11 Blu-ray Disc Format

The Blu-ray disc system (also called BD) uses a 405 nm blue-violet laser and numerical aperture (NA) of 0.85 to achieve high storage capacity. Storage capacity is 25 Gbytes on a single-side, single-layer 12 cm disc. A single-side, dual-layer disc can hold 50 GB, or 9 hours of high-definition video. Track pitch is 0.32 μm, and the shortest pit length is 0.15 μm. The structure of the BD is shown in Fig. 30-19. The data layer is built on a 1.1 mm thick substrate and covered by a 0.1 mm spin-coated cover layer placed directly over the data layer and an optional top protection layer. The single-speed bit rate is 36 Mbps, the double-speed rate is 72 Mbps, the four times rate is 144 Mbps, and the six times rate is 216 Mbps. BD movies have a maximum data bit rate of 54 Mbps (1.5×); of this, the maximum video bit rate is 40 Mbps. A Blu-ray drive must operate at 1.5× speed to play BD movies. BD supports the ISO 9660 and UDF optical disc file formats. Although backward compatibility is possible, it is not required that BD players must also play CD and DVD-Video. BD drives are found in PS3 players and are available for computer applications.

The BD-ROM data layer is placed on the outer disc surface. The optical path is through a thin polymer layer that provides scratch resistance, not the substrate. Thus the substrate’s optical characteristics are not critical—for example, birefringence is not a concern. Because the objective lens is close to the data layer, optical aberration caused by disc tilt is limited. A 17PP modulation code is used, and a picket code with two Reed-Solomon codes is used for error correction.

The BD-ROM standard defines four player profiles. They describe functionality such as built-in persistent memory, local storage capability, secondary video decoder (for PiP), secondary audio decoder (for commentary and interactive content), virtual file system, and Internet connection capability. The four profiles are known as BD-Video (Grace Period Profile—Profile 1.0), Bonus View (Final Standard Profile—Profile 1.1), BD-Live (Profile 2.0), and BD Audio-Only (Profile 3.0).

The mandatory video codecs for BD-ROM players are VC-1 (SMPTE 421M), MPEG-4 H.264 Advanced Video Codec (AVC), and MPEG-2. The VC-1 and H.264 codecs are preferred; compared to MPEG-2, they provide greater compression and hence longer content run times, with similar quality. The BD format supports a wide range of video resolutions ranging from low to high resolution. The MPEG-2 transport stream is compatible with broadcast DTV.

Mandatory audio codecs for BD-ROM players are Dolby Digital, DTS, and linear uncompressed PCM (LPCM). A BD can hold up to up to eight channels of uncompressed LPCM audio. Optional audio codecs include Dolby Digital Plus, Dolby TrueHD (using MLP), DTS-HD Master Audio, and DTS-HD High Resolution Audio. Primary soundtracks must use a mandatory codec while secondary soundtracks can use either a mandatory or optional codec.

BD optionally allows use of the advanced access content system (AACS) for digital rights management, copy protection and content distribution control. AACS uses the advanced encryption standard (AES) to encrypt contents using one or more title keys. Title keys are formed from a media key, and the media’s unique volume ID embedded on every disc. A broadcast...
encryption scheme is used such that each player has a unique set of decryption keys. Content providers can revoke the decryption keys in individual players. If a given key is compromised, that key can be revoked in future content, rendering it useless for decrypting future content. In addition, BD+ is a virtual machine resident in authorized players. It allows inclusion of executable security programs on BD. For example, programs can verify that AACS keys have not been altered, that hardware has not been tampered with, and can fix insecure systems. The BD-ROM Mark is cryptographic data that is physically stored in a manner that is different from other BD data; disc copies that do not contain the mark are not playable.

BDs can contain geographic region coding; content coded in a certain region will only play on that region’s players. Region coding is optional; discs coded without a region code are playable in any player. There are three worldwide regions. Region A: North America, Central America, South America, Japan, Taiwan, North Korea, South Korea, Hong Kong, Southeast Asia; Region B: Europe, Greenland, French territories, Middle East, Africa, Australia, New Zealand. Region C: India, Bangladesh, Nepal, Mainland China, Pakistan, Russia, Central, South Asia. BDs use the Java software platform (a version called BD-J) for interactive content on discs. BD-J is a part of the Globally Executable MHP (GEM) standard; GEM is a version of the Multimedia Home Platform (DVB-MHP) standard.

A number of experimental BD architectures have been developed. They include a four-layer disc holding 100 GB, a six-layer disc holding 200 GB, and a ten-layer disc holding 250 GB. Alternative formats have been developed. The BD9 (Mini Blu-ray) format uses a red laser DVD to hold BD data. The disc is rotated at 3× speed to provide a minimum bit rate of 30.24 Mbps. Playing times are thus shorter than a conventional BD disc. The AVCREC format also uses red-laser DVD discs to hold BD content; H.264/MPEG-4 AVC compression is used. An experimental three-layer hybrid disc can hold both DVD-Video and BD data. Recordable (BD-R) and rewritable (BD-RE) Blu-ray disc formats are available, using phase-change technology. Dual-layer recordable discs are contemplated. Disc formats such as Blu-ray will further extend the opportunities of optical disc storage for professional and consumer applications.

31.1 Introduction

Over the past forty years, the field of digital signal processing (DSP) has grown from its origins as a collection of techniques for simulating the behavior of analog systems on digital computers into one of the most widely studied and universally used tools in modern technology. The use of DSP algorithms and implementations has become the rule rather than the exception, with applications in many areas such as music, communications, radar, sonar, image processing, robotics, seismology, meteorology, and applied physics. The remarkable growth of this discipline is largely due to two factors. First, DSP is a powerful problem-solving tool because it exploits the theoretical insights of discrete system theory to describe, analyze, and implement many interesting linear and nonlinear algorithms. Second, and more important, there is a special relationship between VLSI technology and DSP applications. The rapid development of digital integrated circuit technology has continually reduced the cost and increased the speed of the arithmetic operations necessary for DSP applications. In addition, DSP algorithms, which have demanding computational requirements but usually a very regular structure, are very well matched to the capabilities of VLSI. Integrated circuits are making complex DSP applications possible, and DSP applications have become a major motivating factor for building fast, complex integrated circuits. Perhaps the most visible embodiments of this phenomenon are the families of DSP microprocessors commonly called DSP chips. These chips have already had an immense impact on technology and are currently in the process of revolutionizing much of our industrial and technological base.

This chapter will introduce some of the important aspects of DSP technology including the fundamentals of DSP, the sampling process for converting analog signals to digital signals, the algorithm development process, and an introduction to programmable DSP devices. References are provided for finding additional information.

31.2 Digital Signal Processing

DSP is a technology and technique for analyzing and extracting information from signals, synthesizing signals, and manipulating signals. The acronym DSP is often used as both a noun and an adjective. DSP also often stands for digital signal processor—the actual microprocessor/computer that is used to implement the system. Common applications of DSP include cellular telephones, MP3 players, surround sound receivers, compact disc players, digital cameras, answering machines, and modems.

As with many disciplines, there are different perspectives and different layers of abstraction from which to explore DSP. For the purposes of this chapter, DSP will be approached and introduced from the theoretical, physical, and embedded software perspectives.

The theoretical perspective is concerned with the question “is something possible” and is built from fundamentals of DSP theory. This foundation includes linear system theory, complex number theory, and applied mathematics. The theoretical level provides a common language for DSP researchers to study and advance the state of the art.

The physical perspective is concerned with the devices that are used to implement DSP systems. These devices include the programmable digital signal processors that perform mathematical operations at a very high speed, and the details of converting an analog signal into a digital signal and then back to an analog signal.

The embedded software perspective is concerned with the actual software that makes the digital signal processors perform the desired tasks. This software is called embedded because it is executed internally on the DSP device and is only user accessible through some user interface, effectively hidden or embedded in the product, hiding the implementation details from the user.

31.3 DSP Signals and Systems Theory

The concepts of signals and systems are critical to an understanding of DSP. Signals can be a function of continuous time (i.e., analog) or of discrete time. Continuous-time signals have a signal value at any given instant of time while discrete-time signals only have a signal value at discrete instants of time. Values of discrete-time signals between the samples are determined by mathematically interpolating between the known sample values.

Signals represent the data that is to be processed. Examples include an audio file that needs to be compressed for low bit-rate storage or transmission or an image that will be searched for a particular object. A system is a transformation that maps an input signal (or multiple input signals) to an output signal (or multiple output signals)—i.e., the black box that maps inputs to outputs. In the music compression example, the output signal could be an MP3 file that was created by compressing an input signal. In the image example the output signal could simply be a yes/no decision along with positioning information. DSP systems are typically designed from simpler subsystems much like computer
software is developed—subroutine by subroutine (one level of abstraction at a time). This section will introduce some fundamental systems and also introduce the useful properties that some systems possess.

### 31.3.1 Sequences

Discrete-time signals, also called sequences, are most often created by sampling analog, or continuous-time, signals. By sampling a continuous-time signal, a sequence of samples, really a sequence of numbers, can be processed and manipulated in a digital signal processor. Before going further into the sampling process, an introduction to signal and system theory will be presented, starting with discrete-time signals.

Discrete-time signals are represented mathematically as a sequence of numbers. The notation used will denote a sequence, $x$, as $x = \{x[n]\}$ where $n$ is the index of the $n^{th}$ element in the sequence. In terms of notation, $x[n]$ represents both the $n$th sample in the sequence and the entire sequence that is a function of $n$. The index, $n$, can range over all values from $-\infty$ to $+\infty$.

From a programming perspective, a sequence can be thought of as an infinitely large array of data indexed by an integer variable. In reality, an infinitely long array is not practical, so a sequence is usually represented as a continuous stream of data. Often it is assumed that the sequence starts at time = 0 $(n = 0)$ and ends some finite time later $(n = M)$.

There are several sequences that are fundamental building blocks of DSP systems. These are the unit impulse, the unit step sequence, and the sinusoid (cosine or sine). The unit impulse is a signal that has a value of 1 at index $n = 0$ and is 0 everywhere else as shown in Fig. 31-1. Mathematically, this is denoted by

$$\delta[n] = \begin{cases} 0, & n \neq 0 \\ 1, & n = 0 \end{cases} \quad (31-1)$$

Having defined the unit impulse, it is possible to represent a sequence $x[n]$ as a sum of delayed impulses that have a value of $x[k]$ at $n = k$. Mathematically this is formulated as

$$x[n] = \sum_{k} x[k] \delta[n - k] \quad (31-2)$$

which simply says that the value of $x[n]$ is the collection of its individual samples at time $n = k$.

![Figure 31-1. Unit impulse sequence has a value of 1 at $n = 0$ and is 0 everywhere else.](image_url)

The unit step is a signal that starts at index 0 with value 1 and has value 1 for all positive indices as shown in Fig. 31-2. Mathematically, this is denoted by

$$u[n] = \begin{cases} 0, & n < 0 \\ 1, & n \geq 0 \end{cases} \quad (31-3)$$

![Figure 31-2. The unit step sequence has a value of 1 for $n \geq 0$ and is 0 everywhere else.](image_url)

The cosine signal is a sinusoid of frequency $\omega$ and phase $\phi$. An example of the cosine signal is shown in Fig. 31-3. Mathematically, the cosine signal is denoted by

$$\cos[n] = \cos(\omega n + \phi) \quad (31-4)$$

All sequences can also be represented by the numbers that are the sample values $x[n]$. Table 31-1 shows the sample values for the sequence in Fig. 31-4. Only the first sixteen sample values are listed because the sequence repeats itself after the 16th value ($x[15]$).

### 31.3.2 Systems

Systems transform input signals into output signals. Some commonly used systems include the ideal delay system that delays the output relative to the input and the moving average system that performs some simple low-pass filtering. Systems operate on a signal by operating on each sample individually or groups of samples at a time. For instance, multiplying a sequence by a constant can be implemented by multiplying each sample of the sequence by the constant. Similarly, the addition of two sequences is performed by adding the signals.
together on a sample-by-sample basis. Other systems, such as an MPEG audio compression system may operate on frames of data that have 1152 samples in each frame. The choice of whether to operate sample-by-sample or frame-by-frame is made by the system designer and algorithm developer.

A fundamental system is the ideal delay. The ideal delay system delays or advances a sequence by the delay amount. This system is defined by the equation

\[ y[n] = x[n - n_d], \quad -\infty < n < \infty \]  

(31-5)

where,

\( n_d \) is an integer that is the delay of the signal.

The ideal delay system creates an output \( y[n] \) by shifting the input signal, \( x \), by \( n_d \) samples to the right when \( n_d \) is positive. This means that the value of the output signal \( y[n] \) at a particular index \( n \) is the value of the input signal at index \( n - n_d \). For example if the signal is delayed by three samples, then \( n_d = 3 \) and the output value \( y[7] \) is equal to the value of \( x[4] \)—i.e., the value of \( x[k] \) at \( k = 4 \) now appears at \( y[j], j = 7 \). The system shifted the input signal three samples to the right as shown in Fig. 31-5.

The moving average system takes an average of the input signal over some window and then moves to the next sample and takes an average over the new window, etc. The general moving average system is defined by the equation below, where \( M_1 \) and \( M_2 \) are positive integers. It is called a moving average because to compute each output, \( y[n] \), the filter must be moved to the next index and the average recomputed.

\[ y[n] = \frac{1}{M_1 + M_2 + 1} \sum_{k = -M_1}^{M_2} x[n - k] \]  

(31-6)

Figure 31-3. A cosine sequence of period 16. This particular cosine sequence is an infinite sequence of values that repeat with a period of 16 samples.

Figure 31-4. The product of the cosine sequence with the unit step sequence, \( u[n] \). Notice that all the signal values for \( n < 0 \) are set to 0.

Figure 31-5. The cosine signal from Fig. 31-4 delayed by \( n_d = 3 \) samples. This delay shifts the sequence to the right by three samples.
Chapter 31

The average sums values together starting $M_1$ samples forward from the current point and moving $M_2$ samples back from the current point and divides by the number of points that were summed together to form an average that smooths out the signal. The moving average is a digital filter that removes high frequency information through averaging.

31.3.3 System Properties

System properties are a convenient way to describe broad classes of systems. Important system properties include linearity, shift invariance, causality, and stability. These properties are important because they lead to a representation of systems that can be readily analyzed.

31.3.3.1 Linearity

A linear system is one where the output of a sum of linearly scaled input signals is equal to the sum of the linearly scaled output signals. Mathematically, a system, $T\{\cdot\}$, is linear when

$$y_1[n] = T\{x_1[n]\}$$

and

$$y_2[n] = T\{x_2[n]\}$$

Then

$$T\{ax_1[n] + bx_2[n]\} = T\{ax_1[n]\} + T\{bx_2[n]\}$$

$$aT\{x_1[n]\} + bT\{x_2[n]\} = ay_1[n] + by_2[n]$$

(31-7)

This means that when the input to a linear system is a sum of signals, the output is the sum of the signals transformed individually.

As an example, consider a system that performs a scalar multiply $y[n] = \alpha x[n]$ (when $\alpha > 1$, $y[n]$ is a louder version of $x[n]$, and when $\alpha < 1$, $y[n]$ is a quieter version of $x[n]$). This system is linear because

$$y[n] = \alpha(ax_1[n] + bx_2[n])$$

$$= (\alpha ax_1[n] + \alpha bx_2[n])$$

An example of a nonlinear system would be a compressor/limiter because the output of a compressor/limiter to a sum of signals is generally not equal to the sum of the compressor/limiters applied to the signals individually.

31.3.3.2 Time Invariance

A time-invariant system is one where a delay in the input signal causes the output to be delayed by the same amount. Mathematically, a system, $T\{\cdot\}$, is time invariant if when $y[n] = T\{x[n]\}$ then

$$T\{x[n - N]\} = y[n - N]$$

(31-8)

When the input, $x[n]$, to a linear system is delayed, the output, $y[n]$, is delayed correspondingly. There is no absolute time reference associated with the system. The combination of time invariance and linearity makes the design and analysis of a large class of DSP theory and applications much simpler due to the convolution operation and Fourier analysis tools.¹

31.3.3.3 Causality

A causal system is one where the output of the system at a given time only depends on the present and past values of the input signal. No future data can be required to produce an output signal at the present time in a causal system. In the moving average system of Eq. 31-6, the system is causal only if $M_1 = 0$.

31.3.3.4 Stability

A system is bounded input/bounded output stable if and only if every bounded input sequence produces a bounded output sequence. A sequence is bounded if each value in the sequence is less than infinity. For real applications, stability is critically important because a system would stop operating properly should it ever become unstable.

31.3.4 Linear Time-Invariant Systems

When the linearity property is combined with the time-invariance property to form a linear time-invariant (LTI) system, then the analysis of systems is very straightforward. Because a sequence can be represented as a sum of weighted delayed impulses as shown in Eq. 31-2, and an LTI system response is the sum of the component responses of the sequence components as shown in Eq. 31-7, the response of an LTI system is completely determined from its response to an impulse. Since an input signal can be represented as a collection of delayed and scaled impulses, the response to the full sequence is known. The response of a system to an impulse is commonly referred to as the impulse response of the system. Mathematically,
\[ x[n] = \sum_{k} x[k] \delta[n-k] \]

i.e., the sequence \( x[n] \) is a sum of scaled and delayed impulses. If \( h_k[n] = T\{\delta[n-k]\} \), i.e., the system response to the delayed impulse at \( n = k \), then the output \( y[n] \) can be formed as

\[
y[n] = T\{x[n]\} = T\left\{ \sum_{k} x[k] \delta[n-k] \right\} = \sum_{k} x[k] h_k[n] \quad (31-9)
\]

If the system is also time invariant, then \( h_k[n] = h[n-k] \), and the output \( y[n] \) is given by

\[
y[n] = \sum_{k} x[k] h[n-k] = \sum_{k} h[k] x[n-k] \quad (31-10)
\]

This representation is known as the convolution sum and is commonly written as \( y[n] = x[n] * h[n] \). The convolution system takes two sequences, \( x[n] \) and \( h[n] \), and produces a third sequence \( y[n] \). For each value of \( y[n] \), the computation requires multiplying \( x[k] \) by \( h[n-k] \) and summing over all valid indices for \( k \) where the signals are non-zero. To compute the output \( y[n+1] \), move to the next point, \( n+1 \), and perform the same computation. The convolution is an LTI system and is a building block for many larger systems.

As an example, consider the convolution of the sequences in Fig. 31-6 where \( h[n] \) has only three non-zero sample values and \( x[n] \) is a cosine sequence that has non-zero sample values for \( n \geq 0 \).

The computation of

\[
y[n] = \sum_{k=0}^{2} h[k] x[n-k]
\]

is performed as follows. Values of \( x[n] \) for \( n < 0 \) are 0. Only the computation for the first three output samples are shown.

\[
\]
\[
\]
\[
\]

Figure 31-6. A convolution example with two sequences. \( x[n] \) is the same signal from Fig. 31-4 with values shown in Table 31-1, and \( h[n] \) has the values shown above.

31.4 Frequency Domain Representation

Having defined an LTI system, it is possible to look at the signal from the frequency domain perspective and understand how a system changes the signals in the frequency domain. The frequency domain represents signals as a combination of various frequencies from low frequency to high frequency. Each time-domain signal has a representation as a collection of frequency components where each frequency component can be thought of as sinusoids or tones. Sinusoids are important because a sinusoidal input to a linear time-invariant system generates an output of the same frequency but with amplitude and phase determined by the system. This property makes the representation of signals in terms of sinusoids very useful.
As an example, assume an input signal $x[n]$ is defined as $x[n] = e^{j\omega n}$—i.e., a complex exponential (Euler’s relationship from complex number theory that states that $e^{j\omega n} = \cos(\omega n) + j\sin(\omega n)$, where $\omega$ is the radian frequency that ranges from $0 \leq \omega \leq 2\pi$), then using the convolution sum of

$$y[n] = \sum_{k} h[k]x[n-k]$$

generates

$$y[n] = \sum_{k} h[k]e^{j\omega(n-k)} \quad (31-11)$$

By defining

$$H(e^{j\omega}) = \sum_{k} h[k]e^{-j\omega k}$$

we have

$$y[n] = H(e^{j\omega})e^{j\omega n}$$

where,

$H(e^{j\omega})$ represents the phase and amplitude determined by the system.

This shows that a sinusoidal (or, in this case, the complex exponential) input to a linear time invariant system will generate an output that has the same frequency but with an amplitude and phase determined by the system.

$H(e^{j\omega})$ is known as the frequency response of the system and describes how the LTI system will modify the frequency components of an input signal. The transformation

$$H(e^{j\omega}) = \sum_{k} h[k]e^{-j\omega k}$$

is known as the Fourier transform of the impulse response, $h[n]$. If $H(e^{j\omega})$ is a low-pass filter, then it has a frequency response that attenuates high frequencies but not low frequencies—hence it passes low frequencies. If $H(e^{j\omega})$ is a high-pass filter, then it has a frequency response that attenuates low frequencies but not high frequencies.

In many instances it is more useful to process a signal or analyze a signal from the frequency domain than in the time domain either because the phenomenon of interest is frequency based or our perception of the phenomenon is frequency based.

An example of this is the family of MPEG audio compression standards that exploits the frequency properties of the human auditory system to dramatically reduce the number of bits required to represent the signal without significantly reducing the audio quality.

### 31.5 The Z-Transform

The Z-transform is a generalization of the Fourier transform that permits the analysis of a larger class of sys-
tems than the Fourier transform. In addition, the analysis of systems is easier due to the convenient notation of the Z-transform.\(^1\) The Fourier transform is defined as

\[ X(e^{j\omega}) = \sum_k x[k]e^{-j\omega k} \]

while the Z-transform is defined as

\[ X(z) = \sum_k x[k]z^{-k} \]

When working with linear time invariant systems, an important relationship is that the Z-transform of the convolution of two sequences is equal to the multiplication of the Z-transforms of the two sequences, i.e., \( y[n] = x[n] * h[n] \Leftrightarrow Y(z) = X(z)H(z) \). \( H(z) \) is referred to as the system function (a generalization of the transfer function from Fourier analysis).

A common use of the Z domain representation is to analyze a class of systems that are defined as linear constant-coefficient difference equations that have the form of

\[ \sum_{k=0}^{N} a_k y[n-k] = \sum_{k=0}^{M} b_k x[n-k] \quad (31-13) \]

where, the coefficients \( a_k \) and \( b_k \) are constant (hence the name constant coefficient).

This general difference equation forms the basis for both finite impulse response (FIR) linear filters, and infinite impulse response (IIR) linear filters. Both FIR and IIR filters are used to implement frequency selective filters (e.g., high-pass, low-pass, bandpass, bandstop, and parametric filters) and other more complicated systems.

FIR filters are a special case of Eq. 31-13, where except for the first coefficient, all the \( a_k \) are set to 0, leading to the equation

\[ y[n] = \sum_{k=0}^{M} b_k x[n-k] \quad (31-14) \]

The important fact to notice is that each output sample \( y[n] \) in the FIR filter is formed by multiplying the sequence of coefficients (also known as filter taps) by the input sequence values. There is no feedback in an FIR filter—i.e., previous output values are not used to compute new output values. A block diagram of this is shown in Fig. 31-8 where the \( z^{-1} \) blocks are used to denote a signal delay of one sample (i.e., the Z-transform of the system \( h[n] = \delta[n-1] \)).

An IIR filter contains feedback in the computation of the output \( y[n] \)—i.e., previous output values are used to create current output values. Because of this feedback, IIR filters can be created that have a better frequency response (i.e., steeper slope for attenuating signals outside the band of interest) than FIR filters for a given amount of computation. However, most DSP architectures are optimized for computing FIR filters—i.e., multiplying and adding signals together continuously—so the choice of which filter style to use will depend on the particular application.

31.6 Sampling of Continuous-Time Signals

The most common way to generate a digital sequence is to start with a continuous-time (analog) signal and create a discrete-time signal. For example, speech signals are continuous-time signals because they are continuous waves of acoustic pressure. A microphone is the transducer that converts the acoustic signal into a continuous-time electric signal. In order to process this signal digitally, it is necessary to convert this signal into the digital domain. Finally, after processing, it is often necessary to convert the discrete-time signal back into a continuous-time signal for playback through a loudspeaker system.

The process of converting an analog signal to a digital signal is often be modeled as a two-step process, as shown in Fig. 31-9, of converting a continuous-time signal to a discrete-time signal (with infinite resolution of the amplitude) and then quantizing the discrete-time signal into finite precision values (creating the digital sequence) that can be processed by a computer.\(^1\) The process of converting the continuous-time signal into a discrete-time signal will be introduced, and then quantization will be reviewed. The quantization step is necessary to create a sample value that has a data word size that is compatible with the arithmetic capabilities of the target DSP. All real-world analog-to-digital converters (A/Ds) perform both the sampling and quantization process internal to the A/D device, but it is useful to discuss the subsystems separately because they have different significance and design trade-offs.
31.6.1 Continuous to Discrete Conversion

The most common method for converting a continuous-time signal, \( x_c(t) \), into a discrete-time signal, \( x[n] \), is to uniformly sample the signal every \( T \) seconds with the equation

\[
x[n] = x_c(nT), \quad -\infty < n < \infty
\]

(31-15)

This generates a sequence of samples, \( x[n] \), where the value of \( x[n] \) is the same as the value of \( x_c(t) \) whenever \( t = nT \)—i.e., at each sampling interval \( T \). \( 1/T \) is known as the sampling frequency and is usually expressed in Hertz or cycles per second.

Mathematically, when a continuous-time signal is sampled, the resulting signal has a frequency response that is related to the underlying continuous-time signal frequency response and the sampling rate. As shown next, this has significant ramifications for how often the signal must be sampled in order for the digital sequence to be reconstructed into an analog signal that accurately represents the original signal.

The sampling process will be analyzed in the frequency domain where it will be assumed that a band limited signal, \( x_c(t) \), is to be sampled periodically with sample period \( T \). A band-limited signal is one that has no signal energy higher than a particular frequency, \( \Omega_N \), as shown in Fig. 31-10, where \( \Omega \) represents the frequency axis of the signal. The reason the signal is assumed to be band limited is to prevent frequency aliasing, as will be evident shortly. The assumption of being band limited is significant although generally easily realizable in real-world systems.

The sampling of the continuous-time signal, \( x_c(t) \), generates a signal, \( x_s(t) \), from equation

\[
x_s(t) = \sum_{n=-\infty}^{\infty} x_c(nT)\delta(t-nT)
\]

(31-16)

\( x_s(t) \) is the collection of values of \( x_c(t) \) at the sampling interval of \( T \). A convenient representation of this signal is as a collection of delayed and weighted impulse functions. The amplitude is the value at the sampling instant and the samples are spaced out by the sampling period \( T \). The process can be analyzed in the frequency domain by first representing the Fourier transform of the impulse sequence as a sequence of impulses in the frequency domain. This means that a sequence of equally spaced impulses in the time domain have a frequency representation that is a sequence of equally spaced impulses in the frequency domain, spaced by the sampling frequency \( 2\pi/T \). This is shown as

\[
S(j\Omega) = \frac{2\pi}{T} \sum_{k=-\infty}^{\infty} \delta(\Omega - k\Omega_s)
\]

(31-17)

where,

\( \Omega_s = 2\pi/T \) is the sampling frequency in radians/second.

The Fourier transform of the sampled signal, \( x_s(t) \), becomes

\[
X_s(j\Omega) = \frac{1}{T} \sum_{k=-\infty}^{\infty} X_c(j(\Omega - k\Omega_s))
\]

(31-18)
Now the frequency response of the sampled continuous-time signal becomes a collection of shifted copies of the original frequency response of the analog signal $X_c(j\Omega)$. Fig. 31-10 shows the frequency response of $X_c(j\Omega)$, the impulse train, $S(j\Omega)$, and the resulting frequency response of the sampled signal, $X_s(j\Omega)$.

This frequency response, $X_s(j\Omega)$, can also be interpreted as the convolution in the frequency domain between the frequency response of the continuous-time signal and the frequency response of the impulse train, $S(j\Omega)$.

$$X_s(j\Omega) = \frac{1}{2\pi} X_c(j\Omega) * S(j\Omega) \quad (31-19)$$

From Fig. 31-10 it can be seen that as long as the sampling frequency minus the highest frequency is greater than the highest frequency, $\Omega_S - \Omega_N > \Omega_N$, the frequency copies do not overlap. This condition can be rewritten as $\Omega_S > 2\Omega_N$, which means that the sampling frequency must be at least twice as high as the highest frequency in the signal. If the sampling frequency is less than the highest frequency in the signal, $\Omega_S < 2\Omega_N$, then the frequency copies overlap as shown in Fig. 31-11. This overlap causes the frequencies of the adjacent spectral copies to be added together, which results in the loss of spectral information. It is impossible to remove the effects of aliasing once aliasing has happened. The overlap is caused because the sampling frequency, $\Omega_S$, is not high enough relative to the highest frequency in the continuous-time signal $X_c(j\Omega)$. As shown above, the sampling frequency must be at least twice as high as the highest frequency in the continuous-time signal in order to prevent this overlap, or aliasing, of frequencies.

![Figure 31-11](image)

**Figure 31-11.** Sampling where the sampling frequency, $\Omega_S$, is less than twice the highest frequency, $\Omega_N$.

### 31.6.2 Reconstructing the Continuous-Time Signal

As seen from sampling a continuous-time signal, if the signal is not sampled fast enough, then the resulting frequency response of the sampled signal will have overlapping copies of the frequency response of the original signal. Assuming the signal is sampled fast enough (at least twice the bandwidth of the signal), the continuous-time signal can be reproduced by simply removing all of the spectral copies except for the desired one. This frequency separation can be performed with an ideal low-pass filter with gain, $T$, and cut-off frequency, $\Omega_c$, where the cut-off frequency is higher than the highest frequency in the signal as well as the frequency where the first frequency replica starts,—i.e., $\Omega_N < \Omega_c < \Omega_S - \Omega_N$. Fig. 31-12 shows the repeated frequency spectrum and the ideal low-pass filter. Fig. 31-13 shows the result of applying the low-pass filter to $X_s(j\Omega)$.

### 31.6.3 Sampling Theory

The requirements for sampling are summarized by the Nyquist sampling theorem.¹ Let $x_c(t)$ be a band-limited signal with $X_c(j\Omega) = 0$ for $|\Omega| \geq \Omega_N$. Then $x_c(t)$ is uniquely determined by its samples, $x[n] = x_c(nT)$, if $\Omega_S = 2\pi/T \geq 2\Omega_N$. The frequency $\Omega_N$ is referred to as the Nyquist frequency, and the frequency $2\Omega_N$ is referred to as the Nyquist rate. This theory is significant because it states that as long as a continuous-time signal is band-limited and sampled at least twice as fast as the highest frequency, then it can be exactly reproduced by the sampled sequence.
The sampling analysis can be extended to the frequency response of the discrete time sequence, $x[n]$, by using the relationships $x[n] = x_c(nT)$ and

$$X(e^{j\omega}) = \frac{1}{T} \sum_{k=-\infty}^{\infty} x[n] e^{-j\omega n}$$

The result is that

$$X(e^{j\omega}) = \frac{1}{T} \sum_{k=-\infty}^{\infty} X_c(f) e^{-j\omega n}$$

(31-20)

$X(e^{j\omega})$ is a frequency-scaled version of the continuous-time frequency response, $X_s(j\Omega)$, with the frequency scale specified by $\omega = \Omega T$. This scaling can also be thought of as normalizing the frequency axis by the sample rate so that frequency components that occurred at the sample rate now occur at $2\pi$. Because the time axis has been normalized by the sampling period $T$, the frequency axis can be thought of as being normalized by the sampling rate $1/T$.

### 31.6.4 Quantization

The discussion up to this point has been on how to quantify the effects of periodically sampling a continuous-time signal to create a discrete-time version of the signal. As shown in Fig. 31-9, there is a second step—namely, mapping the infinite-resolution discrete-time signal into a finite precision representation (i.e., some number of bits per sample) that can be manipulated in a computer. This second step is known as quantization. The quantization process takes the sample from the continuous-to-discrete conversion and finds the closest corresponding finite precision value and represents this level with a bit pattern. This bit pattern code for the sample value is usually a binary two’s-complement code so that the sample can be used directly in arithmetic operations without the need to convert to another numerical format (which takes some number of instructions on a DSP processor to perform). In essence, the continuous-time signal must be both quantized in time (i.e., sampled), and then quantized in amplitude.

The quantization process is denoted mathematically as

$$x[n] = Q(x[n])$$

where, $Q(*)$ is the nonlinear quantization operation, $x[n]$ is the infinite precision sample value.

Quantization is nonlinear because it does not satisfy Eq. 31-7—i.e., the quantization of the sum of two values is not the same as the sum of the quantized values due to how the nearest finite precision value is generated for the infinite-precision value.

To properly quantize a signal, it is required to know the expected range of the signal—i.e., the maximum and minimum signal values. Assuming the signal amplitude is symmetric, the most positive value can be denoted as $X_M$. The signal then ranges from $+X_M$ to $-X_M$ for a total range of $2X_M$. Quantizing the signal to $B$ bits will decompose the signal into $2^B$ different values. Each value represents $2X_M/2^B$ in amplitude and is represented as the step size $\Delta = 2X_M2^{-B} = X_M2^{-(B-1)}$. As a simplified example of the quantization process, assume that a signal will be quantized into eight different values which can be conveniently represented as a 3-bit value.

Fig. 31-14 shows one method of how an input signal, $x[n]$, can be converted into a 3-bit quantized value, $Q(x[n])$. In this figure, values of the input signal between $-\Delta/2$ and $\Delta/2$ are given the value 0. Input signal values between $\Delta/2$ and $3/2$ are represented by their average value $\Delta$, and so forth. The eight output values range from $-4\Delta$ to $3\Delta$ for input signals between
Values larger than 7Δ/2 are set to 3Δ and values smaller than −9Δ/2 are set to −4Δ—i.e., the numbers saturate at the maximum and minimum values, respectively.

With certain assumptions about the signal, such as the peak value being about four times the rms signal value, it can be shown that the signal to noise ratio (SNR) of the A/D converter is approximately 6 dB per bit. Each additional bit in the A/D converter will contribute 6 dB to the SNR. A large SNR is usually desirable, but that must be balanced with overall system requirements, system cost, and possibly other noise issues inherent in a design that would reduce the value of having a high-quality A/D converter in the system. The dynamic range of a signal can be defined as the range of the signal levels over which the SNR exceeds a minimum acceptable SNR.

There are cost-effective A/D converters that can shape the quantization noise and produce a high-quality signal. Sigma-Delta converters, or noise-shaping converters, use an oversampling technique to reduce the amount of quantization noise in the signal by spreading the fixed quantization noise over a bandwidth much larger than the signal band. The technique of oversampling and noise shaping allows the use of relatively imprecise analog circuits to perform high-resolution conversion. Most digital audio products on the market use these types of converters.

### 31.6.5 Sample Rate Selection

The sampling rate, 1/T, plays an important role in determining the bandwidth of the digitized signal. If the analog signal is not sampled often enough, then high-frequency information will be lost. At the other extreme, if the signal is sampled too often, there may be more information than is needed for the application, causing unnecessary computation and adding unnecessary expense to the system.

In audio applications it is common to have a sampling frequency of 48 kHz = 48,000 Hz, which yields a sampling period of 1/48,000 = 20.83 μs. Using a sample rate of 48 kHz is why, in many product data sheets, the amount of delay that can be added to a signal is an integer multiple of 20.83 μs.

The choice of which sample rate to use depends on the application and the desired system cost. High-quality audio processing would require a high sample rate while low bandwidth telephony applications require a much lower sample rate. A table of common applications and their sample rate and bandwidths are shown in Table 31-3. As shown in the sampling process, the maximum bandwidth will always be less than ½ the sampling frequency. In practice, the antialiasing filter will have some roll-off and will band limit the signal to less than ½ the sample rate. This bandlimiting will further reduce the
bandwidth, so the final bandwidth of the audio signal will be a function of the filters implemented in the specific A/D and the sample rate of the system.

31.7 Algorithm Development

Once a signal is digitized, the next step in a DSP system is to process the signal. The system designer will begin the design process with some goal in mind and will use the algorithm development phase to develop the necessary steps (i.e., the algorithm) for achieving the goal.

The design cycle for a DSP system generally has three distinct phases as shown in Fig. 31-16: an abstract algorithm conceptualization phase, in which various mathematical algorithms and systems are explored; an algorithm development phase, where the algorithms are tested on large amounts of data; and a system implementation phase, where specific hardware is used to realize the system.

![Figure 31-16. The three phases of DSP application development.](image)

Traditionally, the three phases in the DSP design cycle have been performed by three entirely different groups of engineers using three entirely different classes of tools, although this process has converged as development tools have improved. The algorithm conceptualization phase is most often performed by researchers in a laboratory environment using highly interactive, graphically oriented DSP simulation and analysis tools. In this phase, the researcher begins with the concept of what to accomplish and creates the simulation environment that will enable changes and reformulations of the approach to the problem. No consideration is given, at this point, to the computational performance issues. The focus is on proof of concept issues—proving that the approach can solve the problem (or a temporarily simplified version of the problem).

In the algorithm development phase, the algorithms are fine-tuned by applying them to large databases of signals, often using high-speed workstations to achieve the required throughput. During this step it is often necessary to refine the high-level conceptualization in order to address issues that arose while running data through the system. Simulations are characterized by having many probes on the algorithm to show intermediate signal values, states, and any other useful information to aid in troubleshooting both the algorithm and the implementation of the simulation.

Once the simulation performs as desired, the next step is to create a real-time implementation of the simulation. The purpose of the real-time implementation is to better simulate the final target product, to begin to understand what the real-time memory and computational requirements will be, and to run real-time data through the system. There is no substitute for running real-time data through the system because real-time data typically exhibits characteristics that were either not anticipated or have unintended consequences in the simulation environment. Real-time data is generally more stressful to an algorithm than simulated, or non-real-time, data.

Often, with the introduction of real-time data, it may be necessary to go to the conceptual level again and further refine the algorithm.

Although advanced development tools and high-speed processors have blurred the distinction between simulation and real-time implementation, the goal of the real-time implementation is to “squeeze as much algorithm as possible” into the target processor (or processors). Squeezing more into the target processor is a desirable goal because it is usually much less expensive to use a single signal processor than to use multiple processors.

31.8 Digital Signal Processors

Programmable digital signal processors are microprocessors with particular features suited to performing arithmetic operations such as multiplication and addition very efficiently. Traditionally, these enhancements have improved the performance of the processor at the expense of ease of programmability.

A typical microprocessor will have an arithmetic and logic unit for performing arithmetic operations, a memory space, I/O pins, and possible other peripherals
such as serial ports and timers. A DSP processor will often have fewer peripherals, but will include a hardware multiplier, often a high-speed internal memory space, more memory addressing modes, an instruction cache and a pipeline, and even a separation of the program and data memory spaces to help speed program execution. The hardware multiplier allows the DSP processor to perform a multiplication in a single clock cycle while microprocessors typically take multiple clock cycles to perform this task. With clock cycles easily exceeding 100 MHz, up to 100 million multiplies can occur every second. At this rate, 2083 multiplies can occur in the time span required to collect one sample of data at a 48 kHz sample rate (100 M/48,000).

A high-speed internal memory bank can be used to speed the access to the data and/or program memory space. By making the memory high speed, the memory can be accessed twice within a single clock cycle, allowing the processor to run at maximum performance. This means that proper use of internal memory enables more processing to take place within a given speed processor when compared to using external memory.

The instruction cache is also used to keep the processor running more efficiently because it stores recently used instructions in a special place in the processor where they can be accessed quickly, such as when looping program instructions over signal data.

The pipeline is a sequential set of steps that allow the processor to fetch an instruction from memory, decode the instruction, and execute the instruction. By running these subsystems in parallel, it is possible for the processor to be executing one instruction while it is decoding the next one and fetching the instruction after that. This streamlines the execution of instructions.

31.8.1 DSP Arithmetic

Programmable DSPs offer either fixed-point or floating-point arithmetic. Although floating-point processors are typically more expensive and offer less performance than fixed-point processors, VLSI hardware advances are minimizing the differences. The main advantage of a floating-point processor is the ability to be free of numerical scaling issues, simplifying the algorithm development and implementation process.

Most people naturally think in terms of fractions and decimal points, which are examples of floating-point numbers. Typically, floating-point DSPs can represent very large and very small numbers and use 32-bit (or longer) words composed of a 24-bit mantissa and an 8-bit exponent, which together provide a dynamic range from $2^{-127}$ to $2^{128}$. This vast range in floating-point devices means that the system developer does not need to spend much time worrying about numerical issues such as overflow (a number too large to be represented) or underflow (a number too small to be represented). In a complicated system, there is enough to worry about without having to worry about numerical issues as well.

Fixed-point arithmetic is called fixed-point because it has a fixed decimal point position and because the numbers have an implicit scale, depending on the range that must be represented. This scale must be tracked by the programmer when performing arithmetic on fixed-point numbers. Most DSPs use the fixed-point 2s-complement format, in which a positive number is represented as a simple binary value and a negative value is represented by inverting all the bits of the corresponding positive value and then adding 1. Assuming a 16-bit word, there are $2^{16} = 65,536$ possible combinations or values that can be represented which allows the representation of numbers ranging from the largest positive number of $2^{15} - 1 = 32,767$ to the smallest negative (e.g., most negative) number of $-2^{15} = -32,768$.

There are many times when it is important to represent fractions in addition to integer numbers. To represent fractions, the implied position of the decimal point must be moved. When using 16-bit arithmetic to represent fractions only, with no integer component, a Q15 arithmetic format with an implied decimal point and 15 bits of fraction data to the right of the decimal point could be used. In this case, the largest number that can be represented is still $2^{15} - 1$, but now this number represents $32,767/32,768 = 0.999969482$, and the smallest negative number is still $-2^{15}$, but this number represents $-32,768/32,768 = -1$. Using Q15 arithmetic, it is possible to represent numbers between 0.999969482 and −1. As another example, representing numbers that range between 16 and −16 would require Q11 arithmetic (4 bits before the implied decimal point). An implementation may use different implied decimal positions for different variables in a system.

Because of the smaller word size and simpler arithmetic operations when compared to floating-point processors, fixed-point DSPs typically use less silicon area than their floating-point counterparts, which translates into lower prices and less power consumption. The trade-off is that, due to the limited dynamic range and the rules of fixed-point arithmetic, an algorithm designer must play a more active role in the development of a fixed-point DSP system. The designer has to decide whether the given word width (typically 16 or 24 bits) will be interpreted as integers or fractions, apply scale factors if required, and protect against possible
register overflows at potentially many different places in the code. Overflow occurs in two ways in a fixed-point DSP. Either a register overflows when too many numbers are added to it or the program attempts to store N bits from the accumulator and the discarded bits are important. A complete solution to the overflow problem requires the system designer to be aware of the scaling of all the variables so that overflow is sufficiently unlikely. An underflow occurs if a number is smaller than the smallest number that can be represented. Floating-point arithmetic keeps track of the scaling automatically in order to simplify the programmer's job. The exponent keeps track of where the decimal point should be. Checking for overflow/underflow and preventing these conditions makes changing a DSP algorithm more difficult because, not only are algorithmic changes required, there are also numeric issues to contend with. Usually, once an implementation for a particular application has matured past the development stage, the code (which may have begun as floating-point code) may be ported to a fixed-point processor to allow the cost of the product to be reduced.

The dynamic range supported in a fixed-point processor is a function of the bit width of the processor's data registers. As with A/D conversion, each bit adds 6 dB to the SNR. A 24-bit DSP has 48 dB more dynamic range than a 16-bit DSP.

31.8.2 Implementation Issues

The implementation of an algorithm into a real system is often much more complicated than using a compiler to automatically optimize the code for maximum performance. Real-time systems have constraints such as limited memory, limited computational performance, and most importantly, need to handle the real-time data that is continuously sent from the A/D converter to the DSP and the real-time data that must be sent from the DSP back to the D/A converter. Interruptions in this real-time data are typically not acceptable because, for example, in an audio application, these interruptions will cause audible pops and clicks in the audio signal.

Real-time programming requires that all of the computation required to produce the output signal must happen within the amount of time it takes to acquire the input signal from the A/D converter. In other words, each time an input sample is acquired, an output sample must be produced. If the processing takes too long to produce the output, then, at some point, incoming data from the A/D will not be able to be processed, and input samples will be lost. As an example, assume a system samples at 48 kHz and performs parametric equalization on a signal. Assuming that each band of parametric equalization requires 5 multiplies and 4 adds, which can be implemented in 9 clock cycles, then a 100 MHz DSP has 2083 instructions that can be executed in the time between samples. These instructions would allow a maximum of 231 bands of parametric equalization (2083/9 = 231). Now, realistically, the system is performing other tasks such as collecting data from the A/D converter, sending data to the D/A converter, handling overhead from calling subroutines and returning from subroutines, and is possibly responding to interrupts from other subsystems. So the actual number of bands of equalization could be significantly less than the theoretical maximum of 231 bands.

DSPs will have a fixed amount of internal memory and a fixed amount of external memory that can be addressed. Depending on the system to be designed, it can be advantageous to minimize the amount of external memory that is required in a system because that can lead to reduced parts costs, reduced manufacturing expense, and higher reliability. However, there is usually a trade-off between computational requirements and memory usage. Often, it is possible to trade memory space for increased computational power and vice versa. A simple example of this would be the creation of a sine wave. The DSP can either compute the samples of a sine wave, or look-up the values in a table. Either method will produce the appropriate sine wave, but the former will require less memory and more CPU while the latter will require more memory and less CPU. The system designer usually makes a conscious decision regarding which trade-off is more important.

31.8.3 System Delay

Depending on the application, one of the most important issues in an implementation is the amount of delay or latency that is introduced into the system by the sampling and processing. Fig. 31-17 shows the typical digital system. The analog signal comes into the A/D converter that digitizes and quantizes the signal. Once digitized, the signal is typically stored in some data buffers or arrays of data. The data buffers could be one sample long or could be longer depending on whether the algorithm operates on a sample-by-sample basis or requires a buffer of data to perform its processing. The system buffers are usually configured in a ping-pong fashion so that while one buffer is filling up with new data from the A/D, the other is being emptied by the DSP as it pulls data from the buffer to process the data.
Following the system buffer may be a data conversion block that converts the data from a fixed-point integer format provided by the A/D to either some other fixed-point format or a floating-point processor, depending on the DSP and the numerical issues. Following this, there may be some application buffers that store buffers of data to give the DSP some flexibility in how much time it takes to process a single block of data. The application buffers can be viewed as a rubber band that allows the DSP to use more time for some frames of data and less time for other frames of data. As long as the average amount of time required to process a buffer of data is less than the amount of time required to acquire that buffer of data, the DSP will make real-time. If the amount of time required to process a buffer takes longer than the time to acquire the buffer, then the system will not make real time and have to drop samples. In this case the system will eventually miss real time and have to drop samples.

After the application buffers, the DSP algorithm performs the operations that are desired and then passes the data to possibly another set of application buffers that in turn can be converted from the numerical format of the DSP to the format required by the D/A converter. Finally the data will be sent to the D/A converter and converted back into an analog signal.

An accounting of the delay of the system should include all delays beginning when the analog signal comes in contact with the A/D converter to when the analog signal leaves the D/A converter. Table 31-4 shows the potential delays in each of the blocks of Fig. 31-17. For this exercise, it is assumed that a frame of data consists of $N$ samples, where $N \geq 1$. Each frame of delay adds $N \cdot 1/T$ seconds of delay to the system. For example, a delay of 16 samples at 48 kHz corresponds to $16/48,000 = 333.3 \mu s$.

### Table 31-4. A Summary of Delay Issues in a Typical DSP System

<table>
<thead>
<tr>
<th>Block</th>
<th>Delay</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>A/D</td>
<td>From 1 to 16 samples</td>
<td>Most A/D converters have some amount of delay built in due to the processing that is done. Oversampling A/Ds in particular have more delay than other types of A/Ds.</td>
</tr>
<tr>
<td>System Buffers</td>
<td>Adds at least 1 frame of delay</td>
<td>In the ping-pong buffer scheme, the system is always processing the last frame of data while the A/D is supplying the data from the next frame of data.</td>
</tr>
<tr>
<td>Data conversion</td>
<td>Possibly none</td>
<td>The conversion of the data format may be lumped with the algorithm processing delay.</td>
</tr>
<tr>
<td>Application buffers</td>
<td>Adds M-1 frames of delay for M buffers</td>
<td>Generalizing the ping-pong buffer scheme to M buffers, the system is always processing the oldest buffer, which is M-1 buffers behind the most recent buffer.</td>
</tr>
<tr>
<td>DSP algorithm</td>
<td>Variable, although usually at least 1 frame</td>
<td>There are two primary ways a DSP algorithm adds delay. One is processing delay and the other is algorithmic delay. Processing delay occurs because the processor is not infinitely fast, so it takes some amount of time to perform all of the computation. If the DSP has no extra CPU cycles after performing the computation, then the processing time adds a full frame of delay to the system. If it takes more than a frame of delay to perform the computation, then the system will not make real time. The algorithmic delay comes from any requirement to use data from future frames of data (i.e., buffer the data) in order to make decisions about the current frames of data and other delays inherent in the algorithm process.</td>
</tr>
<tr>
<td>D/A</td>
<td>From 1 to 16 samples</td>
<td>As with the A/D converter there is some delay associated with converting a digital signal into an analog signal. Current converters typically have no more than 16 samples of delay.</td>
</tr>
</tbody>
</table>
Further complicating the delay measurements is the possible requirement of sending information to an external system. This could be in the form of sending a bitstream to a remote decoder, receiving a bitstream from a remote encoder, and also any error detection and/or correction on a bitstream that may be required.

### 31.8.4 Choosing a DSP

The choice of which DSP to use for a particular application depends on a collection of factors including:

- **Cost.** DSPs range in price from several dollars to hundreds of dollars. Low-cost DSP processors are typically 16-bit fixed-point devices with limited amounts of internal memory and few peripherals. Low-cost DSPs are typically suited for extremely high volume applications, where the exact capabilities required, and no more, are built into the chip.

  High-cost DSPs typically are newer processors that have a great deal of internal memory or other architectural features including floating-point arithmetic and high speed communication ports.

- **Computational Power:** MHz, MIPs, MFLOPs. Computational power is measured in several different ways including processor speed (MHz), millions of instructions per second (MIPS), and millions of floating-point operations per second (MFLOPS). The computational power of a processor is usually directly related to cost. An MIP means that one million instructions can be executed per second. The instructions that can be executed could include memory loads and stores or perhaps arithmetic operations. An MFLOP means one million floating-point operations can be executed per second. A floating-point operation includes multiplies and/or adds. Often the architecture of the DSP allows the DSP to execute two (or more) floating-point operations per instruction. In this case the MFLOPs would be twice (or more) the MIPs rating of the processor.

  Higher-speed processors allow the user to pack more features into a DSP product, but with a higher cost.

- **Power Consumption.** Depending on the application, low power may be important for long battery life or low heat dissipation. DSPs will have a power rating and, often, a watt/MIP rating to estimate power consumption.

- **Architecture.** Different manufacturers’ DSPs have different features and trade-offs. Some processors may allow extremely high-speed computational rates but at the expense of being difficult to program. Some may offer ease of multiprocessing, multiple arithmetic processors, or other features.

- **Arithmetic Precision.** The use of floating-point arithmetic simplifies arithmetic operations. Fixed-point processors often have lower cost but often require additional instructions to maintain the level of numerical accuracy that is often required. The final production volume of the end product often dictates whether the added development time is worth the cost savings.

- **Peripherals.** Certain features of processors such as the ability to share processor resources among linked processors or access to external memory/devices can have a significant impact on which processor to use for a particular application. Integrated timers, serial ports, and other features can reduce the number of additional parts required in a design.

- **Code Development.** The amount of code already developed for a particular processor family may dictate the choice of processors. Real-time code development takes significant time and the investment can be substantial. The ability to reuse existing code is a significant time saver in getting products to market.

- **Development Tools.** The development tools are critical to the timely implementation of an algorithm on a particular processor. If the tools are not available or are not functional, the development process will most likely be extended beyond any reasonable time estimate.

- **Third Party Support.** DSP processor manufacturers have a network of companies that provide tools, algorithm implementations, and hardware solutions for particular problems. It is possible that some company has already implemented, and makes a living out of implementing, the type of solution that is required for a given application.

### 31.9 Programming a DSP

DSPs, like many other processors, are only useful if they can input and output data. The software system used to input and output data is called an I/O system. As shown in Fig. 31-17, a DSP application program typi-
cally processes an input stream of data to produce some output data. The processing of this data is performed under the direction of the application program, which usually includes one or more algorithms programmed on the DSP. The DSP application program consists of acquiring the input stream data, using the algorithms to process the data, and then outputting the processed data to the output data stream. An example of this is a speech data compression system where the input stream is a data stream representing uncompressed speech. The output stream, in this case, is the compressed speech data and the application consists of getting the uncompressed input speech data, compressing the data, and then sending the compressed data to the output stream.

One of the most important factors that a DSP I/O system must address is the idea of real-time. An extremely important aspect of these real-time A/D and D/A systems is that the samples must be produced and consumed at a fixed rate in order for the system to work in real-time. Although an A/D or D/A converter is a common example of a real-time device, other devices not directly related to real-time data acquisition can also have real time constraints. This is particularly true if they are being used to supply, collect, or transfer real-time information from devices such as disk drives and interprocessor communication links. In the speech compression example, the output stream might be connected to a modem that would transmit the compressed speech to another DSP system that would uncompress the speech. The I/O system should be designed to interface to these devices (or any other) as well.

Another important aspect of a real-time I/O system is the amount of delay imposed from input to output. For instance, when DSPs are used for in-room reinforcement or two-way speech communication (i.e., telecommunications), the delay must be minimized. If the DSP system causes a noticeable delay, the conversation would be awkward and the system would be considered unacceptable. Therefore, the DSP I/O system should be capable of minimizing I/O delay to a reasonable value.

Programming a DSP is usually accomplished in a combination of C and assembly languages. The C code provides a portable implementation that can potentially be run on multiple different platforms. Assembly language allows for a more computationally efficient implementation at the expense of increased development time and decreased portability. By starting in C, the developer can incrementally optimize the implementation by benchmarking which subroutines are taking the most time, optimizing these routines, and then finding the next subroutine to optimize.

The typical C code shell for implementing a DSP algorithm is shown in Fig. 31-18. Here, the C code allocates some buffer memory to store signal data, opens an I/O signal stream, and then gets data, processes the data, and then sends the data to the output stream. The input and output streams typically have lower level device drivers for talking directly to the A/D and D/A converters, respectively.

```c
#include <stdio.h>
#include <aspi_io.h>
#include <malloc.h>
#define LEN 800

void main(argc,argv)
char **argv;
int argc;
{
    SIG_Stream input, output;
    SIG_Attrs sig_attrs;
    BUF_Buffer buffer;
    buffer = BUF_create(SEG_DRAM,LEN,0);
    input = SIG_open(argv[1],SIG_READ,buffer,0);
    SIG_getattrs(input,&sig_attrs);
    output = SIG_open(argv[2],SIG_WRITE,buffer,&sig_attrs);
    while (SIG_get(input,buffer))
    {
        /* data processing of buffer */
        my_DSP_algorithm(buffer);
        SIG_put(output,buffer);
    }
    return(0);
}
```

This chapter has introduced the fundamentals of DSP from a theoretical perspective (signal and system theory), and a practical perspective. The concepts of real-time systems, data acquisition, and digital signal processors have been introduced. DSP is a large and encompassing subject and the interested reader is encouraged to learn more through the exhaustive treatment given to this material in the references.\(^1,2\)

32.1 Introduction

Many audio professionals think of system grounding as a black art. How many times have you heard someone say that a cable is picking up noise, presumably from the air like a radio receiver? Even equipment manufacturers often don’t have a clue what’s really going on when there’s a problem. The most basic rules of physics are routinely overlooked, ignored, or forgotten. As a result, myth and misinformation have become epidemic! This chapter is intended to enable sound engineers to understand and either avoid or solve real-world noise problems. The electronic system engineering joke that cables are sources of potential trouble connecting two other sources of potential trouble contains more truth than humor. Because equipment ground connections have profound effects on noise coupling at signal interfaces, we must appreciate how interfaces actually work as well as when, why, and how equipment is grounded. Although the subject can’t be reduced to just a few simple rules, it doesn’t involve rocket science or complex math either.

For convenience in this chapter, we’ll use the term noise to mean to signal artifacts that originate from sources external to the signal path. This includes hum, buzz, clicks, or pops originating from the power line and interference originating from radio-frequency devices. A predictable amount of white noise is inherent in all electronic devices and must be expected. This random noise, heard as hiss, will also limit the usable dynamic range of any audio system, but this is not the subject of this chapter!

Any signal accumulates noise as it flows through the equipment and cables in a system. Once it contaminates a signal, noise is essentially impossible to remove without altering or degrading the signal. Therefore, noise and interference must be prevented along the entire signal path. It might seem trivial to transfer signal from the output of one audio device to the input of another but, in terms of noise and interference, signal interfaces are truly the danger zone! Let’s start with some basic electronics that apply to interfaces.

32.2 Basic Electronics

Fields can exert invisible forces on objects within them. In electronics, we’re concerned with electric and magnetic fields. Almost everyone has seen a demonstration of iron filings sprinkled on paper used to visualize the magnetic field between the north and south poles of a small magnet. A similar electric field exists between two points having a constant voltage difference between them. Fields like these, which neither move nor change in intensity, are called static fields.

If a field, either magnetic or electric, moves in space or fluctuates in intensity, the other kind of field will be generated. In other words, a changing electric field will set up a changing magnetic field or a changing magnetic field will set up a changing electric field. This interrelationship gives rise to electromagnetic waves, in which energy is alternately exchanged between electric and magnetic fields as they travel through space at the speed of light.

Everything physical is made of atoms whose outermost components are electrons. An electron carries a negative electric charge and is the smallest quantity of electricity that can exist. Some materials, called conductors and most commonly metals, allow their outer electrons to move freely from atom to atom. Other materials, called insulators and most commonly air, plastic, or glass, are highly resistant to such movement. This movement of electrons is called current flow. Current will flow only in a complete circuit consisting of a connected source and load. Regardless of how complex the path becomes, all current leaving a source must return to it!

32.2.1 Circuit Theory

An electric potential or voltage, sometimes called emf for electromotive force, is required to cause current flow. It is commonly denoted $E$ (from emf) in equations and its unit of measure is the volt, abbreviated $V$. The resulting rate of current flow is commonly denoted $I$ (from intensity) in equations and its unit of measure is the ampere, abbreviated $A$. How much current will flow for a given applied voltage is determined by circuit resistance. Resistance is denoted $R$ in equations and its unit of measure is the ohm, symbolized $\Omega$.

Ohm’s Law defines the quantitative relationship between basic units of voltage, current, and resistance:

$$E = I \times R$$

which can be rearranged as

$$R = \frac{E}{I}$$

$$I = \frac{E}{R}$$

For example, a voltage $E$ of 12 V applied across a resistance $R$ of 6 $\Omega$ will cause a current flow $I$ of 2 A.

Circuit elements may be connected in series, parallel, or combinations of both, Figs. 32-1 and 32-2.
Although the resistance of wires that interconnect circuit elements is generally assumed to be negligible, we will discuss this later.

In a parallel circuit, the total source current is the sum of the currents through each circuit element. The highest current will flow in the lowest resistance, according to Ohm’s Law. The equivalent single resistance seen by the source is always lower than the lowest resistance element and is calculated as

\[ R_{EQ} = \frac{1}{\frac{1}{R1} + \frac{1}{R2} + \frac{1}{R} \ldots + \frac{1}{Rn}} \]  

(32-1)

In a series circuit, the total source voltage is the sum of the voltages across each circuit element. The highest voltage will appear across the highest resistance, according to Ohm’s Law. The equivalent single resistance seen by the source is always higher than the highest resistance element and is calculated as

\[ R_{EQ} = R1 + R2 + R3 \ldots + Rn \]  

(32-2)

Voltages or currents whose value (magnitude) and direction (polarity) are steady over time are generally referred to as dc. A battery is a good example of a dc voltage source.

### 32.2.2 ac Circuits

A voltage or current that changes value and direction over time is generally referred to as ac. Consider the voltage at an ordinary 120 V, 60 Hz ac receptacle.

Since it varies over time according to a mathematical sine function, it is called a sine wave. Figure 32-3 shows how it would appear on an oscilloscope where time is the horizontal scale and instantaneous voltage is the vertical scale with zero in the center. The instantaneous voltage swings between peak voltages of +170 V and −170 V. A cycle is a complete range of voltage or current values that repeat themselves periodically (in this case every 16.67 ms). Phase divides each cycle into 360° and is used mainly to describe instantaneous relationships between two or more ac waveforms. Frequency indicates how many cycles occur per second of time. Frequency is usually denoted \( f \) in equations, and its unit of measure is the hertz, abbreviated Hz. Audio signals rarely consist of a single sine wave. Most often they are complex waveforms consisting of many simultaneous sine waves of various amplitudes and frequencies in the 20 Hz to 20,000 Hz (20 kHz) range.

### 32.2.3 Capacitance, Inductance, and Impedance

An electrostatic field exists between any two conductors having a voltage difference between them. Capacitance is the property that tends to oppose any change in the strength or charge of the field. In general, capacitance is increased by larger conductor surface areas and smaller spacing between them. Electronic components expressly designed to have high capacitance are called capacitors. Capacitance is denoted \( C \) in equations and its unit of measure is the Farad, abbreviated F. It’s very important to remember that unintentional or parasitic capacitances exist virtually everywhere. As we will see, these parasitic capacitances can be particularly significant in cables and transformers!

Current must flow in a capacitor to change its voltage. Higher current is required to change the voltage rapidly and no current will flow if the voltage is held constant. Since capacitors must be alternately charged and discharged in ac circuits, they exhibit an apparent ac resistance called capacitive reactance. Capacitive reactance is inversely proportional to both capacitance and
frequency since an increase in either causes an increase in current, corresponding to a decrease in reactance.

\[ X_C = \frac{1}{2\pi fC} \]  
(32-3)

where,

- \( X_C \) is capacitive reactance in ohms,
- \( f \) is frequency in hertz,
- \( C \) is capacitance in farads.

In general, capacitors behave as open circuits at dc and gradually become short circuits, passing more and more current, as frequency increases.

As shown in Figure 32-4, a magnetic field exists around any conductor carrying current at right angles to the axis of flow. The strength of the field is directly proportional to current. The direction, or polarity, of the magnetic field depends on the direction of current flow. Inductance is the property that tends to oppose any change in the strength or polarity of the field. Note that the fields around the upper and lower conductors have opposite polarity. The fields inside the loop point in the same direction, concentrating the field and increasing inductance. An electronic component called an inductor (or choke) is most often made of a wire coil with many turns to further increase inductance. Inductance is denoted \( L \) in equations and its unit of measure is the henry, abbreviated H. Again, remember that unintentional or parasitic inductances are important, especially in wires!

\[ X_L = 2\pi fL \]  
(32-4)

where,

- \( X_L \) is inductive reactance in ohms,
- \( f \) is frequency in hertz,
- \( L \) is inductance in henrys.

In summary, inductors behave as short circuits at dc and gradually become open circuits, passing less and less current, as frequency increases.

Impedance is the combined effect of both resistance and reactance for circuits that contain resistance, capacitance, and inductance, which is the case with virtually all real-world circuits. Impedance is represented by the letter \( Z \) and is measured in ohms. Impedance can be substituted for \( R \) in the Ohm’s Law equations. Impedance is a more general term than either resistance or reactance and, for ac circuits is the functional equivalent of resistance.

### 32.2.4 Single Wires

The electrical properties of wire are often overlooked. Consider a 10 ft length of #12 AWG solid copper wire.

1. The resistance of a wire is directly proportional to its length, inversely proportional to its diameter, and depends strongly on the material. From standard wire tables, we find the dc resistance of #12 AWG annealed copper wire is 1.59 \( \Omega/1000 \) ft or 0.0159 \( \Omega \) for a 10 ft length. At frequencies below about 500 Hz, this resistance largely sets the impedance.

2. The inductance of a straight wire is nearly independent of its diameter but is directly proportional to its length. From the formula for the inductance of a straight round wire, we find its inductance is 4.8 \( \mu \)H. As shown in Fig. 32-5, this causes a rise in impedance beginning at about 500 Hz, reaching 30 \( \Omega \) at 1 MHz (AM radio). Replacing the wire with a massive 1⁄2 inch diameter copper rod would reduce impedance only slightly to 23 \( \Omega \).
3. Electromagnetic waves travel through space or air at the speed of light. The physical distance traveled by a wave during one cycle is called wavelength. The equation is

\[ M = \frac{984}{f} \]  

(32-5)

where,

\[ M \] is wavelength in feet,

\[ f \] is frequency in MHz.

For 1 MHz AM radio, 100 MHz FM radio, and 2 GHz cell phone signals, wavelengths are about 1000 ft, 10 ft, and 6 inches, respectively.

4. Any wire will behave as an antenna at frequencies where its physical length is a quarter-wavelength or multiples thereof. This is responsible for the impedance peaks and dips seen at 25 MHz intervals in Fig. 32-5.

32.2.5 Cables and Transmission Lines

A cable consists of two or more conductors that are kept in close proximity over their length. Cables, such as those for ac power and loudspeakers, are generally used to convey power to a load. In a pair of such conductors, because the same current flows to and from the load in opposite directions, the magnetic fields have the same intensity but are of opposite polarity as shown in Fig. 32-6. In theory, there would be zero external field, and zero net inductance, if the two conductors could occupy the same space. The cancellation of round trip inductance due to magnetic coupling varies with cable construction, with typical values of 50% for zip cord,

70% for a twisted pair, and 100% for coaxial construction.

At very high frequencies, a cable exhibits very different characteristics than it does at, say, 60 Hz power frequencies. This is caused by the finite speed, called propagation velocity, at which electrical energy travels in wires. It is about 70% of the speed of light for typical cables making wavelengths in cable correspondingly shorter. A cable is called electrically short when its physical length is under 10% of a wavelength at the highest frequency of interest. Wavelength at 60 Hz for typical cable is about 2200 miles (mi), making any power cable less than 220 mi long electrically short. Likewise, the wavelength at 20 kHz for typical cable is about 34,500 ft, making any audio cable less than about 3500 ft long electrically short. Essentially identical instantaneous voltage and current exists at all points on an electrically short cable and its signal coupling behavior can be represented by lumped resistance, capacitance, and magnetically coupled inductance as shown in Fig. 32-7. Its equivalent circuit can then be analyzed by normal network theory.

32.2.5 Cables and Transmission Lines

A cable consists of two or more conductors that are kept in close proximity over their length. Cables, such as those for ac power and loudspeakers, are generally used to convey power to a load. In a pair of such conductors, because the same current flows to and from the load in opposite directions, the magnetic fields have the same intensity but are of opposite polarity as shown in Fig. 32-6. In theory, there would be zero external field, and zero net inductance, if the two conductors could occupy the same space. The cancellation of round trip inductance due to magnetic coupling varies with cable construction, with typical values of 50% for zip cord,
Grounding and Interfacing

than 7 ft for 10 MHz video, 8 inch for 100 MHz FM radio, and 0.8 inch for 1000 MHz CATV signals. Significantly different instantaneous voltages exist along the length of a transmission line. For all practical purposes, its electrical equivalent is a distributed circuit consisting of a large number of small inductors and resistors in series and capacitors in parallel. If an electrical impulse were applied to one end of an infinitely long cable, it would appear to have a purely resistive impedance. This characteristic impedance of the cable is a result of its inductance and capacitance per unit length, which is determined by its physical construction. Theoretically, the electrical impulse or wave would ripple down the infinite length of the cable forever. But actual transmission lines always have a far end. If the far end is left open or shorted, none of the wave’s energy can be absorbed and it will reflect back toward the source. However, if the far end of the line is terminated with a resistor of the same value as the line’s characteristic impedance, the wave energy will be completely absorbed. To the wave, the termination appears to be simply more cable. A properly terminated transmission line is often said to be matched. Generally, impedances of both the driving source and the receiving load are matched to the characteristic impedance of the line. In a mismatched line, the interaction between outgoing and reflected waves causes a phenomenon called standing waves. A measurement called standing-wave ratio (SWR) indicates mismatch, with an SWR of 1.00 meaning a perfect match.

32.3 Electronics of Interfaces

32.3.1 Balanced and Unbalanced Interfaces

An interface is a signal transport subsystem consisting of three components: a driver (one device’s output), a line (interconnecting cable), and a receiver (another device’s input). These components are connected to form a complete circuit for signal current, which requires a line having two signal conductors. The impedances of the signal conductors, usually with respect to ground, are what determine whether an interface is balanced or unbalanced. A concise definition of a balanced circuit is:

A balanced circuit is a two-conductor circuit in which both conductors and all circuits connected to them have the same impedance with respect to ground and to all other conductors. The purpose of balancing is to make the noise pickup equal in both conductors, in which case it will be a common-mode signal that can be made to cancel out in the load.

The use of balanced interfaces is an extremely potent technique to prevent noise coupling into signal circuits. It is so powerful that many systems, including telephone systems, use it in place of shielding as the main noise reduction technique.

Theoretically, a balanced interface can reject any interference, whether due to ground voltage differences, magnetic fields, or capacitive fields, as long as it produces identical voltages on each of the signal lines and the resulting peak voltages don’t exceed the capabilities of the receiver.

A simplified balanced interface is shown in Fig. 32-8. Any voltage that appears on both inputs, since it is common to the inputs, is called a common-mode voltage. A balanced receiver uses a differential device, either a specialized amplifier or a transformer, that inherently responds only to the difference in voltage between its inputs. By definition, such a device will reject—i.e., have no response to—common-mode voltages. The ratio of differential gain to common-mode gain of this device is its common-mode rejection ratio, or CMRR. It’s usually expressed in dB, and higher numbers mean more rejection. Section 32.5.1 will describe how CMRR often degrades in real-world systems and how it has traditionally been measured in ways that have no relevance to real-world system performance.

---

**Figure 32-8. Basic balanced interface.**

Two signal voltages have symmetry when they have equal magnitudes but opposite polarities. Symmetry of the desired signal has advantages, but they concern head room and crosstalk, not noise or interference rejection. The noise or interference rejection property is independent of the presence of a desired differential signal. Therefore, it can make no difference whether the desired signal exists entirely on one line, as a greater voltage on one line than the other, or as equal voltages on both of them. However, the symmetry myth is widespread. A typical example is: Each conductor is always equal in voltage but opposite in polarity to the other. The circuit that receives this signal in the mixer is called a differential amplifier and this opposing polarity of the
conductors is essential for its operation. Like many others, it describes a balanced interface in terms of signal symmetry but never mentions impedances! Even the BBC test for output balance is actually a test for signal symmetry. The idea that balanced interface is somehow defined by signal symmetry is simply wrong! It has apparently led some designers, mostly of exotic audiophile gear, to dispense with a differential amplifier input stage in their push-pull amplifiers. They simply amplify the (assumed) symmetrical input signals in two identical, ground-referenced amplifier chains. No mechanism exists to reject common-mode voltage (noise and interference) and it is actually amplified along with the signal, creating potentially serious problems. Rejection of common-mode voltages is the single most important function of a balanced receiver.

In an unbalanced circuit, one signal conductor is grounded (near-zero impedance) and the other has some higher impedance. As we will discuss in Section 32.5.4, the fact that not only signal but ground noise currents flow and cause voltage drops in the grounded conductor makes an unbalanced interface inherently susceptible to a variety of noise problems.

### 32.3.2 Voltage Dividers and Impedance Matching

Every driver has an internal impedance, measured in ohms, called its output impedance. Actual output impedance is important, as we discuss below, but often absent from equipment specifications. Sometimes, especially for consumer gear, the only impedance associated with an output is listed as recommended load impedance. While useful if listed in addition to output impedance, it is not what we need to know! A perfect driver would have a zero output impedance but, in practical circuit designs, it’s neither possible nor necessary. Every receiver has an internal impedance, measured in ohms, called its input impedance. A perfect receiver would have an infinite input impedance but again, in practical circuit designs, it’s neither possible nor necessary.

Figs. 32-8 and 32-9 illustrate ideal interfaces. The triangles represent ideal amplifiers having infinite impedance input—i.e., draw no current—and zero impedance output—i.e., deliver unlimited current—and the line conductors have no resistance, capacitance, or inductance. The signal voltage from the driver amplifier causes current flow through the driver output impedance(s) $Z_o$, the line, and receiver input impedance $Z_i$. Note that the output impedance of the balanced driver is split into two equal parts. Because current is the same in all parts of a series circuit and voltage drops are proportional to impedances, this circuit is called a voltage divider.

The goal of an interface is, with rare exception, to deliver maximum signal voltage from the output of one device to the input of another. Making $Z_i$ much larger than $Z_o$ assures that most of the signal voltage is delivered to the receiver and very little is lost in the driver. In typical devices, $Z_o$ ranges from 30 Ω to 1 kΩ and $Z_i$ ranges from 10 kΩ to 100 kΩ, which transfers 90–99.9% of the available—i.e., unloaded or open circuit—signal voltage.

![Figure 32-9. Basic unbalanced interface.](image)

**Matching** is a term that often causes confusion. A little math and Ohm’s Law will prove that when $Z_o$ and $Z_i$ are equal, maximum power is transferred from source to load, although half the signal voltage is lost. If transmission line effects apply, $Z_o$ and $Z_i$ must terminate or match the characteristic impedance of the line to prevent reflection artifacts. Although modern audio systems seldom use cables long enough for transmission line effects to apply or benefit from maximum power transfer, early telephone systems did both. Telephone systems began by using miles of existing open wire telegraph lines that, due to their wire size and spacing, had a characteristic impedance of 600 Ω. Since amplifiers didn’t yet exist, the system was entirely passive and needed to transfer maximum power from one phone to another. Therefore, transformers, filters, and other components were designed for 600 Ω impedances to match the lines. These components were eventually incorporated into early sound reinforcement, radio, and recording systems. And the 600 Ω legacy still lives on, even though modern requirements for it are all but extinct.

Sometimes, instead of meaning equal, matching is used to mean optimizing some aspect of circuit performance. For example, the output transformer in a vacuum-tube power amplifier is used to optimize power output by converting or impedance matching the low-impedance loudspeaker to a higher impedance that suits the characteristics of the tubes. Similarly, the modern technique of making $Z_i$ much larger than $Z_o$ to transfer maximum voltage in signal interfaces is often referred to as **voltage matching**. It uses 10 kΩ or higher input impedances, called bridging because many inputs
Grounding and Interfacing

can be paralleled across the same output line with negligible drop in level. About 60 $\Omega$ has been suggested as the optimum $Z_o$ for driving up to 2000 ft of typical shielded twisted pair cable in these balanced interfaces.\(^5\)

### 32.3.3 Line Drivers and Cable Capacitance

A line driver and cable interact in two important ways. First, output impedance $Z_o$ and the cable capacitance form a low-pass filter that will cause high-frequency roll-off. A typical capacitance for either unbalanced or balanced shielded audio cable might be about 50 pF/ft. If output impedance were 1 k$\Omega$ (not uncommon in unbalanced consumer gear), response at 20 kHz would be $-0.5$ dB for 50 ft, $-1.5$ dB for 100 ft, and $-4$ dB for 200 ft of cable. If the output impedance were 100 $\Omega$ (common in balanced professional gear), the effects would be negligible for the same cable lengths. Low-output impedance is especially important when cable runs are long. Also be aware that some exotic audio cables have extraordinarily high capacitance.

Second, cable capacitance requires additional high-frequency current from the driver. The current required to change the voltage on a capacitance is directly proportional to the rate of change or *slew rate* of the voltage. For a sine wave,

$$SR = 2\pi f V_p$$  \hspace{1cm} (32-6)

where,

$SR$ is slew rate in volts per second,

$f$ is frequency in hertz,

$V_p$ is peak voltage.

$$I = SR \times C$$  \hspace{1cm} (32-7)

where,

$I$ is current in A,

$SR$ is slew rate in V/$\mu$s,

$C$ is capacitance in $\mu$F.

For example, we have a cable with a slew rate of 1 V/$\mu$s at 20 kHz for a sine-wave of 8 $V_p$ or 5.6 $V_{rms}$, which is also +17 dBu or +15 dBV. For a cable of 100 ft at 50 pF/ft, $C$ would be 5000 pF or 0.005 $\mu$F. Therefore, peak currents of 5 mA are required to drive just the cable capacitance to +17 dBu at 20 kHz. Obviously, increasing level, frequency, cable capacitance, or cable length will increase the current required. Under the previous conditions, a cable of 1000 ft would require peak currents of 50 mA. Such peak currents may cause protective current limiting or clipping in the op-amps used in some line drivers. Since it occurs only at high levels and high frequencies, the audible effects may be subtle.

Of course, the load at the receiver also requires current. At a +17 dBu level, a normal 10 k$\Omega$ balanced input requires a peak current of only 0.8 mA. However, a 600 $\Omega$ termination at the input requires 13 mA. Matching 600 $\Omega$ sources and loads not only places a current burden on the driver but, because 6 dB (half) of signal voltage is lost, the driver must generate +23 dBu to deliver +17 dBu to the input. Unnecessary termination wastes driver current and unnecessary matching of source and load impedances wastes head room!

### 32.3.4 Capacitive Coupling and Shielding

Capacitances exist between any two conductive objects, even over a relatively large distance. As we mentioned earlier, the value of this capacitance depends on the surface areas of the objects and the distance. When there are ac voltage differences between the objects, these capacitances cause small but significant currents to flow from one object to another by means of the changing electric field (widely referred to as *electrostatic* fields although technically a misnomer since static means unchanging).

Strong electric fields radiate from any conductor operating at a high ac voltage and, in general, weaken rapidly with distance. Factors that increase coupling include increasing frequency, decreasing spacing of the wires, increasing length of their common run, increasing impedance of the victim circuit, and increasing distance from a ground plane. For some of these factors, there is a point of diminishing returns. For example, for parallel 22-gauge wires, there is no significant reduction in coupling for spacing over about 1 in.\(^6\) Capacitive coupling originates from the voltage at the source. Therefore, coupling from a power circuit, for example, will exist whenever voltage is applied to the circuit regardless of whether load current is flowing.

Capacitive coupling can be prevented by placing electrically conductive material called a shield between the two circuits so that the electric field, and the resulting current flow, linking them is diverted. A shield is connected to a point in the circuit where the offending current will be harmlessly returned to its source, usually called *ground*—more about ground later. For example, capacitive coupling between a sensitive printed wiring board and nearby ac power wiring could be prevented by locating a grounded metal plate (shield) between them, by completely enclosing the board in a thin metal box, or by enclosing the ac power wiring in a thin metal box.
Similarly, as shown in Fig. 32-10, shielding can prevent capacitive coupling to or from signal conductors in a cable. Solid shields, such as conduit or overlapped foil, are said to have 100% coverage. Braided shields, because of the tiny holes, offer from 70% to 98% coverage. At very high frequencies, where the hole size becomes significant compared with interference wavelength, cables with combination foil/braid or multiple braided shields are sometimes used.

**32.3.5 Inductive Coupling and Shielding**

When any conductor cuts magnetic lines of force, in accordance with the law of induction, a voltage is induced in it. If an alternating current flows in the conductor, as shown at the left in Fig. 32-11, the magnetic field also alternates, varying in intensity and polarity. We can visualize the magnetic field, represented by the concentric circles, as expanding and collapsing periodically. Because the conductor at the right cuts the magnetic lines of force as they move across it, an ac voltage is induced over its length. This is the essential principle of a transformer. Therefore, current flowing in a wire in one circuit can induce a noise voltage in another wire in a different circuit. Because the magnetic field is developed only when current flows in the source circuit, noise coupling from an ac power circuit, for example, will exist only when load current actually flows.

If two identical conductors are exposed to identical ac magnetic fields, they will have identical voltages induced in them. If they are series connected as shown in Fig. 32-12, their identical induced voltages tend to cancel. In theory, there would be zero output if the two conductors could occupy the same space.

Magnetic fields become weaker rapidly as distance from the source increases, usually as the square of the distance. Therefore, cancellation depends critically on the two conductors being at precisely the same distance from the magnetic field source. Twisting essentially places each conductor at the same average distance from the source. So-called star quad cable uses four conductors with those opposing each other connected in parallel at each cable end. The effective magnetic center for each of these pairs is their center line and the two sets of pairs now have coincident center lines reducing the loop area to zero. Star quad cable has approximately 100 times (40 dB) better immunity to power-frequency magnetic fields than standard twisted pair. The shield of a coaxial cable also has an average location coincident with the center conductor. These construction techniques are widely used to reduce susceptibility of balanced signal cables to magnetic fields. In general, a smaller physical area inside the loop results in less magnetic radiation as well as less magnetic induction.

Another way to reduce magnetic induction effects is shown in Fig. 32-13. If two conductors are oriented at a 90° (right) angle, the second doesn’t cut the magnetic lines produced by the first and will have zero induced voltage. Therefore, cables crossing at right angles have minimum coupling and those running parallel have maximum coupling. The same principles also apply to circuit board traces and internal wiring of electronic equipment.

Magnetic circuits are similar to electric circuits. Magnetic lines of force always follow a closed path or circuit, from one magnetic pole to the opposite pole, always following the path of least resistance or highest
conductivity. The magnetic equivalent of electric current and conductivity are flux density and permeability. High-permeability materials have the ability to concentrate the magnetic force lines or flux. The permeability of air and other nonmagnetic materials such as aluminum, plastic, or wood is 1.00. The permeability of common ferromagnetic materials is about 400 for machine steel, up to 7000 for common 4% silicon transformer steel, and up to 100,000 for special nickel alloys. The permeability of magnetic materials varies with flux density. When magnetic fields become very intense, the material can become saturated, essentially losing its ability to offer an easy path for any additional flux lines. Higher permeability materials also tend to saturate at a lower flux density and to permanently lose their magnetic properties if mechanically stressed.

The basic strategy in magnetic shielding is to give the flux lines a much easier path to divert them around a sensitive conductor, circuit, or device. In general, this means that the shield must be a complete enclosure with a high magnetic permeability. The choice of the most effective shielding material depends on frequency. At low frequencies, below say 100 kHz, high-permeability magnetic materials are most effective. We can calculate how effective a conduit or cable shield will be at low frequencies:

\[
SE = 20 \log \left( 1 + \frac{\mu t}{d} \right)
\]

where,
SE is shielding effect in dB,
\(\mu\) is permeability of shield material,
t and d are the thickness and diameter (in the same units) of the conduit or shield.\(^7\)

Thus, standard 1 inch EMT, made of mild steel with a low-frequency permeability of 300, will provide about 24 dB of magnetic shielding at low frequencies, but this will diminish to zero around 100 kHz. Fortunately, only low-frequency magnetic fields are generally a problem. In severe cases, nesting one magnetic shield inside another may be necessary.

Typical copper braid or aluminum foil cable shielding has little effect on magnetic fields at audio frequencies. If a shield is grounded at both ends, it behaves somewhat like a shorted turn to shield the inner conductors from magnetic fields.\(^8\) Depending on the external impedance between the grounded ends of a cable shield, it may begin to become effective against magnetic fields somewhere in the 10 kHz to 100 kHz range. Box shields of aluminum or copper are widely used to enclose RF circuits because they impede magnetic fields through this eddy current action and are excellent shielding for electric fields as well. There is an excellent explanation of this high-frequency shielding in reference 9. However, copper or aluminum shielding is rarely an effective way to prevent noise coupling from audio-frequency magnetic fields.

### 32.4 Grounding

Historically, grounding became necessary for protection from lightning strokes and industrially-generated static electricity—i.e., belts in a flour mill. As utility power systems developed, grounding became standard practice to protect people and equipment. As electronics developed, the common return paths of various circuits were referred to as ground, regardless of whether or not they were eventually connected to earth. Thus, the very term *ground* has become vague, ambiguous, and often fanciful. Broadly, the purpose of grounding is to electrically interconnect conductive objects, such as equipment, in order to minimize voltage differences between them. An excellent general definition is that a ground is simply a return path for current, which will always return to its source. The path may be intentional or accidental—electrons don’t care and don’t read schematics!\(^10\)

Grounding-related noise can be the most serious problem in any audio system. Common symptoms include hum, buzz, pops, clicks, and other noises. Because equipment manufacturers so often try to explain away these problems with the nebulous term *bad grounding*, most system installers and technicians feel that the entire subject is an incomprehensible black art. Adding to the confusion are contradictory rules proposed by various experts. Ironically, most universities teach very little about the real-world aspects of grounding. Graduates take with them the grounding fantasy that all grounds are equipotential—that is, have the same voltage. The fantasy certainly allows them to avoid complicated real-world interpretation of all those ground symbols on a schematic diagram, but the same
fantasy can lead to noise disaster in their audio equipment and system designs.

Grounding has several important purposes and most often a single ground circuit serves, intentionally or accidentally, more than one purpose. We must understand how these ground circuits work and how noise can couple into signal circuits if we expect to control or eliminate noise in audio systems.

### 32.4.1 Earth Grounding

An earth ground is one actually connected to the earth via a low-impedance path. In general, earth grounds are necessary only to protect people from lightning. Before modern standards such as the National Electrical Code (NEC or just Code) were developed, lightning that struck a power line was often effectively routed directly into buildings, starting a fire or killing someone. Lightning strikes are the discharge of giant capacitors formed by the earth and clouds. Strikes involve millions of volts and tens of thousands of amperes, producing brief bursts of incredible power in the form of heat, light, and electromagnetic fields. Electrically, lightning is a high-frequency event, with most of its energy concentrated in frequencies over 300 kHz! That’s why, as we discussed in Section 32.2.4, wiring to ground rods should be as short and free of sharp bends as possible. The most destructive effects of a strike can be avoided by simply giving the current an easy, low-impedance path to earth before it enters a building. Because overhead power lines are frequent targets of lightning, virtually all modern electric power is distributed on lines having one conductor that is connected to earth ground frequently along its length.

Fig. 32-14 shows how ac power is supplied through a three-wire split single-phase service to outlets on a typical 120 Vac branch circuit in a building. One of the service wires, which is often uninsulated, is the grounded neutral conductor. Note that both the white neutral and the green safety ground wires of each branch circuit are tied or bonded to each other and an earth ground rod (or its equivalent grounding electrode system) at the service entrance as required by Code. This earth ground, along with those at neighboring buildings and at the utility poles, provide the easy paths for lightning to reach earth.

Telephone, CATV, and satellite TV cables are also required to divert or arrest lightning energy before it enters a building. The telco-supplied gray box or NIU provides this protection for phone lines as x grounding blocks do for CATV and satellite dishes. NEC Articles 800, 810, and 820 describe requirements for telephone, satellite/TV antennas, and CATV, respectively. All protective ground connections should be made to the same ground rod used for the utility power, if the ground wire is 20 ft or less in length. If longer, separate ground rods must be used, and they must be bonded to the main utility power grounding electrode with a #6 AWG wire. Otherwise, because of considerable soil resistance between separate ground rods, thousands of volts could exist between them when lightning events occur or downed power lines energize the signal lines. Without the bond such events could seriously damage a computer modem, for example, that straddles a computer grounded to one rod via its power cord and a telephone line protectively grounded to another.

### 32.4.2 Fault or Safety Grounding

Any ac line powered device having conductive exposed parts (which includes signal connectors) can become a shock or electrocution hazard if it develops certain internal defects. Insulation is used in power transformers, switches, motors, and other internal parts to keep the electricity where it belongs. But, for various reasons, the insulation may fail and effectively connect live power to exposed metal. This kind of defect is called a fault. A washing machine, for example, could electrocute someone who happened to touch the machine and a water faucet (assumed grounded via buried metal pipes) at the same time.

NEC requires that 120 Vac power distribution in homes and buildings use a three-wire system as shown in Fig. 32-15. To prevent electrocution, most devices have a third wire connecting exposed metal to the safety ground pin of these outlets. The outlet safety ground is routed, through either the green wire or metallic conduit, to the neutral conductor and earth ground at the main breaker panel. The connection to neutral allows high fault current to flow, quickly tripping the circuit breaker, while the earth ground connection minimizes
any voltage that might exist between equipment and other earth-grounded objects, such as water pipes, during the fault event. Power engineers refer to voltage differences created by these fault events as step or touch potentials. The neutral (white) and line (black) wires are part of the normal load circuit that connects the voltage source to the load. The green wire or conduit is intended to carry fault currents only.

NEC also requires safety grounding of wiring raceways and equipment cabinets, including rack cabinets. Per Article 250-95, safety grounding wires, which may be bare or insulated, must have a minimum size of #14 copper for a 15 A or #12 copper for a 20 A branch circuit to assure rapid circuit breaker action. This grounding path must be bonded to the safety grounding system, not to building steel or a separate earth ground system! Separate earth grounds cannot provide safety grounding!! As shown in Fig. 32-16, soil resistance is far too high to guarantee tripping of a circuit breaker under fault conditions. With safety grounds in place, potentially deadly equipment faults simply cause high currents from power line hot to safety ground, quickly tripping circuit breakers and removing power from those branch circuits. Safety grounding in many residential and commercial buildings is provided through metal conduit, metallic J-boxes, and saddle-grounded or SG outlets. Technical or isolated grounding will be discussed in Section 32.7.

When trying to track down and correct system noise problems, it is easy to assume that power outlets are wired correctly. Low-cost outlet testers, which generally cost less than $10.00, will find dangerous problems such as hot-neutral or hot-ground reversals and open connections. Because they check for correct voltages between the pins, and both neutral and ground are normally at 0 V, they cannot detect a neutral-ground reversal. This insidious wiring error can create nightmarish noise problems in an audio system. Finding the error by visual inspection of outlets is one possibility, but this could get labor intensive if the number of outlets is large. For large systems, and even those that can’t be powered down, a sensitive, noncontact, clamp-on current probe can help identify the forks in the road when troubleshooting. Code requires that neutral and safety ground be bonded only at the power service disconnecting means that is generally at the main breaker panel. Serious system noise problems can also occur when an extraneous neutral-to-ground connection exists elsewhere in the building wiring. A special test procedure can be used to determine this condition.

NEVER, NEVER use devices such as three-prong-to two-prong ac plug adapters—a.k.a. ground lifters—to solve a noise problem! Such an adapter is intended to provide a safety ground (via the cover plate screw to a grounded saddle outlet and J-box) in cases where three-prong plugs must be connected to two-prong receptacles in pre-1960 buildings, Fig. 32-17.

Figure 32-15. Fault protection is provided by safety ground to neutral bond.

Figure 32-16. Fault protection is not provided by an earth ground connection!

Figure 32-17. This is intended to provide a safety ground.

Consider two devices with grounding ac plugs that are connected by a signal cable. One device has a ground lifter on its plug and the other doesn’t. If a fault occurs in the lifted device, the fault current flows through the signal cable to get to the grounded device. It’s very likely that the cable will melt and catch fire!
Also consider that consumer audio and video equipment is responsible for about ten electrocutions every year in the United States. In a typical year, this equipment causes some 2000 residential fires that result in 100 civilian injuries, 20 deaths, and over $30 million in property losses, Fig.32-18\textsuperscript{16,17}

Some small appliances, power tools, and consumer electronics are supplied with two-prong (ungrounded) ac plugs. Sometimes called double insulated, these devices are specially designed to meet strict UL and other requirements to remain safe even if one of their two insulation systems fails. Often there is a one-shot thermal cutoff switch inside the power transformer or motor windings to prevent overheating and subsequent insulation breakdown. Only devices that carry a UL-listed label and originally supplied with ungrounded ac plugs should ever be operated without safety grounding. Devices originally supplied with grounding three-prong plugs must always be operated with the safety ground properly connected!

32.4.3 Signal Grounding and EMC

EMC stands for electromagnetic compatibility, which is a field concerned with interference from electronic devices and their susceptibility to the interference created by other devices. As the world becomes increasingly wireless and digital, the general electromagnetic environment is becoming increasingly hostile. Engineers working in other disciplines, most notably information technology or IT—where signal/data frequencies are very high and narrowband—tend to minimize our difficulties in making audio systems robust against hostile electrical environments. In fact, high-quality audio systems are unique among electronic systems in two ways:

1. The signals cover a very broad, nearly 5 decade, range of frequencies.
2. The signals can require a very wide, currently over 120 dB, dynamic range.

Adding to the difficulty is the fact that ac power frequencies and their harmonics also fall within the system’s working frequency range. As you might suspect, grounding plays a pivotal role in controlling both emissions and susceptibility in both electronic devices and systems. In general, the same principles and techniques that reduce emissions will also reduce susceptibility. Grounding schemes generally fall into one of three categories:

1. Single point or star grounding.
2. Multipoint or mesh grounding.
3. Frequency selective transitional or hybrid grounding.

At frequencies below about 1 MHz (which includes audio), virtually all experts agree that star grounding works best because system wiring is electrically short compared to the wavelengths involved. At these low frequencies, the dominant noise coupling problems arise from the simple lumped parameter behavior of wiring and electronic components. This includes the resistance and inductance of wires, the noise currents resulting from capacitances between utility power and system grounds, and magnetic and capacitive coupling effects.

On the other hand, at higher frequencies, system wiring can become electrically long and transmission line effects, such as standing waves and resonances, become the dominant problems. For example, because a 25 ft (7.5 m) audio cable is a quarter wavelength long at 10 MHz, it becomes an antenna. At frequencies of 100 MHz or higher, even a 12 in (30 cm) wire can no longer be considered low impedance path. To be effective at these frequencies, therefore, grounding schemes must emulate a flat metal sheet having extremely low inductance called a ground plane. In practice, this can usually only be approximated with a multipoint ground system using wires. The wire lengths between points must remain well under a quarter-wavelength so, as frequency increases, larger numbers of increasingly shorter wires must be used to create the mesh. Ultimately, only a real ground plane can produce low-impedance ground connections at very high frequencies. Even a ground plane is not a perfect or equipotential—i.e., zero volts at all points—ground. Because it has finite resistance, significant voltage...
differences can be developed between connection points to it. Therefore, it should come as no surprise that IT and RF engineers prefer mesh grounding techniques while audio engineers prefer star grounding techniques.

At power and audio frequencies, a so-called ground loop allows noise and signal currents to mix in a common wire. Single-point grounding avoids this by steering signal currents and noise currents in independent paths. But at ultrasonic and radio frequencies, noise currents tend to bypass wires because they look like inductors and tend to flow instead in unintended paths consisting of parasitic capacitances. This makes star grounding essentially useless in controlling high-frequency interference in practical systems. Mesh grounding does a better job of controlling high-frequency interference, but since many ground loops are formed, low-frequency noise can easily contaminate signals. For audio systems, sometimes even inside audio equipment, there is clearly a conflict. This conflict can be resolved by the hybrid grounding scheme. Capacitors can be used to create multiple high-frequency ground connections while allowing audio-frequency currents to take a path determined by the directly wired connection. Thus, the ground system behaves as a star system at low frequencies and a mesh system at high frequencies. This technique of combining ground plane and star grounding is quite practical at the physical dimensions of a circuit board or an entire piece of equipment. At the system level the same conflict exists regarding grounding of audio cable shields. Ideally, at low frequencies, a shield should be grounded at one end only, but for maximum immunity to RF interference it should be grounded at both ends (and even intermediate points, if possible). This situation can be resolved by grounding one end directly and the other end through a small capacitor. The shield grounding issue will be discussed further in Section 32.5.2.

32.4.4 Grounding and System Noise

Most real-world systems consist of at least two devices that are powered by utility ac power. These power line connections unavoidably cause significant currents to flow in ground conductors and signal interconnect cables throughout a system. Properly wired, fully Code-compliant premises ac wiring generates small ground voltage differences and leakage currents. They are harmless from a safety viewpoint but potentiality disastrous from a system noise viewpoint. Some engineers have a strong urge to reduce these unwanted voltage differences by shorting them out with a large conductor. The results are most often disappointing.

Other engineers think that system noise can be improved experimentally by simply finding a better or quieter ground. They hold a fanciful notion that noise current can somehow be skillfully directed to an earth ground, where it will disappear forever! In reality, since the earth has resistance just like any other conductor, earth ground connections are not at zero volts with respect to each other or any other mystical or absolute reference point.

32.4.4.1 Power Line Noise

The power line normally consists of a broad spectrum of harmonics and noise in addition to the pure 60 Hz sine wave voltage. The noise is created by power supplies in electronic equipment, fluorescent lights, light dimmers, and intermittent or sparking loads such as switches, relays, or brush-type motors (i.e., blenders, shavers, etc.). Fig. 32-19 shows how sudden changes in load current, zero to full in about a microsecond for a triac light dimmer in this case, generate bursts of high-frequency noise on the power line 120 times per second. Even an ordinary light switch will briefly arc internally as it is switched off and its contacts open, generating a single similar burst. This noise contains significant energy to at least 1 MHz that is launched into the power wiring. The wiring behaves like a complex set of misterminated transmission lines gone berserk, causing the energy to reflect back and forth throughout the premises wiring until it is eventually absorbed or radiated. Power line noise can couple into signal paths in several ways, usually depending on whether the equipment uses two-prong or three-prong (grounding) ac power connections.
32.4.4.2 Parasitic Capacitances and Leakage Current Noise

In every ac-powered device, parasitic capacitances (never shown in schematic diagrams!) always exist between the power line and the internal circuit ground and/or chassis because of the unavoidable interwinding capacitances of power transformers and other line connected components. Especially if the device contains anything digital, there may also be intentional capacitances in the form of power line interference filters. These capacitances cause small but significant 60 Hz leakage currents to flow between power line and chassis or circuit ground in each device. Because the coupling is capacitive, current flow increases at higher noise frequencies. Fig. 32-20 shows the frequency spectrum of current flow in 3 nF of capacitance connected between line and safety ground at an ac outlet in a typical office.

![Typical leakage current from line to safety ground coupled via 3000 pF capacitance into a 75 Ω spectrum analyzer input.](image)

This tiny current, although it poses no shock hazard, causes hum, buzz, pops, clicks, and other symptoms when it couples into the audio signal path. This capacitive coupling favors higher frequencies, making buzz a more common symptom than pure hum. We must accept noisy leakage currents as a fact of life.

32.4.4.3 Parasitic Transformers and Inter-Outlet Ground Voltage Noise

Substantial voltages are magnetically induced in premises safety ground wiring when load current flows in the circuit conductors as shown in Fig. 32-21. The magnetic fields that surround the line and neutral conductors, which carry load current, magnetically induce a small voltage over the length of the safety ground conductor, effectively forming a parasitic transformer. The closer the safety ground conductor is to either the line or neutral conductor, the higher the induced voltage. Because, at any instant in time, line and neutral currents are equal but flow in opposite directions, there is a plane of zero magnetic field exactly midway between the line and neutral conductors as shown in Fig. 32-22. Therefore, Romex® and similar bonded cables generally generate significantly lower induced voltages than individual wires in conduit, where the relative positioning of the wires is uncontrolled.

The voltage induced in any transformer is directly proportional to the rate of change of load current in the circuit. With an ordinary phase-control light dimmer the peak voltages induced can become quite high. When the dimmer triggers current on 120 times per second, it switches on very quickly (a few microseconds) as shown in Fig. 32-23. Since the magnetic induction into safety ground favors high frequencies, noise coupling problems in a system will likely become most evident when a light dimmer is involved. The problems are usually worst at about half-brightness setting of the dimmer.

This parasitic transformer action generates small ground voltage differences, generally under 1 V, between ac outlets. The voltage differences tend to be higher between two outlets on different branch circuits, and higher still if a device on the branch circuit is also connected to a remote or alien ground such as a CATV feed, satellite dish, or an interbuilding tie line. We must accept interoutlet ground noise voltage as a fact of life.

32.4.4.4 Ground Loops

For our purposes, a ground loop is formed when a signal cable connects two pieces of equipment whose connections to the power line or other equipment causes a power-line-derived current to flow in the signal cable.

The first, and usually worst, kind of ground loop occurs between grounded devices—those with three-prong ac plugs. Current flow in signal cables, as shown in Fig. 32-24, can easily reach 100 mA or more.

The second kind of ground loop occurs between floating devices—those with two-prong ac plugs. Each pair of capacitances NF (for EMI filter) and CP (for power transformer parasitic) in the schematic form a capacitive voltage divider between line and neutral, causing some fraction of 120 Vac to appear between chassis and ground. For UL-listed ungrounded equipment, this leakage current must be under 0.75 mA (0.5 mA for office equipment). This small current can cause an unpleasant, but harmless, tingling sensation as
it flows through a person’s body. More relevant is the fact that these noisy leakage currents will flow in any wire connecting such a floating device to safety ground, or connecting two floating devices to each other as shown in Fig. 32-25.

32.5 Interface Problems in Systems

If properly designed balanced interfaces were used throughout an audio system, it would theoretically be noise-free. Until about 1970, equipment designs allowed real-world system to come very close to this ideal. But since then, balanced interfaces have fallen victim to two major design problems—and both can properly be blamed on equipment manufacturers. Even careful examination of manufacturers’ specifications and data sheets will not reveal either problem—the devil is in the details. These problems are effectively concealed because the marketing departments of most manufacturers have succeeded in dumbing down their so-called specifications over the same time period.
First is degraded noise rejection, which appeared when solid-state differential amplifiers started replacing input transformers. Second is the pin 1 problem that appeared in large numbers when PC boards and plastic connectors replaced their metal counterparts. Both problems can be avoided through proper design, of course, but in this author’s opinion, part of the problem is that the number of analog design engineers who truly understand the underlying issues is dwindling and engineering schools are steering most students into the digital future where analog issues are largely neglected. Other less serious problems with balanced interfaces are caused by balanced cable construction and choices of cable shield connections.

On the other hand, unbalanced interfaces have an intrinsic problem that effectively limits their use to only the most electrically benign environments. Of course, even this problem can be solved by adding external ground-isolation devices, but the best advice is to avoid them whenever possible in professional systems!

### 32.5.1 Degraded Common-Mode Rejection

Balanced interfaces have traditionally been the hallmark of professional sound equipment. In theory, systems comprised of such equipment are completely noise-free. However, an often overlooked fact is that the common-mode rejection of a complete signal interface does not depend solely on the receiver, but on how the receiver interacts with the driver and the line performing as a subsystem.

In the basic balanced interface of Fig. 32-26, the output impedances of the driver \( Z_o / 2 \) and the input impedances of the receiver \( Z_{cm} \) effectively form the Wheatstone bridge shown in Fig. 32-27. If the bridge is not balanced or nulled, a portion of the ground noise \( V_{cm} \) will be converted to a differential signal on the line. This nulling of the common-mode voltage is critically dependent on the ratio matching of the pairs of driver/receiver common-mode impedances \( R_{cm} \) in the – and + circuit branches. The balancing or nulling is unaffected by impedance across the two lines, such as the signal input impedance \( Z_i \) in Fig. 32-28 or the signal output impedance of the driver. It is the common-mode impedances that matter!

The bridge is most sensitive to small fractional impedance changes in one of its arms when all arms have the same impedance. It is least sensitive when the
upper and lower arms have widely differing impedances—e.g., when upper arms are very low and lower arms are very high, or vice versa. Therefore, we can minimize the sensitivity of a balanced system (bridge) to impedance imbalances by making common-mode impedances very low at one end of the line and very high at the other. This condition is consistent with the requirements for voltage matching discussed in Section 32.3.2.

Most active line receivers, including the basic differential amplifier of Fig. 32-28, have common-mode input impedances in the 5 kΩ to 50 kΩ range, which is inadequate to maintain high CMRR with real-world sources. With common-mode input impedances of 5 kΩ, a source imbalance of only 1 Ω, which could arise from normal contact and wire resistance variations, can degrade CMRR by 50 dB. Under the same conditions, the CMRR of a good input transformer would be unaffected because of its 50 MΩ common-mode input impedances. Fig. 32-29 shows computed CMRR versus source imbalance for different receiver common-mode input impedances. Thermal noise and other limitations place a practical limit of about 130 dB on most actual CMRR measurements.

common-mode input impedances are raised to about 50 MΩ, 94 dB of ground noise rejection is attained from a completely unbalanced 1 kΩ source, which is typical of consumer outputs. When common-mode input impedances are sufficiently high, an input can be considered truly universal, suitable for any source—balanced or unbalanced. A receiver using either a good input transformer or the InGenius® integrated circuit25 will routinely achieve 90–100 dB of CMRR and remain unaffected by typical real-world output imbalances.

The theory underlying balanced interfaces is widely misunderstood by audio equipment designers. Pervasive use of the simple differential amplifier as a balanced line receiver is evidence of this. And, as if this weren’t bad enough, some have attempted to improve it. Measuring input X and Y input impedances of the simple differential amplifier individually leads some designers to alter its equal resistor values. However, as shown in Fig. 32-30, if the impedances are properly measured simultaneously, it becomes clear that nothing is wrong. The fix grossly unbalances the common-mode impedances, which destroys the interface CMRR for any real-world source. This and other misguided improvements completely ignore the importance of common-mode input impedances.

The same misconceptions have also led to some CMRR tests whose results give little or no indication of how the tested device will actually behave in a real-world system. Apparently, large numbers of designers test the CMRR of receivers with the inputs either shorted to each other or driven by a laboratory precision signal source. The test result is both unrealistic and misleading. Inputs rated at 80 dB of CMRR could easily deliver as little as 20 dB or 30 dB when used in a real system. Regarding their previous test, the
IEC had recognized that test is not an adequate assurance of the performance of certain electronically balanced amplifier input circuits. The old method simply didn’t account for the fact that source impedances are rarely perfectly balanced. To correct this, this author was instrumental in revising IEC Standard: 60268-3 Sound System Equipment – Part 3: Amplifiers. The new method, as shown in Fig. 32-31, uses typical ±10 Ω source impedance imbalances and clearly reveals the superiority of input transformers and some new active input stages that imitate them. The new standard was published August 30, 2000. The Audio Precision APx520 and APx525, introduced in 2008, are the first audio instruments to offer the new CMRR test.

32.5.2 The Pin 1 Problem

In his now famous paper in the 1995 AES Journal, Neil Muney says:

*This paper specifically addresses the problem of noise coupling into balanced line-level signal interfaces used in many professional applications, due to the unappreciated consequences of a popular and widespread audio equipment design practice which is virtually without precedent in any other field of electronic systems.*

Common impedance coupling occurs whenever two currents flow in a shared or common impedance. A noise coupling problem is created when one of the currents is ground noise and the other is signal. The common impedance is usually a wire or circuit board trace having a very low impedance, usually well under an ohm. Unfortunately, common impedance coupling has been designed into audio equipment from many manufacturers. The noise current enters the equipment via a terminal, at a device input or output, to which the cable shield is connected via a mating connector. For XLR connectors, it’s pin 1 (hence the name); for ¼ inch connectors, it’s the sleeve; and for RCA/IHF connectors, it’s the shell.
To the user, symptoms are indistinguishable from many other noise coupling problems such as poor CMRR. To quote Neil again,

*Balancing is thus acquiring a tarnished reputation, which it does not deserve. This is indeed a curious situation. Balanced line-level interconnections are supposed to ensure noise-free system performance, but often they do not.*

In balanced interconnections, it occurs at line inputs and outputs where interconnecting cables routinely have their shields grounded at both ends. Of course, grounding at both ends is required for unbalanced interfaces.

Fig.32-32 illustrates several examples of common impedance coupling. When noise currents flow in signal reference wiring or circuit board traces, tiny voltage drops are created. These voltages can couple into the signal path, often into very high gain circuitry, producing hum or other noise at the output. In the first two devices, pin 1 current is allowed to flow in internal signal reference wiring. In the second and third devices, power line noise current (coupled through the parasitic capacitances in the power transformer) is also allowed to flow in signal reference wiring to reach the chassis/safety ground. This so-called *sensitive equipment* will produce additional noise independent of the pin 1 problem. For the second device, even disconnecting its safety ground (not recommended) won’t stop current flow through it between input and output pin 1 shield connections.

*Figure 32-31. Old and new IEC tests for CMRR compared.*

*Figure 32-32. How poor routing of shield currents produces the pin 1 problem.*
Fig. 32-33 shows three devices whose design does not allow shield current to flow in signal reference conductors. The first uses a star connection of input pin 1, output pin 1, power cord safety ground, and power supply common. This technique is the most effective prevention. Noise currents still flow, but not through internal signal reference conductors. Before there were printed circuit boards, a metal chassis served as a very low-impedance connection (effectively a ground plane) connecting all pins 1 to each other and to safety ground. Pin 1 problems were virtually unknown in those vintage designs. Modern printed circuit board-mounted connectors demand that proper attention be paid to the routes taken by ground noise currents. Of course, this same kind of problem can and does exist with RCA connectors in unbalanced consumer equipment, too.

Fortunately, tests to reveal such common impedance coupling problems are not complex. Comprehensive tests using lab equipment covering a wide frequency range have been described by Cal Perkins and simple tests using an inexpensively built tester called the hummer have been described by John Windt. Jensen Transformers, Inc. variant of the Hummer is shown in Fig. 32-34. It passes a rectified ac current of 60–80 mA through the potentially troublesome shield connections in the device under test to determine if they cause the coupling.

The glow of the automotive test lamp shows that a good connection has been made and that test current is indeed flowing. The procedure:

1. Disconnect all input and output cables, except the output to be monitored, as well as any chassis connections (due to rack mounting, for example) from the device under test.
2. Power up the device.
3. Meter and, if possible, listen to the device output. Hopefully, the output will simply be random noise. Try various settings of operator controls to familiarize yourself with the noise characteristics of the device under test without the hummer connected.
4. Connect the hummer clip lead to the device chassis and touch the probe tip to pin 1 of each input or output connector. If the device is properly designed, there will be no output hum or change in the noise floor.
5. Test other potentially troublesome paths, such as from an input pin 1 to an output pin 1 or from the safety ground pin of the power cord to the chassis (a three-to-two-prong ac adapter is handy to make this connection).

Note: Pin 1 might not be connected directly to ground in some equipment—hopefully, this will be at inputs only! In this case, the hummer’s lamp may not glow—this is OK.

### 32.5.3 Balanced Cable Issues

At audio frequencies, even up to about 1 MHz, cable shields should be grounded at one end only, where the signal is ground referenced. At higher frequencies, where typical system cables become a small fraction of a wavelength, it’s necessary to ground it at more than
one point to keep it at ground potential and guard against RF interference.26,27 Based on my own work, there are two additional reasons that there should always be a shield ground at the driver end of the cable, whether the receiver end is grounded or not, see Figs. 32-35 and 32-36. The first reason involves the cable capacitances between each signal conductor and shield, which are mismatched by 4% in typical cable. If the shield is grounded at the receiver end, these capacitances and driver common-mode output impedances, often mismatched by 5% or more, form a pair of low-pass filters for common-mode noise. The mismatch in the filters converts a portion of common-mode noise to differential signal. If the shield is connected only at the driver, this mechanism does not exist. The second reason involves the same capacitances working in concert with signal asymmetry. If signals were perfectly symmetrical and capacitances perfectly matched, the capacitively coupled signal current in the shield would be zero through cancellation. Imperfect symmetry and/or capacitances will cause signal current in the shield. This current should be returned directly to the driver from which it came. If the shield is grounded at the receiver, all or part of this current will return via an undefined path that can induce crosstalk, distortion, or oscillation.28

As discussed in Section 32.2.5, twisting essentially places each conductor at the same average distance from the source of a magnetic field and greatly reduces differential pickup. Star quad cable reduces pickup even further, typically by about 40 dB. But the downside is that its capacitance is approximately double that of standard shielded twisted pair.

SCIN, or shield-current induced noise, may be one consequence of connecting a shield at both ends. Think of a shielded twisted pair as a transformer with the shield acting as primary and each inner conductor acting as a secondary winding, as shown in the cable model of Fig. 32-37. Current flow in the shield produces a magnetic field which then induces a voltage in each of the inner conductors. If these voltages are identical, and the interface is properly impedance balanced, only a common-mode voltage is produced that can be rejected by the line receiver. However, subtle variations in physical construction of the cable can produce unequal coupling in the two signal conductors. The difference voltage, since it appears as signal to the receiver, results in noise coupling. Test results on six commercial cable types appear in reference.29 In general, braided shields perform better than foil shields and drain wires.

And, to make matters even worse, grounding the shield of balanced interconnect cables at both ends also excites the pin 1 problem if it exists. Although it might appear that there’s little to recommend grounding at both ends, it is a widely accepted practice. As you can see, noise rejection in a real-world balanced interface can be degraded by a number of subtle problems and
imperfections. But, as discussed in Section 32.6.4, it is virtually always superior to an unbalanced interface!

### 32.5.4 Coupling in Unbalanced Cables

The overwhelming majority of consumer as well as high-end audiophile equipment still uses an audio interface system introduced over 60 years ago and intended to carry signals from chassis to chassis inside the earliest RCA TV receivers! The ubiquitous RCA cable and connector form an unbalanced interface that is extremely susceptible to common impedance noise coupling.

As shown in Fig. 32-38, noise current flow between the two device grounds or chassis is through the shield conductor of the cable. This causes a small but significant noise voltage to appear across the length of the cable. Because the interface is unbalanced, this noise voltage will be directly added to the signal at the receiver.\(^{33}\) In this case, the impedance of the shield conductor is responsible for the common impedance coupling. This coupling causes hum, buzz, and other noises in audio systems. It’s also responsible for slow-moving hum bars in video interfaces and glitches, lock-ups, or crashes in unbalanced—e.g., RS-232—data interfaces.

Consider a 25 ft interconnect cable with foil shield and a #26 AWG drain wire. From standard wire tables or actual measurement, its shield resistance is found to be 1.0 Ω. If the 60 Hz leakage current is 300 μA, the hum voltage will be 300 μV. Since the consumer audio reference level is about –10 dBV or 300 mV, the 60 Hz hum will be only relative to the signal. For most systems, this is a very poor signal-to-noise ratio! For equipment with two-prong plugs, the 60 Hz harmonics and other high-frequency power-line noise (refer to Fig. 32-20) will be capacitively coupled and result in a harmonic-rich buzz.

Because the output impedance of device A and the input impedance of device B are in series with the inner conductor of the cable, its impedance has an insignificant effect on the coupling and is not represented here. Common-impedance coupling can become extremely severe between two grounded devices, since the voltage drop in the safety ground wiring between the two devices is effectively parallel connected across the length of the cable shield. This generally results in a fundamental-rich hum that may actually be larger than the reference signal!

Coaxial cables, which include the vast majority of unbalanced audio cables, have an interesting and under-appreciated quality regarding common-impedance coupling at high frequencies, Fig. 32-39. Any voltage appearing across the ends of the shield will divide itself between shield inductance \(L_s\) and resistance \(R_s\) according to frequency. At some frequency, the voltages across each will be equal (when reactance of \(L_s\) equals \(R_s\)). For typical cables, this frequency is in the 2 to 5 kHz range. At frequencies below this transition frequency, most of the ground noise will appear across \(R_s\) and be coupled into the audio signal as explained earlier. However, at frequencies above the transition frequency, most of the ground noise will appear across \(L_s\). Since \(L_s\) is magnetically coupled to the inner conductor, a replica of the ground noise is induced over its length. This induced voltage is then subtracted from the signal on the inner conductor, reducing noise coupling into the signal. At frequencies ten times the transition frequency, there is virtually no noise coupling at all—common-impedance coupling has disappeared. Therefore, common-impedance coupling in coaxial cables ceases to be a noise issue at frequencies over about 50 kHz. Remember this as we discuss claims made for power line filters that typically remove noise only above about 50 kHz.

Unbalanced interface cables, regardless of construction, are also susceptible to magnetically induced noise caused by nearby low-frequency ac magnetic fields.

---

**Figure 32-38.** Common impedance coupling in an unbalanced audio, video, or data interface.
Unlike balanced interconnections, such noise pickup is not nullified by the receiver.

32.5.5 Bandwidth and RF Interference

RF interference isn’t hard to find—it’s actually very difficult to avoid, especially in urban areas. It can be radiated through the air and/or be conducted through any cables connected to equipment. Common sources of radiated RF include AM, shortwave, FM, and TV broadcasts; ham, CB, remote control, wireless phone, cellular phone, and a myriad of commercial two-way radio and radar transmitters; and medical and industrial RF devices. Devices that create electrical sparks, including welders, brush-type motors, relays, and switches can be potent wideband radiators. Less obvious sources include arcing or corona discharge from power line insulators (common in seashore areas or under humid conditions) or malfunctioning fluorescent, HID, or neon lights. Of course, lightning, the ultimate spark, is a well-known radiator of momentary interference to virtually anything electronic.

Interference can also be conducted via any wire coming into the building. Because power and telephone lines also behave as huge outdoor antennas, they are often teeming with AM radio signals and other interference. But the most troublesome sources are often inside the building and the energy delivered through AC power wiring. The offending source may be in the same room as your system or, worse yet, it may actually be a part of your system! The most common offenders are inexpensive light dimmers, fluorescent lights, CRT displays, digital signal processors, or any device using a switching power supply.

Although cable shielding is a first line of defense against RF interference, its effectiveness depends critically on the shield connection at each piece of equipment. Because substantial inductance is added to this connection by traditional XLR connectors and grounding pigtails, the shield becomes useless at high radio frequencies. Common-mode RF interference simply appears on all the input leads. Because the wire limitations discussed in Section 32.2.4 apply to grounding systems, contrary to widespread belief, grounding is not an effective way to deal with RF interference. To quote Neil Muncy:

Costly technical grounding schemes involving various and often bizarre combinations of massive copper conductors, earth electrodes, and other arcane hardware are installed. When these schemes fail to provide expected results, their proponents are usually at a loss to explain why.35

The wider you open the window, the more dirt flies in. One simple, but often overlooked, method of minimizing noise in a system is to limit the system bandwidth to that required by the signal.36 In an ideal world, every signal-processing device in a system would contain a filter at each input and output connector to appropriately limit bandwidth and prevent out-of-band energy from ever reaching active circuitry. This RF energy becomes an audio noise problem because the RF is demodulated or detected by active circuitry in various ways, acting like a radio receiver that adds its output to the audio signal. Symptoms can range from actual reception of radio signals or a 59.94 Hz buzz from TV signals or various tones from cell phone signals to much subtler distortions, often described as a veiled or grainy audio quality.37 The filters necessary to prevent these problems vary widely in effectiveness and, in some equipment, may not be present at all. Sadly, the performance of most commercial equipment will degrade when such interference is coupled to its input.38

32.6 Solving Real-World System Problems

How much noise and interference are acceptable depends on what the system is and how it will be used. Obviously, sound systems in a recording studio need to be much more immune to noise and interference than paging systems for construction sites.

32.6.1 Noise Perspective

The decibel is widely used to express audio-related measurements. For power ratios,

$$dB = 10\log_{10}\frac{P_1}{P_2}$$

(32-9)

For voltage or current ratios, because power is proportional to the square of voltage or current:
Most listeners describe 10 dB level decreases or increases as halving or doubling loudness, respectively, and 2 dB or 3 dB changes as just noticeable. Under laboratory conditions, well-trained listeners can usually identify level changes of 1 dB or less. The dynamic range of an electronic system is the ratio of its maximum undistorted signal output to its residual noise output or noise floor. Up to 120 dB of dynamic range may be required in high-end audiophile sound systems installed in typical homes.39

32.6.2 Troubleshooting

Under certain conditions, many systems will be acceptably noise-free in spite of poor grounding and interfacing techniques. People often get away with doing the wrong things! But, notwithstanding anecdotal evidence to the contrary, logic and physics will ultimately rule.

Troubleshooting noise problems can be a frustrating, time-consuming experience but the method described in Section 32.6.2.2 can relieve the pain. It requires no electronic instruments and is very simple to perform. Even the underlying theory is not difficult. The tests will reveal not only what the coupling mechanism is but also where it is.

32.6.2.1 Observations, Clues, and Diagrams

A significant part of troubleshooting involves how you think about the problem. First, don’t assume anything! For example, don’t fall into the trap of thinking, just because you’ve done something a particular way many times before, it simply can’t be the problem. Remember, even things that can’t go wrong, do! Resist the temptation to engage in guesswork or use a shotgun approach. If you change more than one thing at a time, you may never know what actually fixed the problem.

Second, ask questions and gather clues! If you have enough clues, many problems will reveal themselves before you start testing. Be sure to write everything down—imperfect recall can waste a lot of time! Troubleshooting guru Bob Pease40 suggests these basic questions:

1. Did it ever work right?
2. What are the symptoms that tell you it’s not working right?
3. When did it start working badly or stop working?
4. What other symptoms showed up just before, just after, or at the same time as the failure?

Operation of the equipment controls, and some elementary logic, can provide very valuable clues. For example, if a noise is unaffected by the setting of a gain control or selector, logic dictates that it must be entering the signal path after that control. If the noise can be eliminated by turning the gain down or selecting another input, it must be entering the signal path before that control.

Third, sketch a block diagram of the system. Fig. 32-40 is an example diagram of a simple home theater system. Show all interconnecting cables and indicate approximate length. Mark any balanced inputs or outputs. Generally, stereo pairs can be indicated with a single line. Note any device that is grounded via a three-prong ac plug. Note any other ground connections such as equipment racks, cable TV connections, etc.

32.6.2.2 The Ground Dummy Procedure

An easily constructed adapter or ground dummy is the key element in this procedure. By temporarily placing the dummy at strategic locations in the interfaces, precise information about the nature and location of the problem is revealed. The tests can specifically identify:

2. Shield current-induced coupling in balanced cables.
3. Magnetic or electrostatic pickup of nearby magnetic or electrostatic fields.
4. Common-impedance coupling (the pin 1 problem) inside defective devices.
5. Inadequate CMRR of the balanced input.

The ground dummy can be made from standard connector wired as shown in Figs. 32-41 and 32-42. Since a dummy does not pass signal, mark it clearly to help prevent it, being accidentally left in a system.

Each signal interface is tested in four steps. As a general rule, always start at the inputs to the power amplifiers and work backward toward the signal sources. Be very careful when performing the tests not to damage loudspeakers or ears! The surest way to avoid possible damage is to turn off the power amplifier(s) before reconfiguring cables for each test step.
For Unbalanced Interfaces

STEP 1: Unplug the cable from the input of Box B and plug in only the dummy as shown below.  
♦ Output quiet?  
No—The problem is either in Box B or farther downstream.

STEP 2: Leaving the dummy in place at the input of Box B, plug the cable into the dummy as shown below.  
♦ Output quiet?  
No—Box B has a pin 1 problem (see Section 4.3 to confirm this).  
Yes—Go to next step.

STEP 3: Remove the dummy and plug the cable directly into the input of Box B. Unplug the other end of the cable from the output of Box A and plug it into the dummy as shown below. Do not plug the dummy into Box A or let it touch anything conductive.  
♦ Output quiet?  
No—Noise is being induced in the cable itself. Reroute the cable to avoid interfering fields (see Section 32.4.2 or 32.4.4).  
Yes—Go to next step.
STEP 4: Leaving the dummy in place on the cable, plug the dummy into the output of Box A as shown below.

- Output quiet?
  No—The problem is common-impedance coupling (see Section 32.4.4). Install a ground isolator at the input of Box B.
  Ye—The noise is coming from (or through) the output of Box A. Perform the same test sequence on the cable(s) connecting Box A to upstream devices.

32.6.2.2.2 For Balanced Interfaces

STEP 1: Unplug the cable from the input of Box B and plug in only the dummy (switch open or NORM) as shown below.

- Output quiet?
  No—The problem is either in Box B or farther downstream.
  Yes—Go to next step.

STEP 2: Leaving the dummy in place at the input of Box B, plug the cable into the dummy (switch open or NORM) as shown below.

- Output quiet?
  N—Box B has a Pin 1 problem (see hummer test, Section 32.4.2, to confirm this).
  Yes—Go to next step.

STEP 3: Remove the dummy and plug the cable directly into the input of Box B. Unplug the other end of the cable from the output of Box A and plug it into the dummy (switch open or NORM) as shown below. Do not plug the dummy into Box A or let it touch anything conductive.

- Output quiet?
  No—Noise is being induced in the cable itself by an electric or magnetic field. Check the cable for an open shield connection, reroute the cable to avoid the interfering field, or replace the cable with a starquad type (see Sections 32.2.5 and 32.4.3).
  Ye—Go to next step.

STEP 4: Leaving the dummy in place on the cable, plug the dummy (switch open or NORM) into the output of Box A as shown below.

- Output quiet?
  No—The problem is shield-current-induced noise (see Section 32.4.3). Replace the cable with a different type (without a drain wire) or take steps to reduce current in the shield.
  Ye—Go to next step.

STEP 5: Leave the dummy and cable as for step 4, but move the dummy switch to the CMRR (closed) position.

- Output quiet?
  No—The problem is likely inadequate common-mode rejection of the input stage of Box B. This test is based on the IEC common-mode rejection test but uses the actual common-mode voltage present in the system. The nominal 10 Ω imbalance may not simulate the actual imbalance at the output of Box A, but the test will reveal input stages whose CMRR is sensitive to source imbalances. Most often, adding a transformer-based ground isolator at the input of Box B will cure the problem.
  Ye—The noise must be coming from (or through) the output of Box A. Perform the same test sequence on the cable(s) connecting Box A to upstream devices.
32.6.3 Solving Interface Problems

32.6.3.1 Ground Isolators

A device called a ground isolator solves the inherent common-impedance coupling problem in unbalanced interfaces. Broadly defined, a ground isolator is a differential responding device with high common-mode rejection. It is not a filter that can selectively remove hum, buzz, or other noises when simply placed anywhere in the signal path. To do its job, it must be installed where the noise coupling would otherwise occur.

A transformer is a passive device that fits the definition of a ground isolator. Transformers transfer a voltage from one circuit to another without any electrical connections between the two circuits. It converts an ac signal voltage on its primary winding into a fluctuating magnetic field that is then converted back to an ac signal voltage on its secondary winding (discussed in detail in Chapter 11).

As shown in Fig. 32-43, when a transformer is inserted into an unbalanced signal path, the connection between device grounds via the cable shield is broken. This stops the noise current flow in the shield conductor that causes the noise coupling, as discussed in Section 32.5.4. As discussed in Chapter 11, the highest noise rejection is achieved with input-type transformers containing Faraday shields. A transformer-based isolator for consumer audio signals using such transformers, the ISO-MAX® model CI-2RR, is shown in Fig. 32-44. To avoid bandwidth loss, such isolators must be located at the receive end of interconnections, using minimum-length cables between isolator outputs and equipment inputs. Conversely, isolators using output-type transformers, such as the ISO-MAX® model CO-2RR and most other commercial isolators, may be freely located but will achieve significantly less noise rejection.

Ground isolators can also solve most of the problems associated with balanced interfaces. The ISO-MAX® Pro model PI-2XX shown in Fig. 32-45 often improves CMRR by 40 dB to 60 dB and provides excellent CMRR even if the signal source is unbalanced. Because it also features DIP switches to reconfigure cable shield ground connections, it can also solve pin 1 problems. Because it uses input-type transformers, it attenuates RF interference such as AM radio by over 20 dB. Again, to avoid bandwidth loss, it must be located at the receive end of long cable runs, using minimum-length cables between isolator outputs and equipment inputs. Other models are available for microphone signals and other applications. The vast majority of commercial hum eliminators and a few special-purpose ISO-MAX® models use output-type transformers, which may be freely located but offer significantly less CMRR improvement and have essentially no RF attenuation.

Several manufacturers make active (i.e., powered) ground isolators using some form of the simple differential amplifier shown in Fig. 32-31. Unfortunately, these circuits are exquisitely sensitive to the impedance of the driving source. Fig. 32-46 compares the measured 60 Hz (hum) rejection of a typical active isolator to a transformer-based isolator. Over the typical range of consumer output impedances, 100 Ω to 1 kΩ, the transformer has about 80 dB more rejection!

Passive isolators based on input-type transformers have other advantages, too. They require no power, they inherently suppress RF interference, and they’re immune to most overvoltages that can be sudden death to active circuitry.

32.6.3.2 Multiple Grounding

When a system contains two or more grounded devices, such as the TV receiver and the subwoofer power amplifier in our example home theater system, a wired ground loop is formed as shown in Fig. 32-47.

As discussed in Sections 32.5.3 and 32.5.4, noise current flowing in the shaded path can couple noise into the signal as it flows in unbalanced cables or through the equipment’s internal the ground path. This system would likely exhibit a loud hum regardless of the input selected or the setting of the volume control because of noise current flow in the 20 ft cable. You might be tempted to break this ground loop by lifting the safety ground at the subwoofer. Reread Section 32.4.2 and don’t do it!

One safe solution is to break the ground loop by installing a ground isolator in the audio path from preamp to subwoofer as shown in Fig. 32-48. This isolator could also be installed in the path from TV receiver to preamp, but it is generally best to isolate the longest lines since they are more prone to coupling than shorter ones.

Another safe solution is to break the ground loop by installing a ground isolator in the CATV signal path at the TV receiver as shown in Fig. 32-49. These RF isolators generally should be installed where the cable connects to the local system, usually at a VCR or TV input. If an RF isolator is used at the input to a splitter, ground loops may still exist between systems served by the splitter outputs since the splitter provides no ground isolation. Although it can be used with a conventional TV or FM antenna, never install an RF isolator between
the CATV drop or antenna and its lightning ground connection (see Section 32.4.1). Isolators will not pass dc operating power to the dish in DBS TV systems. Since most unbalanced interfaces are made to consumer devices that have two-prong ac plugs, isolating the signal interfaces may leave one or more pieces of equipment with no ground reference whatsoever. This could allow the voltage between an isolator’s input and output to reach 50 Vac or more. While this isn’t dangerous (leakage current is limited in UL-listed devices), it would require unrealistically high (CMRR over 140 dB) performance by the isolator to reject it! The problem is solved by grounding any floating gear as shown in Fig. 32-50. This is best done by replacing the two-prong ac plug with a three-prong type and adding a wire (green preferred) wire connected between the safety ground pin of the new ac plug and a chassis ground point. A screw may be convenient as the chassis ground point. Use an ohmmeter to check for continuity between the screw and the outer contact of an RCA connector, which itself can be used if no other point is available. Although, in the example above, an added ground at either the preamp or the power amp would suffice, grounding the device with the highest leakage current—usually those devices with the highest ac power consumption rating—will generally result in the lowest noise floor.

32.6.3.3 Unbalanced to Balanced and Vice Versa

The reader is referred to Chapter 11, Section 11.2.2, Audio Transformers, for a more detailed discussion of these applications. Beware of RCA to XLR adapters! Fig. 32-51 shows how using this adapter to connect an unbalanced output to a balanced input reduces the interface to an unbalanced one having absolutely no ground noise rejection! The potential noise reduction benefit of the balanced input is completely lost. Proper wiring for this interface, shown in Fig. 32-52, results in at least 20 dB of noise rejection even if the balanced input is one of typically mediocre performance. The key difference is that, by using shielded twisted pair cable, the ground noise current flows in a separate conductor that is not part of the signal path. Driving an unbalanced input from a balanced output is not quite as straightforward. Balanced equipment outputs use a wide variety of circuits. Some, such as the one in Fig. 32-53, might be damaged when one output is grounded. Others, including most popular servobalanced output stages, can become unstable unless the output is
Figure 32-46. Measured hum rejection versus source impedance, active differential amplifier versus input transformer isolator.

Figure 32-47. Using an audio ground isolator to break the loop.

Figure 32-48. Using a CATV ground isolator to break the loop.
directly grounded at the driver end, which reduces the interface to an unbalanced one with no noise rejection.\textsuperscript{41} Unless a balanced output already utilizes a built-in transformer, using an external ground isolator such as the one shown in Fig. 32-53 is the only method that will simultaneously avoid weird or damaging behavior and minimize ground noise when used with virtually any output stage. This approach is used in the ISO-MAX\textsuperscript{®} Pro model PC-2XR pro-to-consumer interface.

\subsection*{32.6.3.4 RF Interference}

As mentioned earlier, immunity to RF interference or RFI is part of good equipment design. Testing for RFI susceptibility is now mandated in Europe. Unfortunately, much of the equipment available today may still have very poor immunity. Under unfavorable conditions, external measures may be needed to achieve adequate immunity.\textsuperscript{42}

For RF interference over about 20 MHz, ferrite clamshell cores shown in Fig. 32-54, which are easily installed over the outside of a cable, can be very effective. Some typical products are Fair-Rite #0431164281 and Steward #28A0640-0A.\textsuperscript{43,44} In most cases, they work best when placed on the cable at or near the receive end. Often they are more effective if the cable is looped through the core several times.

If this is inadequate, or the frequency is lower (such as AM radio) you may have to add a low-pass—i.e., high-frequency reject—RFI filter on the signal line. Fig. 32-55 shows sample 50 kHz cutoff, 12 dB per octave low-pass RFI filters for unbalanced or balanced audio applications. For best performance and audio quality, use NP0 (also called C0G)-type ceramic capacitors keeping leads as short as possible, under $\frac{1}{4}$ inch preferred. For stubborn AM radio interference, it may help to increase the value of C up to about 1000 pF maximum. The 680 $\mu$H inductors are small ferrite core types such as J.W. Miller 78F681J or Mouser 434-22-681. If the only interference is above about 50 MHz, a ferrite bead may be used for L. For the balanced filter, inductors and capacitors should be $\pm 5\%$
tolerance parts or better to maintain impedance balance. The balanced filter can be used for low-level microphone lines, but miniature toroidal inductors are recommended to minimize potential hum pickup from stray magnetic fields. These filters, too, are generally most effective at the receive end of the cable.

When possible, the best way to deal with RF interference is to control it at its source. Fig. 32-56 is a schematic of a simple interference filter for solid-state 120 Vac light dimmers rated up to 600 W. It begins attenuating at about 50 kHz and is quite effective at suppressing AM radio interference. It must be installed within a few inches of the dimmer and, unfortunately, the components are large enough that it usually requires an extra-deep or a double knock-out box to accommodate both dimmer and filter. Parts cost is under $10.

A speaker cable can also become an antenna. In a strong RF field, enough voltage can be delivered to the semiconductors in the power amplifier that they become a detector and interference can be heard in the speaker even though the amplifier may be unpowered! More commonly, this problem occurs when the amplifier is powered and RF enters its feedback loop. In either case, the solution depends on the frequency of the interference. Ferrite cores on the cable near the amplifier may...
help. In stubborn cases, a 0.1 μF or a 0.22 μF capacitor directly across the output terminals of the amplifier may also be required.

32.6.3.5 Signal Quality

Audio transformer design involves a set of complex tradeoffs. The vast majority of available audio transformers, even when used as directed, fall short of professional performance levels. As Cal Perkins once wrote, “With transformers, you get what you pay for. Cheap transformers create a host of interface problems, most of which are clearly audible.”

The frequency response of a high-quality audio transformer is typically ruler flat, ±0.1 dB from 20 Hz to 20 kHz and –3 dB at 0.5 Hz and 100 kHz. The extended low-frequency response is necessary to achieve low phase distortion. The high-frequency response is tailored to fall gradually, following a Bessel function. This, by definition, eliminates overshoot on square waves and high-frequency response peaking. Dramatic improvements in sonic clarity due to the Bessel filter action are often reported by Jensen customers who add transformers at power amplifier inputs. On the other hand, cheap transformers often have huge ultrasonic peaks in their response that are known to excite particularly ugly intermodulation distortions in even the finest downstream power amplifiers.

Accurate time domain performance, sometimes called transient response, requires low phase distortion to preserve musical timbre and maintain accurate stereo imaging. Phase distortion not only alters sonic quality, it can also have serious system head room effects. Even though it may have a flat frequency response, a device having high phase distortion can increase peak signal amplitudes up to 15 dB. Phase distortion should never be confused with phase shift. Linear phase shift with frequency is simply a benign time delay: only deviations from linear phase or DLP create true phase distortion. This DLP in a high-quality audio transformer is typically under 2° across the entire audio spectrum.

Harmonic and intermodulation distortion in audio transformers is unusually benign in character and cannot fairly be compared to electronic distortion. By their nature, transformers produce the most distortion when driven at high levels at very low frequencies, where the major distortion product is third harmonic. Transformer distortion mechanisms are frequency selective in a way that amplifiers, for example, are not. Electronic nonlinearities tend to produce harmonic distortions that are constant with frequency while high-quality transformer harmonic distortions drop to well under 0.001% at frequencies over a few hundred Hz. Transformers also tend to have remarkably low intermodulation distortion or IMD, to which the ear is particularly sensitive. Compared to an amplifier of comparable low-frequency harmonic distortion, a transformer typically has only a tenth the IMD. While cheap audio transformers use steel cores producing 1% low-frequency harmonic distortion at any signal level, high-quality transformers use cores of special nickel-iron-molybdenum alloys for vanishingly low distortion.

Of course, noise rejection or CMRR is often the most important property of a ground isolator. As discussed in Section 32.6.3.1 and Chapter 11, a transformer requires an internal Faraday shield (not a magnetic or case shield) to maximize CMRR. Most commercial isolators or hum eliminators consist of tiny imported telephone-grade transformers that do not contain such a shield. Beware of products with vague or nonexistent specs! For example, distortion described as under 0.1% is meaningless because frequency, signal level, and source impedance are not specified. The most common problems with inexpensive isolators are marginal noise reduction, loss of deep bass, bass distortion, and poor transient response. Of course, ad copy and specifications of these transformers will put on their best face, withholding the ugly truth! However, isolators using well-designed and properly applied audio transformers qualify as true high-fidelity devices. They are passive, stable, reliable, and require neither trimming, tweaking, nor excuses.

32.6.3.6 Tips for Balanced Interfaces

Be sure all balanced line pairs are twisted. Twisting is what makes a balanced line immune to interference from magnetic fields. This is especially important in low-level microphone cabling. Wiring at terminal or punch-down blocks and XLR connectors is vulnerable because the twisting is opened up, effectively creating a magnetic pickup loop. In very hostile environments, consider starquad cable because it has less susceptibility.
to magnetic fields. Magnetic coupling is also reduced by separation distance, cables crossing at right angles rather than running parallel, and shielding with magnetic material such as steel EMT conduit.

Pay attention to cable shield grounding. As discussed in Section 32.5.3, the shield must be grounded at the driven end, it may be grounded at both ends, but never grounded only at the receive end. As a standard practice, grounding at both ends is recommended for two reasons:

1. If the device input has marginal RF suppression, grounding the shield at the input will usually reduce problems,
2. It doesn’t require the use of a specially wired cable that might find its way into another system and cause unexpected problems. If special cables are made—to deal with a pin 1 problem, for example—be sure they are clearly marked.

Don’t terminate to reduce noise. Nearly every practical audio system should use unterminated audio circuits. This is standard professional audio practice worldwide. While a 600 Ω termination resistor at an input may reduce noise by up to 6 dB or more, depending on the driver output impedance, it will also reduce the signal by the same amount, so nothing is gained. If noise is caused by RF interference, installation of a suitably small capacitor at the input may be much more appropriate.

Use ground isolators to improve noise rejection. As discussed in Section 32.4.1, common balanced input circuits have generally unpredictable noise rejection in real-world systems. Actual in-system CMRR can be as little as 30 dB when using balanced sources and as little as 10 dB when using unbalanced sources. A quality transformer-based ground isolator can increase the CMRR of even the most mediocre balanced input to over 100 dB.

Beware of the pin 1 problem. As much as 50% of commercial equipment, some from respected manufacturers, has this designed-in problem. If disconnecting the shield at an input or output reduces a hum problem, the device at one or the other end of that cable may be the culprit. See Section 32.5.3 for test methods. Loose connector-mounting hardware is a major cause of pin 1 problems. Never overlook the obvious!

32.6.3.7 Tips for Unbalanced Interfaces

Keep cables as short as possible. Longer cables increase the coupling impedance. Serious noise coupling is nearly certain with 50 ft or 100 ft cables. Even much shorter cables can produce severe problems if there are multiple grounds. And never coil excess cable length.

Use cables with heavy gauge shields. Cables with shields of foil and thin drain wires increase the common-impedance coupling. Use cables with heavy braided copper shields, especially for long cables. See Section 32.7.4 for a recommended high-performance cable. The only property of cable that has any significant effect on audio-frequency noise coupling is shield resistance, which can be measured with an ordinary ohmmeter.

Bundle signal cables. All signal cables between any two boxes should be bundled. For example, if the L and R cables of a stereo pair are separated, nearby ac magnetic fields will induce a current in the loop formed by the two shields, causing hum in both signals. Likewise, all ac power cords should be bundled. This will tend to average and cancel the magnetic and electrostatic fields they radiate. In general, keeping signal bundles and power bundles separated will reduce coupling.

Maintain good connections. Connectors left undisturbed for long periods can oxidize and develop high contact resistance. Hum or other interference that changes when the connector is wiggled indicates a poor contact. Use a good commercial contact fluid and/or gold-plated connectors to help prevent such problems.

Don’t add unnecessary grounds! Additional grounding almost always increases circulating noise currents rather than reducing them. As emphasized earlier, never disconnect or defeat the purpose of safety or lightning ground connections to solve a noise problem—the practice is both illegal and very dangerous!

Use ground isolators at problem interfaces. Transformer-based isolators magnetically couple the signal while completely breaking the noise current path through the cable and connectors. This eliminates common-impedance coupling and can improve immunity to RF interference as well.

Predict and solve problems before an installation. For systems that consist mostly of devices with two-prong power cords, some very simple multimeter measurements on each system device and cable makes it
possible to actually predict hum levels and identify the problem interfaces before a system is installed.49

32.7 Alternative Treatments and Pseudoscience

The audio industry, especially the high-end segment, abounds with misinformation and myth. Science, evidence, and common sense are often discarded in favor of mysticism, marketing hype, and huge profits. Just remember that the laws of physics have not changed! See Fig. 32-57.

![Figure 32-57. Officer Einstein of the Physics Police. Courtesy Coil-Craft.]

32.7.1 Grounding from Technical to Bizarre

In most commercial buildings, the ac outlets on any branch circuit are saddle grounded or SG-types mounted in metallic J-boxes. Since SG outlets connect their safety ground terminals to the J-box, the safety ground network may now be in electrical contact with plumbing, air ducts, or structural building steel. This allows coupling of noisy currents from other loads—which might include air conditioning, elevators, and other devices—into the ground used by the sound system. In a scheme called technical or isolated grounding, safety grounding is not provided by the J-box and conduit but by a separate insulated green wire that must be routed back to the electrical panel alongside the white and black circuit conductors to keep inductance low. The technique uses special insulated ground or IG outlet—marked with a green triangle and sometimes orange in color—which intentionally insulates the green safety ground terminal from the outlet mounting yoke or saddle. The intent of the scheme is to isolate safety ground from conduit. Noise reduction is sometimes further improved by wiring each outlet as a home run back to the electrical panel or subpanel, making each outlet essentially a separate branch circuit.50 This technique is covered by NEC Article 250-74 and its exceptions. In many cases, simply adding a new branch circuit can be just as effective yet far less expensive than implementing a technical ground system.

Many people, believing that the earth simply absorbs noise, have a strong urge to install multiple earth ground rods to fix noise. This is desperation-mode thinking. Code allows extra ground rods, but only if they are bonded to an existing properly implemented safety ground system. Code does not allow them to be used as a substitute soil resistance is simply too high and unstable to be relied on to divert fault currents.51

Equipment grounding via the standard power cord safety ground is logical, easy to implement, and safe. It’s highly recommended for all systems and is the only practical method for portable or often reconfigured systems.

32.7.2 Power-Line Isolation, Filtering, and Balancing

Most sound systems use utility ac power. If it is disconnected, of course, all hum and noise disappears. This often leads to the odd conclusion that the noise is brought in with the power and that the utility company or the building wiring is to blame.52 Devices claiming to cleanse and purify ac power have great intuitive appeal and are often applied without hesitation or much thought. A far more effective approach is to locate, and safely eliminate, ground loops that cause coupling of noise into the signal. This solves the real problem. In reality, when system designs are correct, special power treatment is rarely necessary. Treating the power line to rid it of noise is analogous to repaving all the highways to fix the rough ride of a car. It’s much more sensible to correct the cause of the coupling by replacing the shock absorbers!

First, when any cord-connected line filter, conditioner, or isolation transformer is used, Code requires that the device as well as its load still be connected to safety ground as shown in Fig. 32-58. Cord-connected isolation transformers cannot be treated as separately derived sources unless they are permanently wired into the power distribution system per Code requirements. Sometimes makers of isolation transformers have been known to recommend grounding the shield and output to a separate ground rod. Not only does this violate Code, but the long wire to the remote ground renders the shield ineffective at high frequencies. It is a sobering fact that, while a device may control interference with respect to its own ground reference, it may have little or no effect at the equipment ground.53,54 Because all these
cord-connected devices divert additional 60 Hz and high-frequency noise currents into the safety ground system, they often aggravate the very problem they claim to solve. External, cord-connected filters, or those built into outlet strips, can serve to band-aid badly designed equipment. As shown in Fig. 32-24 (Section 32.4.2), some equipment is sensitive because common-mode power line disturbances, especially at high frequencies, have essentially been invited in to invade the signal circuitry!

![Faraday shield](image)

**Figure 32-58.** Power isolation transformer.

Second, the advertised noise attenuation figures for virtually all these power line devices are obtained in a most unrealistic way. Measurements are made with all equipment (generator, detector, and device under test) mounted to a large metal *ground plane*. Although the resulting specs are impressive, they simply don’t apply to performance in real-world systems where ground connections are made with mere wires or conduit. However, these devices can be very effective when installed at the power service entrance or a subpanel, where all system safety grounds are bonded to a common reference point. For thorough, accurate information about separately derived power distribution and its application to equipment racks, the author highly recommends reference 60.

*Balanced power*, more properly *symmetrical power*, is another seductively appealing concept shown in Fig. 32-59. If we assumed that each system box had neatly matched parasitic capacitances from each leg of the power line to its chassis ground, the resulting noise current flow into the safety ground system would be zero, the interchassis voltage would be zero, and the resulting system noise due to these currents would simply disappear! For example, if $C_1$ and $C_2$ had equal capacitance and the ac voltages across them were equal magnitude but opposite polarity, the net leakage current would indeed be zero. However, for the overwhelming majority of equipment, these capacitances are not equal or even close. In many cases, one is several times as large as the other—it’s just a reality of power transformer construction. Even if the equipment involved has two-prong ac power connections, actual noise reduction will likely be less than 10 dB and rarely exceed 15 dB. And it’s unlikely that equipment manufacturers will ever pay the premium to match transformer parasitic capacitances or use precision capacitors in power line EMI filters. If the equipment involved has three-prong (grounding) ac power connections, the leakage current reduction, if any, provided by symmetrical power will pale by comparison to the magnetically induced voltage differences described in Section 32.3.4. In fact, many of the benefits attributed to symmetrical power may result from simply plugging all system equipment into the same outlet strip or dedicated branch circuit—which is always a good idea.

A GFCI (ground-fault circuit interrupter) works by sensing the difference in current between the hot and neutral connections at an outlet. This difference represents current from the hot conductor that is not returning via neutral. The worst-case scenario assumes that the missing current is flowing through a person. When the difference current reaches 4–7 mA—producing a very unpleasant but non-life-threatening shock—an internal circuit breaker removes power in a fraction of a second. Some power conditioners feature a ground lift switch, touted to eliminate ground loop problems, at their outputs. The National Electrical Code requires that all balanced power units have GFCI-protected outputs (among other restrictions on the use of balanced power). Although safe, ground lifting makes a GFCI-protected circuit prone to nuisance trips. For example, consider the system hook-up shown in Fig. 32-60.

![Balanced power](image)

**Figure 32-59.** Balanced power hopes to cancel ground currents.
For equipment having a grounding (three-conductor) power cord, UL listing requires that its leakage current be no more than 5 mA. Normally, this current would flow through the safety ground path back to neutral and would not trip a GFCI that has an intact safety ground connection. However, if the safety ground is lifted and the equipment is connected to other system equipment via signal cables, the leakage current will flow in these cables to reach ground, and ultimately neutral. Because the current is not returning via the equipment’s own power cord, the GFCI considers it hazardous and may trip, since 5 mA is within its trip range. If multiple pieces of equipment are plugged into a single GFCI-protected circuit, the cumulative leakage currents can easily become high enough to trip the GFCI. This problem severely limits the ability of the GFCI/ground-lift combo to solve ground loop problems—even when balanced power partially cancels leakage currents.

32.7.3 Surge Protection

Haphazard placement of common surge protectors can actually result in damage to interface hardware if the devices are powered from different branch circuits. As shown in Fig. 32-61, very high voltages can occur should there be an actual surge. The example shows a common protective device using three metal-oxide varistors, usually called MOVs, which limit voltage to about 600 V peak under very high-current surge conditions.

For protection against lightning-induced power line surges, this author strongly recommends that MOV protective devices, if used at all, be installed only at the main service entry. At subpanels or on branch circuits to protect individual groups of equipment, use series-mode suppressors, such as those by Surge-X, that do not dump surge energy into the safety ground system, creating noise and dangerous voltage differences.

32.7.4 Exotic Audio Cables

In the broadest general meaning of the word, every cable is a transmission line. However, the behavior of audio cables less than a few thousand feet long can be fully and rigorously described without transmission line theory. But this theory is often used as a starting point for pseudotechnical arguments that defy all known laws of physics and culminate in outrageous performance claims for audio cables. By some estimates, these specialty cables are now about a $200 million per year business.

Beware of cable mysticism! There is nothing unexplainable about audible differences among cables. For example, it is well known that the physical design of an unbalanced cable affects common-impedance coupling at ultrasonic and radio frequencies. Even very low levels of this interference can cause audible spectral contamination in downstream amplifiers. Of course, the real solution is to prevent common-impedance coupling in the first place with a ground isolator, instead of agonizing over which exotic cable makes the most pleasing subtle improvement. Expensive and exotic cables, even if double or triple shielded, made of 100% pure unobtainium, and hand braided by Peruvian virgins, will have NO significant effect on hum and buzz problems! As discussed in Section 32.5.4, shielding is usually a trivial issue compared to common-impedance coupling in unbalanced interfaces. It’s interesting to note that some designer cables selling for $500/meter pair have no overall shield at all—ground and signal wires are simply woven together.
Some exotic audio cables have very high capacitance and can seriously degrade high-frequency response, especially if cables are long and/or a consumer device drives it. For demanding high-performance applications, consider a low-capacitance, low-shield-resistance cable such as Belden #8241F. Its 17 pF/ft capacitance allows driving a 200 ft run from a typical 1 kΩ consumer output while maintaining a –3 dB bandwidth of 50 kHz. And its low 2.6 mΩ/ft shield resistance, equivalent to #14 gauge wire, minimizes common-impedance coupling. It’s also quite flexible and available in many colors.

33.1 Introduction

This chapter is devoted to the explanation and establishment of the proper gain structure of the sound reinforcement system. It has been the author's experience that sound systems are rarely producing the optimum performance that would be indicated by the specification sheets of the individual components. Tangible improvements in performance can often be achieved by some simple adjustments of level controls.

Most technical subjects can be best explained using ideal relationships, and this one is no exception. The real world always falls short of the ideal case, but the ideal can present a model and goal for our efforts. It is the responsibility of the sound practitioner to form an understanding of the trade-offs and apparent contradictions through experience and endless hours in the field. What follows is only an introduction that will benefit those who supplement it with lab and field work.

33.1.1 Interfaces

An interface exists when two components are to be interconnected for the purpose of transferring a signal. One component will be the source (sending) device and the other the load (receiving) device for the electrical signal. At least three major topologies exist for interconnecting devices, the major difference being which electrical parameter of the signal that the interface optimizes the passage of—i.e., voltage, current, or power. This is primarily a function of the ratio between the source impedance and load impedance. At this point we will make our first simplification by assuming that the impedance of these devices is purely resistive with no appreciable reactive component. This is actually a pretty accurate assumption for most electronic components in the signal processing chain.

33.1.1.1 The Matched Interface

A matched interface means that the source and load impedances are equal. This topology has some admirable attributes:

1. Power transfer is maximized.
2. Reflections from load-to-source are eliminated.

Impedance matching is required when the electrical wavelengths of the audio signal are shorter than the interconnecting cable. Examples include antenna circuits, digital interfaces, and long analog telephone lines. A drawback of this interface is that power transfer is optimized at the expense of voltage transfer, and therefore the source device might be called on to source appreciable current. It is also more difficult to split a signal from one output to multiple inputs, as this upsets the impedance match. A component that is operated into a matched impedance is said to be terminated. While the telephone company must use the matched interface due to their electrically long lines, the audio industry departed from the practice many years ago in favor of the voltage-optimized interface for analog interconnects.

Fig. 33-1 shows a matched interface. It is important to note that the selection of 600 Ω as the source and load impedance is arbitrary. It is the impedance ratio that is of importance, not the actual value used.

33.1.1.2 The Constant Voltage Interface

Most analog sound system components are designed to operate under constant voltage conditions. This means that the input impedance of the driven device is at least ten times higher than the output impedance of the source device. This mode of operation assures that output voltage of the driving device is relatively independent of the presence of the driven device—hence the term constant voltage, Fig. 33-2. Constant voltage interfaces can be used in analog audio systems since the typical cable length is far shorter than the electrical wavelength of the signal propagating down the cable.
This makes such lines immune to the detrimental effects of reflections and standing waves. Radio, digital, and telephone engineers are not so fortunate, and impedance matching is required at component interfaces. Constant voltage (sometimes called bridged) interfaces are inherently simpler than their impedance matched cousins. Advantages include the ability for a single output to drive multiple high-impedance inputs (in parallel) without loss of signal or degradation. Also, the constant voltage interface does not require that manufacturers standardize their input and output impedances. As long as the output impedance is low (typically less than 1000 \( \Omega \)) and the input impedance is high (typically greater than 10 k\( \Omega \)) then the two devices are compatible. In practice most output impedances are fairly low (<100 \( \Omega \)), allowing a single low-impedance output to drive several high-impedance inputs, Fig. 33-3.

If the source impedance is large when compared to the load, then a constant current interface is formed. In this topology, the current from the source is determined by the source impedance and is independent of the load impedance. Constant current interfaces are not often used to interface electronic components, and are usually reserved for specialized applications, such as the construction of impedance meters. We will not consider this interface further in this chapter.

### 33.2 Audio Waveform Fundamentals

In a sound reinforcement system, **program sources** provide information that is to be reinforced and presented to a listener. This information can originate in the form of an acoustical wave (acoustic musical instruments or human voices) or an electrical wave (electronic instruments or storage media such as compact disc). In either case, the waveform must be in the electromagnetic domain prior to being presented to the sound system. Acoustic signals must be converted into electromagnetic signals with an appropriate transducer such as a microphone or accelerometer. We will refer to electromagnetic waves within the bandwidth of the human auditory system as **audio waveforms**. Typical audio waveforms are quite complex and are continuously changing in value over time. This makes it difficult to describe them numerically. Several parameters can be used to describe the characteristics of an audio waveform. These include the following:

**Peak-to-Peak Voltage.** The number of volts between the largest positive and largest negative peak of the waveform.

**Peak Voltage.** The highest peak of the waveform, regardless of whether it is positive or negative. For a waveform with amplitude symmetry, it will be one-half the peak-to-peak voltage.

**Average Voltage.** The average of all ± amplitude values of the waveform.

**Root-Mean-Square (rms) Voltage.** Sometimes called the effective value of the waveform, rms describes the ac voltage in terms of the equivalent dc voltage that would produce the same amount of heat into a resistive load. Rms is useful because it indicates the heating value of the waveform. The rms level of a complex audio waveform is also related to its perceived loudness if it is used to drive a loudspeaker. For a sine wave, the rms voltage is 0.707 times the peak voltage. Complex waveforms also have an rms voltage, but finding it requires integration of the waveform over time. The peak-to-rms ratio of a waveform is called its crest factor. Crest factors must be described in terms of a finite span of time. A span of 50 ms correlates well with the integration time of the human hearing system, but other values can be used.

Fig. 33-4 shows a sine wave and speech waveform on a common plot of amplitude versus time. An oscilloscope provides this representation of the data, as does a wave editor application for a personal computer. A
simple analog voltmeter can measure the rms value of a sine wave. Complex waveforms require more sophisticated instruments to yield their effective value.

The peak voltage of the waveform must pass through the sound system component without being clipped. It is the parameter of interest when establishing the gain structure of the system. The crest factor of the signal determines the energy content and therefore the power produced by the amplifier and delivered to the loudspeaker. It is of interest when considering the heat that the loudspeaker must dissipate. Additionally, the rms voltage is the signal parameter that relates most closely to the loudness of the signal as perceived by a human listener.

Since the goal of an audio system is to reproduce appropriate waveforms for a given application, these waveform principles have universal application for all parts of the sound system.

33.3 Gain Structure

The following are general terms of gain structure beginning with how it applies to an individual piece of electronic equipment. It matters little whether the equipment is a mixer, equalizer, amplifier, or other active system component. By active we mean that the device has a power supply for its internal active circuitry. This can be as simple as an internal battery or two, or as complex as an internal or external ac line-powered supply. The power supply voltages establish the maximum amplitude that a waveform can take on as it passes through the component, Fig. 33-4. In audio equipment, most power supplies form a bipolar set of rails—a fixed positive and negative zero frequency (dc) voltage that the waveform is developed between. The value of the rail voltage determines the peak amplitude that the waveform can take on. Exceeding this peak value will cause deformation of the wave, commonly known as clipping. We will proceed under the assumption that the rails are fixed, and indeed they are for most signal processing devices. Some power amplifier topologies use multivalued or fluctuating rails. The principles are the same, but we will not consider such devices here.

Under a no input signal condition, all audio components will still emit a residual output signal. Thermal noise is generated at the molecular level and is present at the output of all system components whether active or passive. The level of the thermal noise determines the noise floor of the component. In practice, other factors can also make a contribution to the residual noise of an electronic device. An undersized power transformer or poor shielding can elevate some frequencies above the broadband thermal noise floor, Fig. 33-5. Equipment designers try to minimize thermal noise by component selection and careful design, but it can never be eliminated. We must accept the fact that it exists. Part of the reason for establishing the proper gain structure of a system is to render the effects of thermal noise insignificant. The thermal noise floor is affected by the settings of the component’s level controls. While a low noise floor can be achieved with all controls set at minimum, this is not realistic, as we cannot operate it that way. The controls should be set at a point appropriate for the operation of the device. A good starting point is a setting that produces the same voltage at the device output that is present at the device input, often called unity by audio practitioners. Level controls placed at their 0 dB setting generally produce this condition, and represent a good starting point for setting up a system.

Figure 33-5. Thermal and spectral noise.

Knowledge of the supply rails and noise floor establishes a dynamic range for the device—the difference in level between the highest possible undistorted peak and the lowest level that the signal can take on without being buried in the noise. The dynamic range is what can happen when a signal is passed through a device. It
is a range of possible values that the waveform can take on. The possibilities are infinite (within a device’s dynamic range) for an analog component and finite for digital components, since digital signals are made up of discrete samples that must be quantized to fixed steps. Fig. 33-6 shows a 1 kHz sine wave driving a component to just below clipping. The level difference between clipping and the noise floor describes the component’s dynamic range.

An example is in order. Let us consider a line level audio signal processor. We can pick any rail voltage that we like, since no universally recognized standard exists. A rail voltage of +17.5 Vdc (and –17.5 Vdc for the negative rail) will allow a peak voltage of 17.5 V to be realized at the device output. It is customary to express this voltage in terms of the rms value of the largest sine wave that the device (peak –3 dB) can produce with an acceptable amount of distortion. An oscilloscope allows observation of the wave and any deformation due to clipping. This rms voltage becomes the maximum output voltage, and when expressed in decibels becomes the component’s maximum output level. This level is expressed in dBm (dB ref. 0.001 W) for impedance matched interfaces (note that knowledge of the circuit impedance is required) or dBV (dB ref. 1 V) or dBu (dB ref. 0.775 V) for constant voltage interfaces (assuming the bridged impedance condition is maintained).

\[
L_{\text{out}} = 20 \log(17.5) - 3 \\
= 21.8 \text{ dBV} \\
= 20 \log \left( \frac{17.5}{0.775} \right) - 3 \\
= 24 \text{ dBu}
\]

Assume that the thermal noise measured at the device output is about 200 μV rms, as measured using an rms broadband voltmeter. Expressed as a level in dBV, the thermal noise floor becomes:

\[
L_{\text{noise}} = 20 \log(0.0002) \\
= -74 \text{ dBV} \\
= 20 \log \left( \frac{0.0002}{0.775} \right) \\
= -71.8 \text{ dBu}
\]

This audio component thus has a dynamic range on the order of 100 dB, a very good figure, and one that is typical for a well-designed piece of audio equipment, whether analog or digital.

With the dynamic range established, it is still necessary to use it effectively. If a weak signal is fed to the component, it may fall far short of the clipping point established by the power supply voltages, placing it unnecessarily close to the component’s noise floor. This will produce a poor signal-to-noise ratio, SNR, even in a component that has a wide dynamic range, Fig. 33-7.

If the input level control is increased beyond unity, the thermal noise will likely increase with the signal voltage, and no increase in SNR is realized. Increasing the drive (source) voltage will improve the SNR, assuming that the sending device has a noise floor lower than the driven device. In some cases, an additional gain stage may be required, as with microphones and phonograph cartridges.

If too strong a signal is fed to the component, the highest amplitude parts of the waveform may not fit within the constraints of the power supply voltages and may drive the component into a nonlinear mode of operation (clipping). This may yield an excellent signal-to-noise performance, but a distorted output
signal rich in harmonic distortion, Fig. 33-8. Gain structure, from a component perspective, is passing the signal through at optimum amplitude—not too strong and not too weak. As such, a system component can be overdriven, underdriven, or optimally driven by a signal source. It is important to note that the SNR of the program source is often the determining factor for the SNR of the entire system, since it can only be improved with very specialized signal processing that is not found in typical reinforcement systems. The old adage “garbage in, garbage out” certainly applies. The SNR will be degraded as it passes through other system components, which is why care must be taken to properly calibrate each stage of the system.

Before discussing the gain structure of a sound system, it is necessary to consider a method for determining the internal gain structure of a system component. This can be done by introducing a stimulus to the component and observing its output signal. It is common practice for technicians to use a stable and repeatable waveform for calibrating the signal-processing chain. A sinusoidal waveform, commonly called a sine wave, is such a waveform. The sine wave is a single frequency tone that is easily generated, fed to an input, and observed at the output of each component in the chain. The previous graphs have shown sine waves displayed on a magnitude versus frequency plot. They resemble a vertical spike due to the narrow frequency bandwidth. An alternate and equally valid display is amplitude versus time. The oscilloscope displays the amplitude of the waveform as a function of time. More advanced models will even provide some statistics, such as peak voltage, rms voltage, frequency, crest factor, level, etc. Let us proceed. A 1000 Hz sine wave is developed across the input terminals of one channel of the mixer. An amplitude is chosen that does not overdrive the input, and that is of sufficient level to drive the mixer to its full undistorted output voltage with all level controls in the signal path set at unity. For microphone inputs, about 0.1 Vrms (–20 dB ref. 1 V) is generally sufficient. As much as 1 Vrms might be required for a line level input. The level controls of the mixer are set as follows:

- Master at unity or 0 dB.
- Channel at unity or 0 dB.
- Trim at unity or 0 dB.

Under these conditions, the voltage amplitude of the output signal should be the same as the voltage amplitude of the input signal—an amplification factor of one or unity, and a gain of 0 dB.

The input voltage has been increased until the main meter of the mixer reads zero. We will speak in more detail about zero later, but for now we will assume that it indicates a voltage in the optimum operating range of the mixer’s overall dynamic range (typically –20 dB rel. clipping). Since program audio waveforms are constantly changing, this operating level allows some room for peaks in the audio waveform to pass undistorted. It is instructive at this point to measure the output voltage of the mixer at meter zero. Using the oscilloscope, either the peak or rms value of the waveform can be measured. It is traditional to measure the rms value, since it is readily measured with much less sophisticated voltmeters than the oscilloscope and correlates well with the loudness and heat production of the signal.

For historical reasons, a common voltage measured at a mixer output with the meter indicating zero is 1.23 Vrms, corresponding to an rms open circuit level of +4 dB ref. 0.775 V (+4 dBu). This level might be termed the operating level of the mixer. A volume indi-
cating meter describes the waveform in a way that correlates with its loudness as perceived by human listeners. The indication of such a meter is in VU, or volume units. When sound systems used the impedance matched interface, this voltage was developed across the input impedance (usually 600 Ω) of the next input stage. Since voltage and impedance were known, the power equation could be used to calculate the output power of the mixer, which became

\[ W = \frac{E^2}{R} \]

\[ L_{out} = 10 \log \frac{(1.23)^2}{600} \]

\[ = 4 \text{ dBm} \]

The power transfer was relevant since the matched interface was used, optimizing the circuit for power transfer. One milliwatt provided a useful reference, as it falls in the middle of the range of power levels found in the sound system. A voltmeter calibrated to read zero at 0.775 V could directly indicate the circuit power level in dBm (assuming a 600 Ω matched impedance interface). This calibration would make the voltmeter a dBm meter when placed across a 600 Ω circuit. When dBm meters are used at other impedances, a correction factor is required. As the sound reinforcement industry migrated to the constant voltage interface, the 0.775 V reference lived on due to the proliferation of voltmeters so calibrated, and signals were then described in dB ref. 0.775 V or dBu. In modern systems, the term level is used to describe the field quantity of interest at a component interface, which is the signal voltage for the constant-voltage interface. This a good place to note that many modern mixers do not use the +4 dBu reference level for meter zero, so the reader is advised to consult the literature or perform a measurement. A more common meter zero level today is 0 dBV, or 1 Vrms.

Let us now advance the trim control (or the drive voltage) until the waveform becomes distorted when viewed on the scope. Some mixers have a clipping indicator to warn of this condition. When the waveform flattens on top, reduce the trim control until the waveform appears undistorted. Since mixers are made up of several stages, it is usually informative to move each the main fader, channel fader, and trim control until clipping is observed to assure that each stage is clipping simultaneously. This produces the maximum output voltage of the mixer at the mixer’s output terminal. Using the scope or a voltmeter, measure the voltage of the waveform. Note that the clipping occurs on the peak of the waveform, yet it is standard practice to measure the rms value of the waveform and include it on the specification sheet. Ideally, this maximum output voltage is at least ten times the voltage measured at the meter zero indication, providing 20 dB of peak room above meter zero. The drive level (or trim control setting) should now be reduced to produce the meter zero operating level of the mixer.

We now have knowledge of the operating and clipping level of the mixer (e.g., +4 dBu and +24 dBu respectively). These values should be recorded in the system documentation. The noise floor of the mixer can be measured by muting the input signal and measuring the mixer’s no signal output voltage, but this is of little interest in practice.

### 33.5 The Unity Method

Our mixer is now at an optimum operating level with good SNR and 20 dB of peak room. The signal from the mixer is fed to the next component in the chain. If the component has input and/or output level controls, they are adjusted to produce the same level of the mixer at that component’s output terminal. In like manner the signal is fed through subsequent signal processors, and the mixer’s level eventually ends up at the input of the power amplifier, whose input sensitivity control is set for the desired output voltage (i.e., the target playback level of the system). As the amplifier’s voltage is impressed across the loudspeaker load, the amplifier supplies current flow as determined by the impedance of the loudspeaker. Power will flow, but the signal level is a linear function of the applied voltage over the useful operating range of the amplifier. So, the output voltage is the parameter of interest in a properly configured amplifier-to-loudspeaker interface under normal operating conditions. Fig. 33-9 shows such a processing chain for a mixer with a 0 dBV meter zero. The unity amplification method has a number of advantages, which include:

1. Ease of calibration.
2. Fast implementation.
3. Easy substitution of components.

Unfortunately, there are some drawbacks to this approach, mostly due to the nonstandardization of clipping levels between product lines and manufacturers. A mixer operating at 0 dBV that clips at +20 dBV will have 20 dB of operating peak room for transient peaks. If the component after the mixer clips at +18 dBV, that component will only have 18 dB of operating peak room. In this case an undistorted full-scale waveform from the mixer would cause clipping in the next component. The
mixer could be turned down a bit if the overload is not severe. If the level mismatch is more than a few dB then a different solution may be required. It should be pointed out that this condition is not as prevalent as it once was, as many postmixin product manufacturers have modified their products to handle the higher output voltages produced by modern mixing consoles.

33.6 An Optimized Method

The drawbacks of the unity amplification method can be overcome with an optimized method of establishing the gain structure of the system. While the unity method establishes a consistent operating voltage from component to component, the optimized method sets each device to clip simultaneously, regardless of the actual signal level. A mixer outputting +24 dBV and an equalizer outputting +20 dBV are both set to reach their clipping point simultaneously. This method often requires the insertion of a resistive attenuator between the mixer and equalizer, allowing the mixer to output its maximum voltage and still not over-drive the equalizer.

To optimize the system gain structure, feed a sine wave to the mixer in the same manner previously described, but this time advance the trim control until clipping occurs at the mixer output. All power amplifiers should be off or fully attenuated. The clipping can be determined with the aid of an oscilloscope or a spectrum analyzer capable of handling at least +30 dB ref. 1 V (+30 dBV). With the mixer set just short of clipping, connect the output of the mixer to the input of the next component (i.e., an equalizer). Set all controls on the equalizer at their unity setting. Move the clipping indicator (scope) to the output of the equalizer and note whether the waveform is clipped. If it is not, the equalizer is capable of passing the full output voltage of the mixer. If the equalizer is clipping, first try reducing the setting of its input level control. This often doesn’t work since the stage being overdriven likely precedes the level control stage. Some manufacturers design their equipment to handle higher input levels than they can output, and the input level control may indeed eliminate the overdrive condition. If not, an attenuator is placed between the mixer and equalizer and adjusted to produce an undistorted waveform from the equalizer. The same procedure is repeated for each subsequent piece of equipment in the processing chain. Compressor/limiters should be set at their highest threshold setting and lowest compression ratio. Crossover networks require either:

1. Selection of a sine wave within the pass band of the output being tested, or
2. Readjust the crossover frequency control to allow the output being tested to pass the test signal. Remember to restore the setting before turning on the amplifier!

Resistive pads for the “too hot” source are available commercially. If a component is being underdriven by the previous one (i.e., the full output voltage of the mixer is insufficient to clip the equalizer), it may be advantageous to increase the underdriven component’s input level until just short of clipping. This will provide a stronger drive voltage to the next component (and possibly an improved signal to noise).

The advantages of the optimized method include:
1. The ability to mix at meter zero without the potential to clip a component farther down the processing chain.
2. Optimized SNR in all components in the chain.
3. The meter mixer can now serve as an accurate indicator for all subsequent components, since all clip simultaneously.

As with all things audio, the optimized method is not without drawbacks. These include:

1. It requires more time and expertise to set up.
2. It requires a method to determine device clipping (scope or spectrum analyzer).
3. It requires the purchase of or construction of pads.
4. It makes component substitution more difficult, since the replacement component may have a different clipping level than the defective one.

A pad of 5–15 dB may be necessary for a professional mixer driving a consumer recorder.

Fig. 33-10 shows a system whose gain structure has been optimized in this manner. The benefit of either method is that a healthy drive voltage with a good SNR is delivered to the power amplifier input. Both methods assure that any digital components in the processing chain are being driven with a voltage high enough to produce optimized A/D conversion.

### 33.7 Setting the Amplifier Sensitivity

Ideally the amplifier’s input stage should handle the full output level of the preceding device without clipping. It is possible for the amplifier input circuit to clip prior to its output stage. This can be tested by setting the amplifier attenuator at a very low level and observing the output waveform of the amplifier when driven with the full undistorted signal level of the preceding device. If clipping is apparent at the amplifier output at a low attenuator setting, the input stage is being overdriven. Insertion of a pad or a reduction in drive voltage will be required.

If an active crossover is in the signal chain, its proper settings should be established prior to switching on and setting the amplifier input sensitivity. These settings are best obtained from the loudspeaker manufacturer.

The amplifier could be calibrated in the same manner as the other components—simply adjust its input sensitivity (volume) control to produce an output signal just short of clipping. Since this may be too loud, it is better to use a broadband program source (pink noise or music) and adjust the amplifier for the desired $L_p$ at the listener position. The procedure is as follows.

With the program material being input to the mixer, the mixer is set to produce a zero meter indication as previously described. Note that this assumes a VI meter and not a peak program meter. The input attenuator of the power amplifier is then advanced until:

1. The desired acoustic level is reached in the audience, or
2. The amplifier begins to indicate clipping.

In either case, don’t turn it up any higher. The gain structure is complete and the system is producing its maximum undistorted $L_p$. The technician can now proceed to fine tuning of the crossover network and equalizer to finish the system calibration.

![Figure 33-10. Optimized system gain structure.](image-url)
33.8 Power Ratings

It is important to note that the amplifier’s wattage rating must be *appropriate* for the loudspeaker. The loudspeaker must not be driven beyond its ability to dissipate heat buildup or beyond its limits of mechanical excursion. In most systems, heat will be a bigger problem than excursion, so the rms value of the amplifier’s output voltage waveform must be managed. Since the continuous power (based on the rms voltage) delivered to the loudspeaker is largely a function of the type (crest factor) of the program material, selection can be complicated.

### 33.8.1 Amplifier Power Ratings

The power ratings of power amplifiers and loudspeakers have little in common. The amplifier is usually rated in accordance with the maximum continuous power that it can deliver reliably with sinusoidal input for a specified span of time into a specified load impedance. This yields a large number for the amplifier power rating (due to the high rms voltage of the sine wave), and most likely a wattage that the amplifier will never be called on to deliver, since the signals that we present to audiences usually bear little resemblance to sine waves. Even so, this rating can be useful for amplifier comparisons and selection. Just remember, you won’t get that much rms voltage across the loudspeaker with real-world program material.

### 33.8.2 Loudspeaker Power Ratings

The loudspeaker’s continuous power rating describes the loudspeaker’s ability to dissipate heat on a continuous basis. A meaningful rating must state at a minimum:

1. The type and crest factor of the signal used.
2. The bandwidth of the signal.
3. The time duration of the test.
4. The rms voltage of the signal.
5. The impedance of the loudspeaker under test.

If the signal used has a crest factor of 6 dB, and the loudspeaker is rated at 50 W continuous, the amplifier size required to run the test would be

\[
17\text{dBW} + 6 \text{ dB} = 23 \text{ dBW} \\
23 \text{ dBW} = 200 \text{ watts continuous}
\]

Figure 33-11. Output voltage of a complex waveform with large peaks.

Power specifications are of little use to system technicians. They must be converted to an equivalent rms voltage so that the system tech can measure the signal with a voltmeter. A simple conversion is to multiply the power rating by eight and take the square root to get the voltage. Bear in mind that if the power rating has been exaggerated, the voltage resulting from this conversion will be too.

Due to the high crest factors of audio program material, power amplifiers normally deliver far below their theoretical maximum sine wave power. This makes it possible (and necessary) to use an amplifier whose continuous power rating exceeds the continuous power rating of the loudspeaker if the intent is to produce the maximum \( L_P \) possible. Care is required on the part of the user to insure that the crest factor of the program material is not reduced excessively by dynamic range control devices (compressors and limiters) and then used to drive the amplifier to the point of clipping. Figs. 33-11 and 33-12 show the same waveform. The peak output voltage of each waveform is the same. A peak limiter was used to reduce the dynamic range of the second waveform, resulting in a 6 dB increase in applied rms voltage (and continuous power) to the loudspeaker (four times). This example shows how that amplifier power (and loudspeaker power dissipation) are highly dependent on the nature of the waveform, not just the amplifier rating. The amplifier selection and setting should ideally depend on the target sound level in the audience. There are no ramifications to operating a loudspeaker below its power rating, and in fact it is good design practice.

One is reluctant to formalize a formula for determining the required amplifier size for several reasons, including:

1. The continuous output power of an amplifier is a function of the crest factor of the program material and can vary by 20 dB or more (a 100:1 ratio!).
2. Amplifier power ratings are based on signals that can bear little resemblance to audio program material.

3. Monitoring actual power delivered to the loudspeaker requires sophisticated equipment and a knowledgeable operator.

4. Standard loudspeaker power handling tests require that the loudspeaker be driven to the point where no permanent damage occurs. This is a bit ambiguous. The author utilizes a power handling test that drives the loudspeaker with increasing rms voltage until its response changes by 3 dB from the small signal (typically 3 Vrms) response. This rms voltage is used to determine the continuous rating of the loudspeaker, either in volts rms or power into a rated impedance.

Even so, a conservative approach is as follows:

1. Determine the loudspeaker’s continuous power rating in watts (from the specification sheet). Determine the maximum rms voltage by taking the square root of eight times the power rating. Note that the voltage is necessary for level setting and verification.

2. Quadruple this rating for the required amplifier size. This will allow program peaks to exceed the continuous rating by 6 dB.

3. Be careful to not clip the amplifier, Fig. 33-13.

If the crest factor of the program material exceeds 6 dB, and the amplifier is operated without clipping, the loudspeaker will simply be operating further below its continuous rating, increasing its reliability and longevity. A careful operator could use a significantly larger amplifier, provided that a high crest factor is maintained and clipping is avoided, Fig. 33-14.

In essence, buy a big amplifier but use it carefully. Don’t overdrive the loudspeaker or the audience! A sound level meter should always be used to check the $L_p$ produced by the system, and this value should be within OSHA exposure guidelines.

33.9 Conclusion

A properly calibrated sound system allows the operator to mix at or near meter zero on the mixer without danger of clipping any system component. Meter zero should also correlate with the maximum desired $L_p$ in the audience. In effect, all components in the system are now functioning as one component, the only difference being that they are housed in separate chassis and interconnected with cables.

34.1 Introduction

There are a multitude of different types of sound systems with purposes as diverse as artificial ambience and voice paging, yet most share common design criteria. This chapter covers many of these design criteria using sound reinforcement systems as examples. Included are discussions of other types of systems such as foldback (stage) monitor systems and some types of playback only systems as well as some of the practical aspects of sound system design such as equipment choice and installation techniques.

Since the third edition of the Handbook for Sound Engineers, digital audio products, driven by DSP chips, have become mainstream choices for signal processing. Packaged loudspeaker systems and line arrays have replaced individual components for most loudspeaker cluster designs. And, most system designers use EASE or Bose Modeler or some other system design software in place of the traditional sound system analysis equations and graphical cluster design methods.

Yet, the original system analysis equations and graphical cluster design methods are the foundation for software programs like EASE and Modeler. An understanding of the original tools offers a modern designer a better understanding of the value, and the limitations, of these software tools.

For these reasons, and for historic completeness, this chapter retains its focus on the original sound system analysis equations, with revisions where appropriate. In addition, while the cluster design discussions use packaged loudspeaker systems or line arrays for most examples, component cluster designs are mentioned where they offer advantages. Finally, this chapter discusses how digital audio is changing system design as it replaces analog technology.

Most of the equations presented in this chapter can be used with either U.S. or metric distances. Just be consistent throughout. In a few cases, one or more constants change depending on the choice of units. The needed changes are noted near the equation. All of the examples use U.S. units.

34.2 Sound Reinforcement System Models

34.2.1 The Four Questions (and a Fifth)

The system design concepts presented in this chapter help to answer four simple questions:

- Question 1: Is it loud enough?
- Question 2: Can everybody hear?
- Question 3: Can everybody understand?
- Question 4: Will it feed back?

The sound reinforcement system models and equations in this chapter provide precise answers to these four questions and, in so doing, help the designer predict the success of the sound system in meeting its goals.

It is important to answer a fifth question, “Does it sound good?” The answer to this question may seem very subjective. However, good sound quality depends very much on favorable answers to the first four questions and these questions have objective answers. Also, good sound quality depends on other objective factors such as low distortion and smooth frequency response. Thus, while there are no equations to answer Question 5, it is possible to answer this question using objective criteria.

34.2.2 The Simplified (Outdoor) Sound Reinforcement System Model

Fig. 34-1 shows a simplified sound reinforcement system with a talker or sound source, a listener, a microphone, and a loudspeaker. (The somewhat awkward term, talker, replaces the term speaker to avoid confusion between the person talking and the loudspeaker system.) The talker could be replaced by a musician playing an instrument with no changes in the following discussions (although a very loud, amplified instrument or direct box connection would change things somewhat).

![Figure 34-1](https://via.placeholder.com/150)

Figure 34-1. A simplified sound reinforcement system. Courtesy Bosch/Electro-Voice.

The primary simplification for this model is to ignore echoes and reverberation. This is a reasonable assumption for an outdoor system, away from any large buildings or other sources of echoes. As discussed later, this simplified description can be readily modified to include the effects of indoor reverberation.
34.2.2.1 Definitions

It is conventional to use the terms $D_s$, $D_1$, $D_2$, and $D_0$ when referring to the distances between the elements of this simple system.

- $D_s$ is the distance between the talker and the microphone.
- $D_0$ is the distance between the talker and the listener (again, the farthest listener when there are many listeners).
- $D_1$ is the distance between the loudspeaker and the microphone.
- $D_2$ is the distance between the loudspeaker and the listener (if there are many listeners, $D_2$ is usually considered to be the distance between the loudspeaker and the farthest listener).
- $L_p$—level of pressure—more commonly known as SPL (sound pressure level)

The terms $D_s$ and $D_0$ start at the talker. The terms $D_1$ and $D_2$ are referenced to the loudspeaker. The first member of each pair measures to the microphone, $D_s$ and $D_1$. The second member of each pair measures to the listener, $D_0$ and $D_2$. It’s easy to remember them this way.

34.2.2.2 Attenuation with Increasing Distance

As the listener moves farther away from the loudspeaker, the sound pressure level $L_p$ (or SPL) at the listener’s ears will decrease. Neglecting the effect of echoes (outdoors, away from buildings this is a good approximation), the $L_p$ will decrease exactly 6.02 dB every time the listener doubles the distance from the loudspeaker, Fig. 34-2). This effect is known as the “inverse-square law” and can be stated mathematically as

$$L_p' = L_p - 20\log\frac{D'}{D} \quad (34-1)$$

Example:

Let,

$L_p = 110$ dB,

$D = 4$ ft,

$D' = 200$ ft.

$$L_p' = 110 - 20\log\frac{200}{4}$$

$$L_p' = 110 - 20\log 50$$

$$L_p' = 110 - 20 \times 1.7$ dB

$$L_p' = 76.0$ dB

34.2.2.3 Acoustic Gain

Of all the reasons for a sound reinforcement system, the most important is implied by its name, sound reinforcement. That is, a sound reinforcement system reinforces a talker’s voice so that the listener hears a louder sound with the system on than with the system off. The term acoustic gain describes the difference, in dB, between the sound pressure level, $L_p$, at the listener’s ears with the system on and with the system off. In most cases, the listener means the farthest listener although the acoustic gain may be specified for any number of different listeners in a complex system. Acoustic gain may be described mathematically by a simple equation

$$\text{Acoustic gain} = L_{p_{on}} - L_{p_{off}} \quad (34-2)$$

Adequate acoustic gain is a primary design goal for a sound reinforcement system. Techniques for reaching this goal are described later. A simple technique for measuring the acoustic gain of a system is to place a sound level meter (SLM) at the position of the farthest listener and measure the $L_p$ from the talker with the system off. Then turn the system on and measure the $L_p$
again. The difference between the two readings is the acoustic gain of the system. (Replace the talker with a pink-noise source, through a small loudspeaker, for a more consistent and accurate reading.)

**34.2.2.4 Feedback and Potential Acoustic Gain (PAG)**

The acoustic gain of this simple sound reinforcement system can be increased by turning up the volume control, but, at some point, this process will be interrupted by feedback (howling). Feedback is an undesirable oscillation of the entire sound reinforcement system that occurs when the sound from the loudspeaker feeds back to the microphone at a level high enough that the system begins to reinforce itself as well as it reinforces the talker.

*Potential Acoustic Gain* or *PAG* is the maximum acoustic gain that can be obtained from the system before feedback occurs. For this simplified system (neglecting reverberation and echoes), PAG can be stated mathematically as

\[
PAG = 20\log\frac{D_0 D_1}{D_2 D_S} \quad (34-3)
\]

where,

- \(D_s\) is the distance between the talker and the microphone,
- \(D_1\) is the distance between the loudspeaker and the microphone,
- \(D_2\) is the distance between the loudspeaker and the farthest listener,
- \(D_0\) is the distance between the talker and the farthest listener.

**34.2.2.5 Number of Open Microphones (NOM)**

This example system has only one microphone. Adding additional open (in-use) microphones increases the possibility of feedback and reduces the potential acoustic gain. The basic PAG equation Eq. 34-3 can be modified to include a number of open microphones (NOM) term as follows

\[
PAG = 20\log\frac{D_0 D_1}{D_2 D_S} - 10\log\text{NOM} \quad (34-4)
\]

**34.2.2.6 Feedback Stability Margin (FSM)**

Eq. 34-4 is theoretically correct but experience shows that a system operated at or very near its PAG will exhibit ringing and probably have an undesirable peaked frequency response. In addition, a sound system operated near its PAG will increase the effective room reverberation time in an indoor system. Thus, a 6 dB feedback stability margin (FSM) is normally subtracted from the calculated PAG. Systems operated 6 dB or more below their PAG are usually free of the problems of feedback or ringing. The final PAG equation for the simplified system, then, should include a FSM modifier as follows

\[
PAG = 20\log\frac{D_0 D_1}{D_2 D_S} - 10\log\text{NOM} - 6 \text{ dB} \quad (34-5)
\]

Example:
Let,

- \(D_s = 2\) ft,
- \(D_0 = 128\) ft,
- \(D_1 = 45\) ft,
- \(D_2 = 90\) ft,
- \(\text{NOM} = 3\).

\[
PAG = 20\log\frac{128(45)}{2(90)} - 10\log 3 - 6 \text{ dB}
\]

\[
= 19.3 \text{ dB}
\]

**34.2.2.7 Noise**

Unwanted noise (traffic, wind, audience noises, etc.) can interfere with the listener’s ability to hear the talker. Ideally, the sound from the loudspeaker should be at least 25 dB above the noise level; that is, there should be a 25 dB SNR.

In some high-noise situations, a 25 dB SNR may not be achievable. Nevertheless, 25 dB is a common rule of thumb that will almost always insure that a listener can hear and understand the talker in an outdoor system.

**34.2.2.8 Head Room and Electrical Power Required (EPR)**

If ambient noise is 45 dB \(L_p\) (usually measured on the A scale of a sound level meter), and a 25 dB SNR is desired, then the desired \(L_p\) at the listener’s ears is 70 dB. That 70 dB, however, is the average level at the listener’s ears, and the peak \(L_p\) must be considered as well. The difference between peak and average level is referred to as the system *headroom*, Fig. 34-3. For a speech-only sound reinforcement system about 10 dB of head room is considered appropriate. Thus, the peak level in this example system would be 80 dB \(L_p\) for an average level of 70 dB \(L_p\).
In a high-noise system, a 10 dB head room factor may not be achievable. By using a limiter, the head room factor can be reduced to as low as 6 dB while maintaining reasonable voice intelligibility. For music-reinforcement systems, on the other hand, as much as 20 dB head room may be desirable to avoid clipping important musical peaks. For the simplified (outdoor) system, however, a 10 dB head room factor will be assumed.

How large an amplifier is needed to achieve the desired $L_p$? And, what information is needed about the loudspeaker? The answers are contained in the electrical power required ($EPR$) equation

$$EPR = 10^{\frac{L_p + H - L_s + 20 \log \frac{D_2}{3.28}}{10}}$$

(34-6)

For metric distances, replace the constant 3.28 with the constant 1.00 where:

- $L_p$ is the average $L_p$ required at distance $D_2$.
- $H$ is the head room in dB.
- $L_s$ is the sensitivity of the loudspeaker (1 W/1 m).
- $D_2$ is the distance to the farthest listener.

Example:

Let

- $L_p = 90$ dB,
- $H = 10$ dB,
- $L_s = 113$ dB (1 W/1 m),
- $D_2 = 128$ ft.

$$EPR = 10^{\frac{90 + 10 - 113 + 20 \log \frac{128}{3.28}}{10}}$$

$$EPR = 76.3 \text{ W}$$

The term $L_s$ is the rated sensitivity of the loudspeaker. This important specification represents the $L_p$ that the loudspeaker will produce at one meter from its mouth with a one watt input power level and must be obtained from the manufacturer’s specifications or from measurements performed in the field. Thus, this sensitivity is usually referred to as the “one-watt/one-meter” (1 W/1 m) sensitivity. In the past, some manufacturers used a one-watt/four-feet (1 W/4 ft) sensitivity rating.

The value of $H$ (head room), of course, may be changed for a particular system, and a different $D_2$ could be used to find the EPR at some other distance.

### 34.2.2.9 Equivalent Acoustic Distance (EAD)

In the simplified system, if the talker were to stand relatively close to the listener, the talker could be heard and understood easily without the need for a sound system. One way of stating the goal of the sound system, then, is to say that it should create the illusion that the talker is close to the listener.

A simple experiment can determine just how close a talker needs to be to a listener for comfortable communication. Simply talk in a normal voice and walk backwards (away from the listener) until communication becomes difficult. Then walk toward the listener again until communication is comfortable. At this point, the equivalent acoustic distance (EAD) has been established. The idea is to use the sound system to create the illusion that the talker is this EAD away from the listener, Fig. 34-4).

In the simplified system, a 25 dB SNR is the goal. That means the $L_p$ at the farthest listener’s ears should reach 70 dB SPL for an assumed noise level of 45 dB SPL. Looking at the chart in Fig. 34-4 for a normal voice talker, and a 70 dB SPL (noise plus 25 dB SNR) level, the normal voice talker would have to be about 2 ft from the listener to achieve this desired $L_p$ level. A raised voice talker would only have to be about 4 ft from the talker. Depending on the talker, one of these distances would be the required EAD. If the actual voice level from a talker (at some reference distance like one meter or four feet) is known, the EAD for the simplified system (outdoors) is as follows

$$EAD = D_s \frac{10}{L_{P_t} - L_{P_d}}$$

(34-7)

where,

- $D_s$ is the reference distance from the talker,
- $L_{P_t}$ is the average $L_p$ from the talker at distance $D_s$,
- $L_{P_d}$ is the desired $L_p$ at the listener.

Example:

Let,

- $D_s = 2$ ft,
- $L_{P_t} = 71$ dB (at 2 ft),
- $L_{P_d} = 65$ dB.
Here, the term $D_s$ is the (reference) distance at which the $L_P$ from the talker was measured. The term $D_s$ (the microphone to talker distance discussed earlier) is used because it is a convenient number (normally about 1 m) and because it will make the next calculation (needed acoustic gain) easier. $L_{Pt}$ is the sound pressure level from the talker at that reference distance $D_s$, and $L_{Pd}$ is the desired sound pressure level at the listener (normally, this will be equal to the ambient noise plus a 25 dB SNR). EAD, then, is the equivalent acoustic distance number to be used in the next calculation, that of needed acoustic gain (NAG).

34.2.2.10 Needed Acoustic Gain (NAG)

The next question to be answered is, “How much acoustic gain is needed to achieve this desired $L_p$ for a given talker’s voice level?” This needed acoustic gain, or NAG, is the gain in decibels needed to produce the desired $L_p$ at the listener’s ears, $L_{Pd}$, given an $EAD$ as calculated previously.

$$NAG = 20 \log \frac{D_o}{EAD}$$

(34-8)

where,

$D_o$ is (as before) the distance from the talker to the farthest listener.

Example:
Let
$D_o = 128$ ft,
$EAD = 4$ ft.

$$NAG = 20 \log \frac{128}{4} = 30.1 \text{ dB}$$

34.2.2.11 Will the System Feed Back?

If the potential acoustic gain (PAG) from Eq. 34-5 is greater than or equal to the needed acoustic gain from Eq. 34-8, there is every reason to believe that the system will be stable and will not feed back. If, on the other hand, the potential acoustic gain is less than the needed acoustic gain, chances are good that the system won’t work because turning up the volume control enough for the farthest listener to hear properly will always cause the system to be at or near feedback.

34.2.2.12 The Effect of Directional Microphones and Loudspeakers

The PAG and NAG equations assume an omnidirectional microphone and an omnidirectional loudspeaker. Some improvement in acoustic gain before feedback
may be obtained by using a directional microphone (i.e., a cardioid pattern microphone) and/or by using a directional loudspeaker (a horn-type loudspeaker or line array). This only occurs if the $D_1$ is less than the critical distance $D_c$. ($D_c$ is discussed in Section 34.2.3.2.4 and is only important in an indoor environment.)

A cardioid microphone could provide as much as 6 dB of additional gain before feedback if the rear of the microphone were pointed directly at the loudspeaker, as often happens with foldback stage monitor loudspeakers. The more typical case of a microphone at a podium and an overhead loudspeaker is a much less favorable arrangement since the side, not the rear, of the microphone will be pointed at the loudspeaker and $D_1$ is at or near $D_c$, providing 1 or 2 dB of additional gain before feedback at best. Because the microphone’s cardioid pattern varies with frequency (it is nearly omnidirectional at low frequencies), even this 1 or 2 dB of feedback reduction may be optimistic. Thus, while a directional microphone may provide some additional gain before feedback, it’s best to plan the system as if an omnidirectional microphone were to be used and take any additional gain provided by a cardioid microphone as a welcome bonus.

A directional loudspeaker may also provide some additional gain before feedback. For a horn-type loudspeaker pointed at the farthest listener, for example, the microphone will be off-axis of the horn, and the sound level at that off-axis angle may be $-6$ dB or more (down) compared to the on-axis level. This could theoretically provide an additional 6 dB gain before feedback. By using a highly directional horn, this 6 dB might be increased to 10 dB or even more. The fault with this theory is that there will almost always be a near-fill loudspeaker aimed at listeners near the microphone. This loudspeaker then becomes the limiting factor in the feedback loop. Even when the nearest listeners are far enough away from the microphone that the near-fill loudspeaker can be aimed well away from the microphone, the system woofer remains a potential feedback problem-causer. A highly directional low-frequency horn is physically very large and, thus, is seldom used in a cluster. A smaller low-frequency horn or vented, box-type, low-frequency component will be almost omnidirectional at low frequencies. Thus, the use of directional horns usually cannot improve gain before feedback because the feedback problems simply shift to below the crossover frequency.

A line array may also provide some additional gain before feedback. A properly designed and installed line array has a narrow vertical dispersion over a wide frequency range. This can keep the sound aimed at the audience and away from the system microphone. At some low frequency, however, the line array’s ability to control its vertical dispersion is degraded and feedback may become an issue below this frequency. Also, it is not always possible to position the line array in such a way to avoid all feedback issues. For example, column-style line arrays are commonly placed to the left and right of the system microphone where their vertical directional control offers little advantage in controlling feedback.

34.2.2.13 How These Equations Answer the Four Questions

There are many other things to consider for even a simplified system. Outdoors, for example, there are the effects of wind, humidity, and temperature layers. (See Chapter 2 and Section 34.6.3.7.) However, the answers to the four questions supply a great deal of information about whether or not a system will actually reinforce sound in a satisfactory manner.

34.2.2.13.1 Question 1: Is It Loud Enough?

Eq. 34-6 helps answer Question 1, “Is it loud enough?.” This equation doesn’t take gain or feedback into account, however. Those concerns are covered in Question 4.

34.2.2.13.2 Question 2: Can Everybody Hear?

This question “Can everybody hear?” involves the coverage patterns of the loudspeakers and the way they are aimed into the audience. This topic is covered in detail in Section 34.3.2 and in Chapters 18 and 35.

34.2.2.13.3 Question 3: Can Everybody Understand?

For the simplified (outdoor) system, the answer to this question is yes if the system is loud enough (Question 1) and if it avoids problems like very poor frequency response and excessive distortion. Indoors, this question also involves the effects of reverberation.

34.2.2.13.4 Question 4: Will It Feed Back?

The answer to the question “Will it feed back?” is no (the desired answer) if PAG is equal to or greater than NAG, Eqs. 34-5 and 34-8.

Again, there’s a lot more to sound system design than answering just four questions, but these particular
four questions are important enough that, in the next section, they form the basis for an expansion of the simplified system to cover the effects of reverberation on indoor systems.

### 34.2.3 Indoor Sound Reinforcement System Model

So far, the discussion of sound reinforcement has been simplified by neglecting the effects of echoes and reverberation. Now, however, it’s time to modify the mathematical model of the sound reinforcement system to include these effects. Doing this, of course, creates a much more useful model, one that can be used successfully both indoors and out.

The equations presented in this section used to determine indoor attenuation, critical distance, potential and needed acoustic gain, and electrical power required are derived from concepts presented by Hopkins and Stryker. The equation for Alcons was derived by Peutz and Klein. The acoustic gain (potential, and needed) equations were developed by Don Davis of Syn-Aud-Con. The critical distance ($D_c$) equation was developed by Don Davis and Mel Sprinkle. The equations have been manipulated and modified by a number of writers to make them more useful to sound system designers. The most notable of these writers are Don and Carolyn Davis.

The equations presented here are basically the same as those used in Sound System Engineering by Don and Carolyn Davis. However, as presented here, the equations have been algebraically manipulated by this author to make them somewhat easier to explain and to make them more adaptable to computer analysis. As in the simplified model, the equations in this section help the designer answer the four questions.

#### 34.2.3.1 Echoes and Reverberation

Echoes and reverberation are both reflections of sound. A reflection is called an echo if the time between the original sound and the reflection is long enough that both sounds can be heard distinctly (about 70 ms or greater). If a room has lots of reflections and they are closely spaced in time so that distinct echoes are not audible, this large number of reflections is known as reverberation. A much more detailed discussion of echoes, reverberation, and general room acoustics can be found in Chapters 1, 3, 5, and 7.

4.2.3.1.1 When an Echo Is a Problem

Some rooms have one or more distinct echoes but very little reverberation. A conference room with carpeting, draperies, padded seating, and acoustical ceiling tile, for example, may have little or no reverberation. That same room, however, may have a hard rear wall that produces a single slap-back echo (so called because it slaps back at talkers every time they try to speak from a location in the front of the room). Other, larger, rooms may have multiple distinct echoes. Superdome-sized rooms are an obvious example. In most cases, problem echoes must be dealt with by acoustic treatment. In some cases, in fact, a sound system will only aggravate an echo problem.

4.2.3.1.2 Can a Reflection Be Useful?

Reflections add to the level perceived by the listener but this additional level may or may not be useful. Mid-to high-level late reflections, which arrive at the listener’s ear more than 50 ms after the direct sound, can muddy the sound or may even be perceived as echoes. Mid-to high-level early reflections, which arrive at the listener’s ear less than 20 ms after the direct sound, cause comb filtering which degrades the system frequency response. Reflections between 20 ms and 50 ms, however, can add to the level in a way that is beneficial to intelligibility and pleasing to the sound quality.

Thus, audible reflections can be useful, questionable, or undesirable, depending primarily on the difference in the arrival time at the listener’s ears (and somewhat on the difference in level between the direct and reflected sound).

Note that the sound from multiple loudspeakers can arrive at a listener’s ears at multiple different times. This effect mimics early reflections and may or may not be useful as discussed above.

4.2.3.1.3 When Reverberation Is Useful

Some reverberation is often desirable, especially for a musical performance. The reverberation of a large cathedral, for example, enhances the organ and choir sound. Some musical compositions, like those written for a pipe organ, are actually intended for a large, reverberant room.

A small amount of reverberation can also enhance a speech reinforcement system. Reverberation can fill out a vocal sound to make it more natural. Those reflections in a reverberant field that reach the listener’s ears a short time (but not too short a time) after the source can
also, as explained previously, improve the ability to understand speech by effectively making it louder.

34.2.3.1.4 When Reverberation Is a Problem

While some reverberation is useful, too much reverberation causes muddy or boomy sound quality in a musical performance and makes speech very difficult to understand. In this case, the reverberation is a problem similar to that of too much ambient noise except that the reverberation gets louder as the signal gets louder so that a reverberation problem cannot be solved by simply turning up the volume control.

34.2.3.2 Reverberation and the Sound Reinforcement System

The indoor sound system model includes two important assumptions:

1. The room has no distinct echoes.
2. The room has a well-developed and statistically random reverberant field, Fig. 34-5.

The first assumption limits the model to rooms with few or no distinct echoes. This is an acceptable limitation since a room with distinct echoes needs acoustic treatment before a sound system can be applied. The second assumption is acceptable for the purposes of this section, although it should be understood that differences in reflecting and absorbing surfaces in most rooms prevent true randomness.

The reason the reverberant field must be considered is that it will help the system maintain a more consistent $L_P$ from seat to seat, even though it will hinder, to some extent, the attempt to provide intelligible sound to every seat.

34.2.3.2.1 Direct/Reverberant Ratio

Direct/reverberant ratio is a ratio of the direct sound at some point in a room to the reverberant sound, which is assumed to be the same everywhere in the room. A high direct/reverberant ratio means good speech intelligibility (if all other factors are favorable).

34.2.3.2.2 Loudspeaker $Q$

$Q$ is a measure of the directional properties of a loudspeaker (also see Chapters 17 and 18). An omnidirectional loudspeaker has a $Q$ of 1. A loudspeaker radiating into a hemisphere has a $Q$ of 2. A loudspeaker radiating into half a hemisphere has a $Q$ of 4 and so on, as shown in Fig. 34-6. A related term, DI (directivity index), is simply ten times the log (base 10) of $Q$. That is

$$ DI = 10 \log Q $$

A loudspeaker with a high $Q$ will have a narrow coverage pattern and will, therefore, concentrate its sound energy on fewer seats than a low-$Q$ loudspeaker. Thus, the high-$Q$ loudspeaker can provide higher levels of direct sound and, likewise, higher direct/reverberant ratios. This leads to better intelligibility, at least in the single loudspeaker case.
Sound System Design 1247

Q compares the on-axis sound intensity of a single loudspeaker to what that intensity would be if the loudspeaker were omnidirectional. Note that sound intensity is proportional to the sound pressure $P_s$ squared.

Because $Q$ is only defined for a single loudspeaker, any mention of the off-axis $Q$ or the $Q$ of a cluster is technically inaccurate. A value for off-axis $Q$ is useful, however, in calculating Alcons (articulation loss of consonents) for a listener not directly on-axis of a loudspeaker. A value for the $Q$ of a cluster could be useful to help determine Alcons for a listener seated on-axis of a single horn in a multihorn system. Thus, the concept of $Q$ is often extended to include these and other ideas.

The off-axis $Q$ of a horn, for example, can be determined from an examination of the on-axis DI and the difference in sound pressure level on axis versus off-axis at the angle of interest. Subtract this difference from the on-axis DI and convert back to $Q$. For example, for a 90° (horizontal) horn, at 45° off-axis horizontally, the SPL is −6 dB from its on-axis value. Thus, if the on-axis DI is 12, the off-axis DI will be 6. In general, if DI is known

$$Q = 10^{\frac{DI}{10}} \quad (34-10)$$

Thus, the off-axis $Q$ in this example is approximately 2.

The concept of the $Q$ of a cluster is more difficult. In theory, it would be possible to calculate the $Q$ of a cluster for a listener seated at any point in the room by comparing the direct $P_s$ at that position with the overall acoustic power output of the entire cluster. In practice, this is a complex calculation since it requires a detailed knowledge of the efficiency of each loudspeaker and the electrical input to each driver as well as the directional characteristics and efficiency of each horn and any alterations that may be made in the horn’s directional characteristics by the baffling effects of the cluster. One way to deal with these problems is discussed in Section 34.3.2.10.2, where the calculation of $D_c$ modifiers is discussed.

34.2.3.2.3 Room Constant

Room constant, $R$ (or $Sa$), is a measure of the relative liveness of a room (a live room has a well-developed, very audible reverberant field). A low room constant, or low $Sa$, means a very live room. A high $R$ or $Sa$ means a dead room. The $R$ or $Sa$ value depends on the size of the room, so a specific value of $R$ or $Sa$ is not enough to judge the reverberation characteristics of a room. Mathematically, room constant may be calculated as

$$R = \frac{Sa}{1 - \bar{a}} \quad (34-11)$$

where,

$S$ is the total surface area of the room,

$\bar{a}$ is the average absorption constant.

One version of the equation for critical distance uses the room constant in place of the $Sa$ term. While room constant was commonly used to specify a room in the past (in the $D_c$ equation), it has fallen into disuse and is usually replaced in most equations by the $Sa$ term.

34.2.3.2.4 Critical Distance ($D_c$)

$D_c$ (critical distance) is the distance from a source at which the direct sound is exactly the same $P_s$ as the reverberant field, Fig. 34-7. Critical distance is important in a number of concepts including intelligibility.

A good estimate of the critical distance for a loudspeaker in a given room can be made by playing a pink-noise source through the loudspeaker and walking away from it holding a sound level meter. At some distance, the $P_s$ will cease to change. Now walk back toward the source until the $P_s$ increases exactly 3 dB. That distance will be the critical distance. (Since the direct sound and reverberant sound are equal here, the total is 3 dB above the reverberant sound alone.) Crit-
ical distance depends on the $Q$ of the source and the absorption in the room; thus, it can vary with frequency, and this test shows only a broadband approximation of critical distance.

For a given loudspeaker in a given room, critical distance can be found from

$$D_c = \frac{\sqrt{QS\bar{a}}}{16\pi N}$$

(34-12)

where,

$Q$ is the $Q$ of the source,
$S$ is the total surface area of the room,
$\bar{a}$ is the average absorption coefficient for the surfaces in the room,
$N$ is the total number of loudspeakers producing the same acoustic power as the loudspeaker pointed at the farthest listener.

Example:
Let
$Q = 5$,
$S = 28,000 \text{ ft}^2$,
$\bar{a} = 0.35$,
$N = 1$.

$$D_c = \frac{\sqrt{5(28,000)0.35}}{16\pi 1}$$

$= 31.2 \text{ ft}$

For a more detailed discussion of the concept of $N$, see Section 34.3.2.10.

### 34.2.3.3 Attenuation of Sound Indoors

The first part of the indoor sound reinforcement system model will tell us what happens to a sound at increasing distances from the source in an indoor environment. The inverse-square law, Eq. 34-1, is still correct indoors, but only for the direct sound. The reverberant sound level is assumed to be the same everywhere—that is, the reverberant sound level does not change with distance from the source. Thus, the total sound level, at any distance from a source, is the sum of the direct sound, which has been attenuated by inverse-square law, and the reverberant sound, which does not change with distance

$$L' = L - \left[20\log \frac{D'}{D} + 10\log \frac{g(D')}{g(D)}\right]$$

(34-13)

where,

$D$ is the original distance from the source,
$D'$ is the new distance from the source,
$L_p$ is the original $L_p$ at $D$,
$L_p'$ is the new $L_p$ at the distance $D'$,
$g(x)$ is found from the equation

$$g(x) = D_c^2 + x^2$$

(34-14)

where,

$x$ is any distance.

Note that the equation for indoor attenuation is exactly the same as Eq. 34-1 for the simplified system (outdoor) attenuation (inverse-square law) except for the final term, which can be interpreted as a contribution from the indoor reverberant field.

Example:
Let
$L_p = 90 \text{ dB}$,
$D = 4 \text{ ft}$,
$D' = 125 \text{ ft}$,
$D_c = 31.2 \text{ ft}$.

$$L'_p = 90 - 20\log \frac{125}{4} + 10\log \frac{g(125)}{g(4)}$$

$= 72.3 \text{ dB}$.

To compare to outdoor attenuation, Eq. 34-1, simply ignore the term

$$10\log \frac{g(D')}{g(D)}$$

Indoor attenuation can also be found from another equation.
\[ L_p' = L_p - \Delta dB \]  
where,  
\[ \Delta dB = \Delta D' - \Delta D \]  
and  
\[ \Delta x = -10 \log \left( \frac{Q}{4\pi x^2} + \frac{4}{S\bar{a}} \right) \]  
where,  
x is any distance.

Example:  
Let,  
\[ L_p = 90 \text{ dB}, \]  
\[ D = 4 \text{ ft}, \]  
\[ D' = 125 \text{ ft}, \]  
\[ Q = 5, \]  
\[ S = 28,000, \]  
\[ \bar{a} = 0.35. \]

\[ \Delta D = -10 \log \left( \frac{5}{4\pi4^2} + \frac{4}{28,000 (0.35)} \right) \]  
\[ = 16 \text{ dB} \]
\[ \Delta D' = -10 \log \left( \frac{5}{4\pi125^2} + \frac{4}{28,000 (0.35)} \right) \]  
\[ = 33.6 \text{ dB} \]
then,  
\[ \Delta dB = 33.6 \text{ dB} - 16 \text{ dB} \]  
\[ = 17.6 \text{ dB} \]  
and  
\[ L_p' = 90 - 17.6 \]  
\[ = 72.4 \text{ dB}. \]

Note: Except for round-off errors, this answer and the answer to the example for Eq. 34-14 are the same.

Eq. 34-15 is more common in the literature but Eq. 34-14 may be easier to understand and to use in a computer program. The two equations are mathematically the same and will produce the same answers given the same data.

34.2.3.4 The Four Questions Again

Question 2: “Can everybody hear?” is discussed in Section 34.3.2. Questions 1, 3, and 4, however, can be answered with the information obtained so far.

34.2.3.4.1 Question 1: Is It Loud Enough?

In the simplified (outdoor) system, the answer to this question depended on the required \( L_p \) at the farthest listener (at \( D_c \)), the required head room in decibels and the sensitivity of the loudspeaker. The answer was given in terms of the required electrical power to be supplied to the loudspeaker (the \( EPR \)).

In the indoor system, reverberation in the room affects the analysis. Yet, although the room adds complexity to the answer to Question 1, it makes things a little easier in the actual design of an indoor sound reinforcement system, because, after the critical distance is passed, the sound can only attenuate another 3 dB. Thus, for distances beyond \( D_c \), no more power is needed to maintain the same \( L_p \). Unfortunately, intelligibility suffers at distances well into the reverberant field. But that is the topic of Question 3. For now, here is the equation for indoor electrical power required

\[ EPR = 10^{ \frac{L_p + H - L_s + 20\log \frac{D_2}{3.28} - 10\log \frac{g(D_2)}{g(3.28)}}{10} } \]  
(34-16)

where,  
\( L_p \) is the average \( L_p \) required at distance \( D_2 \),  
\( H \) is the head room in dB,  
\( L_s \) is the sensitivity of the loudspeaker (1 W/1 m),  
\( D_2 \) is the distance to the farthest listener,  
For metric distances, replace the constant 3.28 with the constant 1.00.

Example:  
Let  
\[ L_p = 90 \text{ dB}, \]  
\[ H = 10 \text{ dB}, \]  
\[ L_s = 113 \text{ dB} (1 \text{ W/1 m}), \]  
\[ D_c = 31.2 \text{ ft}, \]  
\[ D_2 = 128 \text{ ft}. \]

\[ EPR = 10^{ \frac{90 + 10 - 113 + 20\log \frac{128}{3.28} - 10\log \frac{17,357}{989.4}}{10} } \]  
\[ = 4.3 \text{ W} \]

To compare with the simplified system (outdoor) \( EPR \) equation (Eq. 34-6), simply ignore the term...
The value $L_p$ in the first line of the equation is the desired $L_p$ at $D_2$. The value $H$ is a desired value for head room, usually assumed to be 10 dB. That 10 dB, of course, may be changed for a particular system. $D_c$ is the critical distance given in Eq. 34-12. It is instructive to note that this equation is the same as the simplified system (outdoor) EPR equation (Eq. 34-6) except for the term

$$10 \log \frac{g(D_2)}{g(3.28)}$$

which can be interpreted as a contribution from the reverberant field.

EPR can also be found from an equation that is more common in the literature

$$EPR = 10 \log \frac{L_p + H - L_s + \Delta D_2 - 3.28 - L_s}{10}$$

where,

$$\Delta x = -10 \log \left( \frac{Q}{4 \pi x^2} + \frac{4}{S \bar{a}} \right)$$

where,

$x$ is any distance,
other terms are as before,
For metric distances, replace the constant 3.28 with the constant 1.00.

Example:
Let
$L_p = 90$ dB,
$H = 10$,
$D_2 = 128$ ft,
$L_s = 113$ dB/1 W/1 m,
$Q = 5$,
$S = 28,000$,
$\bar{a} = 0.35$.
then
$$\Delta D_2 = 33.6$$
and
$$\Delta 3.28 = 14.3$$
and

$$EPR = 10 \log \frac{90 + 10 + 33.6 - 14.3 - 113}{10}$$
$$= 4.33 \text{ W}$$

Eq. 34-17 may be more familiar to some readers. However, it and Eq. 34-16 are mathematically equivalent and will produce the same answers from the same data. Eq. 34-16, however, may be easier to understand and to use in a computer program.

34.2.3.4.2 Question 3: Can Everybody Understand?
In the simplified (outdoor) system, Question 3 was answered by considering the required SNR and making certain that the sound system output was sufficiently above the ambient noise level to provide intelligible sound (speech). Indoor intelligibility also depends on the reverberation time and the direct/reverberant ratio, and an unfavorable reverberation time or direct/reverberant ratio cannot be made better by merely increasing the SPL from the loudspeakers, since that will also increase the reverberant field level!

If the reverberation time or direct/reverberant ratio is unfavorable, one or more of the following may help:

1. Decrease the reverberant field by adding absorption to the room (usually a costly process).
2. Move the listener closer to the loudspeaker (in a reverberant church with the pews half filled, people sitting near the loudspeakers will hear and understand better than those farther away from the loudspeakers).
3. Move the loudspeakers closer to the listeners (adding additional loudspeakers, as described later, is a common way to improve direct-to-reverberant ratio but this is not a panacea since the new loudspeakers will add to the reverberant level as well as the direct level).
4. Use a loudspeaker with higher $Q$ (this is ideal provided the required $Q$ doesn’t mean that you have a very narrow coverage pattern that cannot cover all the listeners).

How is a direct/reverberant ratio determined? What is a favorable reverberation time or direct/reverberant ratio? It is possible to determine this ratio directly, but it is more common to use the articulation loss of consonants concept. If the Alcons is 10% or less and the SNR is favorable (+15 dB or greater), there is every reason to believe the answer to Question 3 will be yes.

Note that some texts suggest an Alcons of 15% or less is acceptable. Also note that this Alcons equation is
most accurate in rooms with reverberation times of 1.6 s or longer and is not particularly accurate or useful in acoustically dead rooms. In addition, this form of the Alcons equation assumes at least a 25 dB SNR. See Chapter 36 for a thorough discussion of speech intelligibility including additional speech intelligibility measurement standards.

\[
Alcons = \frac{656D_2^2 \cdot RT_{60}^2 N}{QV} \tag{34-18}
\]

where,
- \(D_2\) is the distance between the loudspeaker and the farthest listener,
- \(RT_{60}\) is the room reverberation time,
- \(N\) is a number that attempts to compensate for the fact that there are most likely several loudspeakers in the cluster and only one will be pointed at the farthest listener (but all add to the reverberant field). Note that some texts use \(N + 1\) in place of \(N\),
- \(Q\) is the \(Q\) of the loudspeaker,
- \(V\) is the volume of the room,

For metric distances, replace the constant 656 with the constant 200, \(D^2\) is in m\(^2\) and \(V\) is in m\(^3\) in the metric system.

Example:
Let,
- \(D_2 = 125\) ft,
- \(RT_{60} = 2.5\) s,
- \(V = 500,000\) ft\(^3\),
- \(Q = 10\),
- \(N = 1\).

\[
Alcons = \frac{656(125^2)(2.5^2)(1)}{10(500,000)} = 12.8\% \text{ (less than acceptable)}
\]

One way to interpret \(N\) is the total number of loudspeakers producing the same acoustic power as the loudspeaker pointed at the farthest listener. For a more detailed discussion of the concept of \(N\), see Section 34.3.2.10.

\[
34.2.3.4.3 \text{ Alcons Modified for Audience Absorption and Talker/Listener Factors}
\]

The following equation for \(Alcons\) includes modifiers for the absorption of an audience and for a talker with poor articulation or listeners with less than normal hearing acuity. Use this form of the equation when listener or talker difficulties are expected or when the audience area will be significantly more absorptive than the rest of the room such as a large cathedral with marble walls and ceiling but with pew cushions in the seating area and carpeting on the floor.

\[
Alcons = \frac{656D_2^2 \cdot RT_{60}^2 N}{QV} + k \tag{34-19}
\]

where,
- \(m = \frac{1 - a}{1 - ac}\),
- \(a\) is the average absorption coefficient for the room,
- \(ac\) is the absorption coefficient in the area covered by the loudspeaker (the audience area),
- \(k\) is a correction factor for a talker with poor articulation or listeners with less than normal hearing acuity and is typically in the range of \(1\% – 3\%\),
- other factors are as before.

For metric distances, replace the constant 656 with the constant 200, \(D^2\) is in m\(^2\) and \(V\) is in m\(^3\) in the metric system.

\[
34.2.3.4.4 \text{ Alcons in Terms of } RT_{60} \text{ and Direct, Reverberant, and Noise Levels}
\]

The following equation presents \(Alcons\) in terms of the four factors most critical to intelligibility, which are direct sound level, reverberant sound level, reverberation time, and noise level. Use this form of the equation if the four quantities are known or can be reliably estimated.

\[
Alcons = 100(10^{-2[A + BC - ABC]} + 0.015) \tag{34-20}
\]

where,
- \(A = -0.32\log\left(\frac{E_R + E_N}{10E_D + E_R + E_N}\right)\),
- \(B = -0.32\log\left(\frac{E_N}{10E_R + E_N}\right)\),
- \(C = -0.5\log\left(\frac{T_{60}}{12}\right)\),
- \(E_R = 10^{L_R}\),
- \(E_D = 10^{L_D}\),
- \(E_N = \frac{L_N}{10}\).
$L_R$ is the reverberant level in the 2 kHz octave band, 
$L_D$ is the direct sound level in the 2 kHz octave band, 
$L_N$ is the ambient noise level in the 2 kHz octave band.

### 34.2.3.4.5 Question 4: Will It Feed Back?

The PAG and NAG concepts work indoors, too, but are modified by the room.

$$PAG = 20\log \frac{D_o D_1}{D_s D_2} - 10\log NOM - 6 \text{ dB} - 10\log \frac{g(D_o)g(D_1)}{g(D_s)g(D_2)}$$

(34-21)

where,

$$g(x) = D_c^2 + x^2,$$

other terms are as before.

**Example:**

Let,

- $D_s = 2 \text{ ft}$,
- $D_o = 128 \text{ ft}$,
- $D_1 = 45 \text{ ft}$,
- $D_2 = 90 \text{ ft}$,
- $D_c = 31.2 \text{ ft}$,
- $NOM = 3$.

$$PAG = 20\log \frac{128(45)}{2(90)} - 10\log 3 - 6 \text{ dB} - 10\log \frac{71597}{9779073} = 11.7 \text{ dB}.$$  

To compare to the simplified (outdoor) system PAG Eq. 34-5, simply ignore the term

$$-10\log \frac{g(D_o)g(D_1)}{g(D_s)g(D_2)}$$

Alternate forms of the $PAG$ and $NAG$ equations, which are more common in the literature, follow:

$$PAG = \Delta D_o + \Delta D_1 - \Delta D_s - \Delta D_2 - 10\log NOM - 6 \text{ dB}$$

(34-23)

where,

$$\Delta x = -10\log \left( \frac{Q}{4\pi x^2} + \frac{4}{Sa} \right)$$

(34-24)

where,

$x$ is any distance, 
other terms are as before.

**Example:**

Let

- $D_o = 128 \text{ ft}$,
- $D_1 = 45 \text{ ft}$,
- $D_2 = 90 \text{ ft}$,
- $D_c = 31.2 \text{ ft}$,
- $Q = 5$,
- $S = 28,000 \text{ ft}^2$,
- $a = 0.35$,
- $NOM = 3$.

Then

$$\Delta D_o = 33.6,$$
$$\Delta D_1 = 32.2,$$
$$\Delta D_s = 10.0,$$
$$\Delta D_2 = 33.4,$$

and

$$PAG = 33.6 + 33.2 - 10 - 33.4 - 10\log 3 - 6 \text{ dB} = 11.7 \text{ dB}.$$  

$$NAG = \Delta D_o - \Delta EAD$$

(34-24)

where,
\[ \Delta x = -10 \log \left( \frac{Q}{4 \pi x^2} + \frac{4}{\text{Sa}} \right) \]

where,
\( x \) is any distance,
other terms are as before.

Example:
Let
\( D_o = 128 \text{ ft}, \)
\( EAD = 4 \text{ ft}, \)
\( Q = 5, \)
\( S = 28,000 \text{ ft}^2, \)
\( a = 0.35. \)
then,
\[ \Delta D_o = 33.6 \]
\[ \Delta EAD = 16 \]
and,
\[ NAG = 33.6 + 16.0 \]
\[ = 17.7 \text{ dB} \]

These two equations are mathematically equivalent to Eqs. 34-21 and 34-22 and will produce the same answers given the same data. Eq. 34-21 and 34-22 may be easier to understand and to insert in a computer program.

In addition, it should be noted that some users prefer to place the NOM (number of open microphones) and 6 dB feedback stability margin (FSM) terms in the NAG equation rather than in the PAG equation. This author believes that they belong in the PAG equation since including them produces a value of PAG more nearly equal to that which will be measured in the installed system. While PAG and NAG values will differ with placement of the two terms, the PAG – NAG value (which is the most important result) will be the same regardless of the placement of the two terms.

Also, as before, if PAG is greater than or equal to NAG, it’s reasonable to assume that the system will be stable and not feed back.

In Eq. 34-21, the terms \( D_s, D_1, D_2, D_o, \) and NOM are as explained in the simplified (outdoor) system. In Eq. 34-22, use the simplified system estimate for EAD Eq. 34-7, ignoring the effects of the reverberant field. This puts the estimate on the safe side for the NAG calculation. The equations for PAG and NAG are similar to the equations given for the simplified system, Eqs. 34-5 and 34-8, except for the \( 10 \log [ ] \) terms that can be interpreted as modifications caused by the room reverberant field.

### 34.2.3.4.6 The Effect of Directional Microphones and Loudspeakers

In a reverberant room, the effect of directional microphones is less significant than in the outdoor case. The reason is that the amount of reverberant sound energy picked up by the microphone depends very little on the microphone’s pickup pattern (a cardioid microphone picks up more reverberant sound from the front, which compensates for its reduced rear pickup). A directional microphone will, however, exhibit higher gain in the direction of the talker which has the same effect on feedback as a reduction in \( D_s \). This improvement may be as much as 2 or 3 dB and it is not included in any of the PAG or NAG equations.

Directional loudspeakers may reduce the amount of direct sound energy reaching the microphone but do not substantially reduce the amount of reverberant sound reaching the microphone, since this is usually dominated by the nondirectional low-frequency loudspeakers. Note that the indoor PAG equation Eq. 34-21 already includes the effect of directional loudspeakers on the reverberant field. Thus, it is best to assume that no additional gain before feedback will be provided by directional loudspeakers.

### 34.2.3.5 Validity of the Model in a Geometrically Complex Room

In effect, the equations just presented form a mathematical model of the interactions between a room and a sound system. The question arises, “Just how valid is this model?” The answer is to remember that the model assumes a well-developed, statistically random reverberant field in a room with simple geometry. Thus the model can be very accurate in a room like a high-school gymnasium or a rectangular church. Add balconies, transepts, or other complexities, and the equations, while still useful, cannot adequately describe the entire room.

One way to deal with more complex rooms is to treat them as two or more acoustically separate spaces. A large stage with hardwood floors and reflecting walls and ceiling, for example, may be coupled to an audience seating area with padded seats, carpeting, and draped walls. A reverberant cathedral may have an under-balcony area that is very different acoustically from the main room. System design and the use of the equations will be improved by treating these different spaces as entirely different rooms that just happen to share a common boundary (an imaginary wall).

An equation for the overall combined reverberation time in such a dual-space room is
\[ RT_{60T} = \frac{3}{4} \sqrt[3]{RT_{60A}^3 + RT_{60B}^3}. \] (34-25)

Some rooms, of course, do not lend themselves to analysis by the given equations. One example is the Superdome-sized room that has no true reverberant field because the individual reflections are spaced far enough apart in time that they are more accurately called echoes, not reverberation. These rooms may have an apparent dramatic increase in reverberation when excited by a high sound pressure level sound system (similar to those used for concert sound reinforcement). Another example is the acoustically dry conference room that has no significant reverberant field because of an abundance of carpeting, draperies, padded seating, and acoustical ceiling tile. One approach to design in both of these spaces is to use the simplified (outdoor system) equations where needed, since they deal with the direct sound. In the large space, echoes must be considered (they are not included in any of the equations); in the small space, table top and other nearby reflections must be considered.

34.2.3.6 A Modification for Low RT60 Rooms

The mathematical model presented in this section assumes a well-developed, statistically random reverberant field. Such a reverberant field is unlikely to exist in a corporate conference room or a home living room because of the abundance of sound absorption materials. In many cases, in these small, acoustically dead rooms, the outdoor sound system equations (Eqs. 34-1 through 34-8) can be applied successfully to describe the behavior of sound in the room, Fig. 34-8.

Note: \( D \) and \( D' \) must be greater than calculated \( D_c \) for Eq. 34-26 to work. \( D_c \) calculated for this room = 7.22 ft, so that Eq. 34-26 may be used with \( D = 10 \) and \( D' = 20 \).

Then

\[ L'_p = 90 - 0.734 \left[ \frac{\sqrt{V}}{H(\text{RT60})} \right] \left[ \log \frac{D'}{D} \right] \] (34-26)

where,

\( H \) is the room height,
\( V \) is the room volume.

Example:

Let

\( V = 4275 \text{ ft}^3, \)
\( H = 9.5 \text{ ft}, \)
\( L_p = 90 \text{ dB}, \)
\( \text{RT60} = 0.4 \text{ s}, \)
\( D = 10 \text{ ft}, \)
\( D' = 20 \text{ ft}. \)

Note the similarity between Eq. 34-26 and the inverse-square law Eq. 34-1. The answer, 86.2 dB, is between the 84 dB predicted by Eq. 34-1 and the 88.7 dB predicted by Eq. 34-13. Dimensions are assumed to be in feet. Also, note that Eq. 34-26 should be used only in rooms with very low calculated reverberation.
beration times. Eq. 34-26 will accurately predict attenuation for distances \( D' \), which are greater than the calculated critical distance, \( D_c \), whenever an on-site measurement shows the actual \( L_p \) to be 1 to 5 dB below the predicted \( L_p \) at a distance equal to twice the calculated \( D_c \) from a source.

### 34.3 Loudspeaker Systems for Sound Reinforcement

The answer to Question 2: “Can everybody hear?” comes from evaluating the success of the loudspeaker system, in particular, how well the loudspeakers have been aimed to cover the audience and how well the patterns of individual loudspeakers combine to cover areas with complex shapes. To answer Question 2, then, the following section discusses loudspeaker system components, types of loudspeaker systems, and loudspeaker system design.

#### 34.3.1 Loudspeaker Components

A *transducer* is any device that converts one form of energy to another. Loudspeaker components are transducers because they convert electrical energy into acoustic energy. Packaged loudspeaker systems and line arrays are designed from loudspeaker components including cone-type loudspeakers and their enclosures, compression drivers and their horns, and other components such as ribbon drivers and ring radiators. In the past, sound reinforcement systems often used clusters of individual high-frequency horns and low-frequency woofers (cone loudspeakers in enclosures). Today, most systems use packaged loudspeaker systems or line arrays to cover the audience. See Chapter 19 for more detailed information on loudspeakers and Chapter 20 for additional information on cluster design.

##### 34.3.1.1 Cone Loudspeakers

Large cone loudspeakers (15 and 18 inch diameters) are normally used as the low-frequency components of two-way, three-way, or multiway systems. Also, 12 and 10 inch cone loudspeakers may be used as the low-frequency component in a low-power, two-way system or as the lower midrange component in a three-way or multiway system.

Smaller cone loudspeakers (8 and 4 inch) may be used as low-frequency or midrange components in a packaged loudspeaker system. Other 8 and 4 inch cone loudspeakers are designed for relatively full-range performance and are used in ceiling-type distributed systems and as the components in column loudspeaker systems.

##### 34.3.1.2 Cone Loudspeaker Enclosures

There are three basic types of loudspeaker enclosures in use in professional systems: sealed (often improperly called infinite baffle), vented (also called ported or bass reflex), and horn-loaded. Some manufacturers also offer combination vented and horn-loaded enclosures.

A sealed enclosure is relatively simple to design and construct; it has a smooth frequency response curve, good transient response, and helps protect the loudspeaker from overexcursion at low frequencies. Sealed enclosures are most common in home entertainment systems.

A vented enclosure works as a Helmholtz resonator to boost the low-frequency response of a loudspeaker above the response of a similarly sealed enclosure design. Transient response and frequency response smoothness may suffer somewhat, although these problems are small in a good design. An electrical high-pass filter should be used to help protect the loudspeaker against overexcursion at frequencies below the enclosure resonance frequency \( f_b \). Because of their greater output at low frequencies, vented enclosures are common in professional systems.

Horn-loaded enclosures place a horn in front of the loudspeaker and a sealed compression chamber behind the loudspeaker. The loudspeaker thus becomes a compression driver. Properly designed, a horn-loaded enclosure boosts the overall efficiency of the loudspeaker-enclosure combination above a sealed or vented enclosure and provides some measure of control over the dispersion pattern. In addition, the sealed chamber behind the loudspeaker helps prevent overexcursion at low frequencies. Horn-loaded enclosures are most common for midrange applications, Fig. 34-9.

For low-frequency applications, one type of horn-loaded enclosure, often called a vented horn, adds a vented chamber behind the loudspeaker (instead of the sealed chamber) to boost the low-frequency response below the horn’s cutoff frequency.

Another type of low-frequency, horn-loaded enclosure, known as a folded horn, is a relatively long horn that has been folded back on itself to reduce the external package size, Fig. 34-10.

Because of their efficiency, horn-loaded enclosures were popular in the early days of sound when power amplifiers were small and expensive. Unfortunately, a horn designed to work well at low frequencies is quite
large, and with power amplifiers larger and less expensive per watt, many designers now choose vented enclosures because they fit in the smaller spaces provided in modern buildings. It can be shown mathematically that, for a given amount of total enclosure volume, a loudspeaker system using vented enclosures can produce more total acoustic power than a horn-loaded loudspeaker system. The vented system simply uses more loudspeakers and higher-powered amplifiers to achieve this victory.

34.3.1.3 Compression Drivers and Horns

One class of components is designed specifically for use on a horn. These components are called compression drivers, and they are used almost exclusively as the midrange and high-frequency components of two-way, three-way, and multiway systems. At these frequencies, horn sizes are smaller than at the low frequencies used by low-frequency horns. Because of the efficiency and dispersion control of the horn, especially in the critical midrange and high frequencies, mid- and high-frequency horns and compression drivers, Fig. 34-11, are the midrange and high-frequency components most often used in packaged loudspeaker systems.

There are several types of mid- and high-frequency horn designs. These include exponential (radial), multicell, and constant directivity horns. In the past, exponential horns were commonly used in packaged loudspeaker systems and multicell horns were commonly used in component clusters and in cinema loudspeaker systems.

Today, almost all available horns are constant directivity designs. Constant directivity horns have very good dispersion control (pattern control) over a wide frequency band. Although well-designed constant directivity horns are somewhat larger than exponential or multicell horns, the dispersion control advantage of constant directivity horns is so overwhelming that they
have become the most popular choice for packaged loudspeaker systems.

34.3.1.4 Packaged Loudspeaker Systems

Manufacturers now offer a wide variety of packaged loudspeaker systems, designed for many different applications. The overwhelming popularity of packaged loudspeaker systems is due to several factors. First, a packaged loudspeaker combines two or more loudspeaker components in a single enclosure to cover a wider frequency range. As such, a packaged loudspeaker becomes a wide-range component for cluster design. Second, packaged loudspeaker systems commonly include suspension hardware, which makes them easy to install a cluster in the field. Third, packaged loudspeaker systems are usually trapezoidal in shape which makes it easy to arrange them in a tight, efficient cluster. Fourth, packaged loudspeaker systems are generally more attractive than raw components, which is important in appearance-sensitive installations. Finally, some packaged loudspeakers are self-powered and include sophisticated DSP processors that optimize their performance and help protect the loudspeaker. These electronics simplify system design. For all of these reasons, many designers choose packaged loudspeaker systems for their cluster designs, Fig. 34-12.

There are at least two disadvantages to packaged loudspeaker systems. First, in comparison to component horns, packaged loudspeaker systems offer a limited choice of coverage patterns. For example, it’s unusual to find a true long-throw horn in a packaged loudspeaker system. Second, designers minimize the size of packaged loudspeaker system for efficient cluster packing and for appearance reasons. However, the smaller horns in these packaged loudspeaker systems have reduced pattern control in comparison to the larger horns available as separate components. In some packaged loudspeaker systems, a three-way design with a midrange horn helps to offset this disadvantage.

At least one manufacturer now offers a packaged loudspeaker system where each model is designed to cover an entire room from a single cluster location. The design achieves this goal by using a specially designed mid/high-frequency horn that has a wide horizontal coverage angle aimed at the front of the room tapering gradually to a narrow coverage angle for the rear of the room. These special-purpose loudspeaker systems work best in rectangular rooms with a specific ratio of length to width. Consult with the manufacturer for additional application advice, Fig. 34-13.

34.3.1.5 Line Arrays

There are two primary styles of line array loudspeaker systems. One is the modular line array, also known as a concert line array. This type of line array uses multiple
two-way or three-way enclosures suspended in a vertical line. The other type of line array is a column line array. This type of line array uses multiple cone-type loudspeakers in a single column-style enclosure, Figs. 34-14 and 34-15.

By virtue of their height, both types of line arrays are capable of providing narrow vertical dispersion patterns. This can help the designer keep the sound aimed at the audience and away from a hard reflecting ceiling. Depending on placement it may also help reduce feedback problems by keeping the sound away from system microphones.

Concert line arrays are usually designed with a specific horizontal dispersion pattern provided by horn-type mid- and high-frequency components. Commonly this is a wide angle to cover listeners near the front of the room. In a rectangular room, this wide horizontal dispersion means there will be significant reflections from the walls along the sides of the room. In many rooms, these are beneficial reflections that increase $L_p$ and intelligibility. However, the system designer must be aware of these reflections and confirm that they are useful.
Most column line arrays are designed from cone-type loudspeaker components or ribbon drivers that have very wide horizontal dispersion. As in the concert line-array case, the system designer must confirm that the resulting side-wall reflections will be beneficial for the listeners.

Line arrays offer another benefit to the system designer. For some distance from the line array, the sound level decreases only $3 \text{ dB}$ each time the distance from the line array is doubled. Contrast this to normal inverse-square-law loss of $-6 \text{ dB}$ per doubling of distance. This makes it possible to keep the $L_p$ more constant in an audience area and may also help reduce feedback problems. This effect is frequency dependent and is limited to a distance of about two to two and one half times the height of the array.

Some line arrays include sophisticated electronics and computer software and are steerable. This allows the system designer to aim the vertical dispersion precisely at the audience. Some line arrays even allow two or more lobes that can be aimed at different sections of the audience.

See Chapters 17 and 18 for more information on packaged loudspeaker systems and line arrays.

34.3.1.6 Choosing Loudspeakers

Besides the obvious question of budget, there are several other considerations in choosing loudspeakers that apply to both packaged loudspeaker systems and line arrays.

34.3.1.6.1 Power Handling

The loudspeaker system should be able to handle the expected power output of the chosen power amplifier for an extended period of time over the full-rated frequency range of the loudspeaker.

34.3.1.6.2 Frequency Range and Response

The loudspeaker’s response should be smooth over its intended operating range. If the system will be used primarily for voice, a loudspeaker system whose low-frequency response is limited to 70 or 80 Hz should suffice. For music, the system’s low-frequency response should extend down to 40 Hz or below. Frequencies below 40 Hz are limited to a few instruments, such as pipe organ, keyboards and synthesizers, and bass drums (kick drum). When it is necessary to reinforce these very low frequencies, use a separate subwoofer system to avoid the added stress these low frequencies would place on the normal system woofers.

34.3.1.6.3 Sensitivity

Sensitivity is an indication of the loudspeaker’s efficiency. A loudspeaker’s sensitivity is the $L_p$ (sound pressure level) in dB the loudspeaker will produce at one meter, on-axis, when the input power is one watt. High sensitivity is an advantage because it increases maximum $L_p$. Remember that a decrease of only $3 \text{ dB}$ in sensitivity means double the amplifier power is needed to maintain the same $L_p$.

34.3.1.6.4 Coverage Pattern

Choose the coverage pattern according to the system needs. Packaged loudspeaker systems commonly offer a short-throw ($90^\circ \times 40^\circ$) or medium-throw ($60^\circ \times 40^\circ$) coverage pattern. Some packaged loudspeaker systems may offer wider or narrower coverage patterns. As mentioned, most line arrays have narrow vertical dispersion and wide horizontal dispersion.

Separate horns and woofers are seldom used as the main components in loudspeaker clusters but may be useful for special purposes such as long-throw or balcony coverage or very wide-angle near-throw. Component horns are available in short-throw, medium-throw and long-throw coverage angles. Long-throw component horns are usually $40^\circ$ horizontal by $20^\circ$ vertical and are commonly needed only in large concert systems and permanently installed systems. Medium-throw component horns are usually $60^\circ$ horizontal by $40^\circ$ vertical and are valuable in many portable as well as permanent systems to reach farther back in an audience. Short-throw component horns are usually $90^\circ$ or $120^\circ$ horizontal by $40^\circ$ vertical and are used to reach the front of an audience or may be used to cover an entire audience in a small portable system.

34.3.1.6.5 Evaluating Loudspeaker Sound Quality

Sound quality is primarily a subjective evaluation, which means that personal tastes play an important part. However, the goal of a sound reinforcement system is not to alter but to reinforce and, to some extent, to enhance the sound of a performance. Thus, the subjective evaluation of the sound quality of a loudspeaker
system should be based on how well that loudspeaker system will accurately reinforce a live performance.

For this reason, listening tests done with live sources in acoustically well-designed rooms are ideal evaluations. When it’s possible to do live evaluations, use a strong-voice talker with a well-chosen microphone for speech. Use a single, well-known instrument, such as an acoustic guitar or acoustic piano for musical evaluations. A singing voice, accompanied by a guitar or piano is also a good choice. See Chapter 16 for a discussion of microphones.

When a live test is not possible, use a CD or other high-quality digital recording as a source. Certain well-recorded vinyl LPs may also be suitable. Choose a recording of a solo acoustic guitar, acoustic piano, or a voice accompanied by a guitar or piano.

Choosing these simple musical sources makes it easier to evaluate the fidelity of the loudspeaker system because most people are familiar with the way they ought to sound. If the loudspeaker system colors this in any way, most people will recognize the coloration easily.

Using recordings of loud and dynamic rock music or highly synthesized music of any kind may be a good way to evaluate the ability of the loudspeaker system to handle high-power live sources, but it is not a good way to evaluate the fidelity of a system since distortions or frequency response aberrations in the loudspeaker system may be interpreted as intentional parts of the original performance!

34.3.2 Loudspeaker Systems

There are several styles of loudspeaker systems used in sound reinforcement systems. The most common are the central cluster, split cluster, exploded cluster, and the distributed system. Any of these loudspeaker systems may be designed from component loudspeakers, packaged loudspeakers, or line arrays. In addition, there are variations and combinations of these types. This section discusses some basic design criteria for loudspeaker systems. Chapters 17 and 18 discuss additional details of loudspeaker system design.

34.3.2.1 The Central Cluster

A central cluster is a group of packaged loudspeaker systems or component horns and woofers placed in a central location and aimed at a listening area. The traditional central cluster is placed above a stage (on the proscenium) or above the primary microphone location, Fig. 34-16. A modular line array, suspended in this location, may be considered a central cluster.

A location above the audience makes the difference between the distance from the cluster to the nearest listener and from the cluster to the farthest listener more nearly equal. This, in turn, makes the job of designing the cluster for even audience coverage easier. In most cases, however, the cluster should not be more than about 30–45 ft above the heads of the listeners. This is because listeners seated near the talker can often hear both the unaided talker and the cluster. If the cluster is more than about 30–45 ft above the heads of the listeners, they will notice a hollow sound or even a distinct echo due to the natural delay between the sound from the talker and the sound from the cluster.

The human ear can accurately discriminate the location of sounds from a left-right perspective, but not as well from an up-down perspective. Thus, another advantage of a central cluster, if it is placed near the center of the room or approximately above the primary microphone location (and assuming other factors are favorable), is that the sound will appear to emanate from the talker, and not from the cluster.

A final, significant advantage of a central cluster is that, compared to an equally well-designed distributed loudspeaker system, the central cluster is almost always less costly.

Sometimes, aesthetic considerations prevent the installation of a central cluster. For example, the loudspeakers may block important architectural elements in a religious facility or historical building.

In some rooms, the ceiling is too low compared to the length of the room to allow a central cluster to work well. This problem prevents adequate gain before feedback in the back of the room (PAG is too low). A good rule of thumb is that \( D_2 \) should be no more than about four times \( D_1 \) for a single central cluster to work properly. If the 45 ft height rule is followed, this seems to limit central clusters to rooms with dimensions of 180 ft or less. However, the 45 ft rule can be ignored if the listeners cannot hear the talker without the aid of the
sound system. This is often the case in large indoor sports arenas.

34.3.2.2 Variations on the Central Cluster

Sometimes, in a long room with a relatively low ceiling, a second cluster is installed. The second cluster (and the third if more than two clusters are used) is installed some distance out in the room and the sound emanating from these clusters is electronically delayed so that a listener able to hear both clusters will seem to hear only one source, Fig. 34-17. The second cluster effectively divides the room into two rooms, and the first cluster now only has to cover a room that is half as long.

34.3.2.3 The Split Cluster

One way to install a cluster-type system and preserve central sight lines is to split the cluster with part on the left and part on the right, Fig. 34-18. Unfortunately, this design causes comb filtering in the audience area where the two clusters overlap.

To minimize comb filtering, minimize the amount of overlap between the two clusters. This is easier to accomplish in a room with a central aisle. Another way to minimize this problem, at least partially, is to lower the sound pressure level of one of the clusters about 3 dB and use that lower-level cluster to cover only those listeners who cannot adequately be covered by the other cluster. Design the louder cluster to cover as much of the listening audience as possible.

Line arrays are commonly used in a split-cluster configuration. In particular, column-style line arrays are popular for this application. Because of their narrow vertical dispersion and −3 dB attenuation per doubling of distance, column line arrays can be placed lower than a typical cluster—often at or just above the audience head height. Also, they are perceived as more attractive than other types of loudspeaker systems.

34.3.2.4 Stereo Clusters

For stereo music reinforcement, left and right clusters are required. In order for every listener to hear the stereo effect, both clusters must cover the entire audience. Because this conflicts with the guidelines developed in the previous section, many designers prefer the Left-Center-Right approach discussed next.

34.3.2.5 Left-Center-Right Clusters

For a system that has both voice and stereo or multichannel music, consider a left-center-right cluster design. In this arrangement, the center cluster primarily reinforces the spoken voice and the left and right clusters reinforce the music. It may be difficult for listeners at the left and right edges of the audience to hear the central cluster clearly. In this case, mix a little of the spoken word into the left and right clusters but delay it slightly so the voice appears to come from the central cluster.

It may also be difficult for listeners at the left and right edges of the audience to hear both channels of the music. One way to reduce this problem is to mix some of both the left and right channels of music into the central cluster. Of course, this will reduce the stereo effect for listeners seated in the center of the audience.
Left-center-right clusters are commonly used for dramatic performances where actors’ voices are panned from one side of the stage to the other. In this type of system it is imperative that every listener be able to hear all three clusters.

34.3.2.6 Exploded Clusters

Technically, the term exploded cluster refers to a conventional central cluster where individual packaged loudspeakers have been moved outwards (exploded) along radii from the original position. The term is often used, however, to describe any system where several, smaller clusters are used in place of a single, central cluster. In this sense, a left-center-right cluster system could be considered an exploded cluster.

Exploded clusters are often used in auditoriums with very wide stages and relatively shallow audience areas, Fig. 34-19. Many so-called mega churches in the United States are of this design. A central cluster cannot cover the sides of the room toward the stage effectively. A split cluster (including line arrays) cannot cover the center of the room toward the stage effectively. An exploded cluster is often a good compromise for this type of facility. Typically, left, center, and right clusters will be supplemented by an additional cluster between the left and center clusters and another between the right and center clusters.

![Figure 34-19. An exploded cluster loudspeaker system. Courtesy Community Professional.](image)

34.3.2.7 Rear and Surround Clusters

Rear and surround clusters are primarily used for special effects in live dramatic presentations. Design these clusters for the facility and presentation requirements. For example, if a rear cluster is to reinforce the spoken voice of an off-stage actor, it must cover the entire audience clearly. However, left and right clusters used for ambience effects may not need to cover the entire audience evenly.

34.3.2.8 Designing a Central Cluster in a Simple Rectangular Room

Most sound reinforcement system designers now use EASE or some other loudspeaker system design software to help them design their systems. The following method, used before this type of software was available, is presented for educational purposes and for historical completeness. In addition, some of the concepts presented here, such as methods of choosing loudspeakers, will be of value to a designer using EASE.

34.3.2.8.1 Evaluate the Room

If the room exists, measure its reverberation time and physical dimensions (drawings will help in physical measurements). Calculate the room volume and total surface area. Using the Sabine reverberation time equation, derive the average absorption coefficient, \( \bar{a} \), as follows:

\[
RT_{60} = \frac{0.049 V}{S\bar{a}}
\]  

(34-27)

where,

\( V \) is the room volume,

\( S \) is the room surface,

\( \bar{a} \) is the average absorption coefficient,

For metric distances, replace the constant 0.049 with the constant 0.161.

From this equation, the average absorption coefficient, \( \bar{a} \), can be found with

\[
\bar{a} = \frac{0.049 V}{S(RT_{60})}
\]  

(34-28)

For metric distances, replace the constant 0.049 with the constant 0.161.

If the room is in the planning stages only, estimate its average absorption coefficient, total surface area, and volume from the architectural data.
34.3.2.8.2 Choosing the Cluster Location

The ideal cluster location will probably be approximately above the primary microphone location; that is, in a rectangular room, the cluster should be near the top and at the center of an end wall. Compromise locations are discussed in the following sections.

34.3.2.8.3 Evaluating the Cluster Location

The potential success of a proposed cluster location and cluster design can be evaluated by answering “The Four Questions.” starting with Question 4: “Will it feed back?” Using available data and Eq. 34-21, answer this question before moving on to choose loudspeaker types.

34.3.2.8.4 Choosing the Loudspeakers

The following discussions assume the design will center around constant-directivity packaged loudspeaker systems for a speech or speech and music reinforcement system.

Begin the design by choosing a loudspeaker for coverage in the rear of the room. Use trigonometry or one of the cluster layout methods discussed in Section 34.3.2.9, and determine the horizontal (side-to-side) coverage angle required at the rear of the room. Using more than one loudspeaker to cover an area is discussed in the next section. Remember that the listener’s ears are approximately 4 ft (1.2 m) above the floor when determining required coverage angles. (This can be simulated in most design methods by placing an imaginary floor at 4 ft [1.2 m] above the actual floor.)

Once a rear coverage loudspeaker has been chosen, use its $Q$ value (from the manufacturer’s specification sheet) and the known parameters of the room to answer Question 3: “Can everyone understand?” by calculating the articulation loss of consonants ($Alcons$) from Eq. 34-18. Assume $N = 1$, then do the calculation over again using $N = 2$ and $N = 3$ to simulate the effects of adding loudspeakers to the system. If $Alcons$ is less than or equal to 10% for each of these calculations, the system design will work from the criteria of Question 3. If $Alcons$ exceeds 10% for any of these calculations, a second cluster or a distributed system may be required. (Note that some designers believe an $Alcons$ of 15% or less is acceptable.) It might seem logical, in this case, to simply choose a loudspeaker with a higher $Q$ value, since this would reduce the $Alcons$. That loudspeaker will also have a narrower coverage pattern, however, and might not adequately cover the entire audience. Using additional high $Q$ loudspeaker will not solve the problem either since they increase the value of $N$. Thus, if $Alcons$ is too high, about the only alternative to a second cluster or distributed system is to reduce the room reverberation time with acoustic treatment.

34.3.2.8.5 Aiming the Loudspeakers

If the $Alcons$ is acceptable, choose additional loudspeaker to cover the rest of the room, providing a yes answer to Question 2: “Can everybody hear?” In many rectangular rooms, only one or two additional (wider angle) loudspeakers will be required.

The edge of the defined coverage pattern of a loudspeaker is its –6 dB point. For this reason, it is common practice to overlap the coverage patterns of the loudspeakers in a cluster to compensate for the drop-off in coverage of each individual loudspeaker near the edges of its coverage pattern. A good rule for this practice is to overlap two loudspeakers as little as possible to maintain consistent coverage throughout an audience area. Another good rule is to aim the overlap areas at an unimportant part of the audience area such as an aisle.

Avoid aiming loudspeakers at hard rear or side walls (which could result in echoes) and avoid aiming them directly down at the microphone (which could increase the possibility of feedback). Again, remember to aim the loudspeakers at the listener’s ears (about 4 ft [1.2 m] above the floor for seated listeners or 5 ft [1.5 m] for standing listeners).

Now, re-evaluate Question 4: “Will it feed back?” by performing the calculations for PAG and NAG discussed in Section 34.2.3.4.5. The answers to the PAG and NAG equations may be tempered by recalculating $D_c$ for an increased value of $N$. If feedback seems possible, consider moving the cluster, or consider using an automatic microphone mixer to keep NOM = 1 or, when possible, teach the users to talk closer to the microphone (which reduces $D_s$), see Section 34.4.3. Using directional loudspeakers and microphones may provide some additional gain before feedback, but it’s best not to plan for this additional gain.

34.3.2.8.6 Powering the Cluster

The remaining question, Question 1: “Is the system loud enough?” can be answered by choosing loudspeakers and power amplifiers to satisfy Eq. 34-16 remembering the criteria for head room and SNR.
34.3.2.8.7 Low-Frequency Loudspeakers and Feedback

The published $Q$ for a two-way packaged loudspeaker system is a compromise between the relatively high $Q$ of the high-frequency horn and the lower $Q$ of the woofer. The same is true of three-way and four-way packaged loudspeaker systems. Using this published $Q$ in the PAG and NAG equations may provide an acceptable result. However, the lower $Q$ value of the woofer may, in some systems, result in feedback in the woofer’s frequency range.

34.3.2.8.8 Direct Sound and Feedback

The PAG and NAG equations assume the microphone is entirely in the reverberant field of the loudspeaker cluster. If the microphone is receiving any significant amount of direct sound from either low- or high-frequency loudspeakers, the PAG and NAG equations will not accurately predict feedback problems. This potential direct sound feedback problem must be considered qualitatively in the design of the cluster by aiming the loudspeakers away from the microphones. Since the low-frequency loudspeakers are normally low $Q$ and cannot be effectively aimed away from the microphone, they are often placed nearest the ceiling to be as far from the microphone as physically possible.

34.3.2.8.9 Other Considerations

At this point, the basic cluster design is finished. Consideration should be given, of course, to overall system head room, frequency response, distortion, and other sound-quality factors that help to answer Question 5, “Does it sound good?”

34.3.2.9 Answering Question 2: “Can Everybody Hear”

The cluster design process outlined in the last section includes little help in actually choosing and aiming the horns. Trigonometric methods may suffice for a simple room. For more complex rooms, most designers use EASE or Modeler or another computer software design tool.

34.3.2.9.1 History of Manual/Graphical Cluster Design Tools

Before the advent of EASE, Modeler, or other software design tools, system designers used one of several manual/graphical tools that were extensions of architectural mapping techniques. A user of one of these tools would overlay a graphical representation of the loudspeaker coverage pattern, known as an isobar, onto a specially prepared angular map of the room.

Because both the room map and loudspeaker isobar were angular, moving the isobar around the room map, was equivalent to re-aiming the horn. Thus, the user could aim the loudspeaker to estimate optimum coverage patterns. More than one loudspeaker isobar overlay could be used to estimate the coverage patterns of multiple, overlapping horns.

The concepts behind these methods were developed by several engineers including Thomas McCarthy of North Star Sound, and first commercialized as Altec’s Array Perspective. Fig. 34-20. The disadvantage of the Altec method was its lack of accuracy, especially when horn aiming angles were far from the zero line defined for the room map.

Figure 34-20. Array Perspective, a manual/graphical design method. Courtesy Bosch/Electro-Voice.

Another manual/graphical method, developed by John Prohs and David Harris at Ambassador College, used a transparent plastic sphere onto which the room was mapped. Semispherical plastic overlays represented horn patterns and could be moved around on the room map to simulate aiming the horns. This method resolved most of the accuracy problems of the flat transparency method and was commercialized by Community Light and Sound as the “Cluster Computer.”

A number of noted engineers and consultants contributed to the development of these manual/graphical design tools. Among them were Ed Seeley, Thomas McCarthy, Ted Uzzle, John Prohs and David Harris, Farrel Becker, Peter Tappan, Gene Patronis, and Bob Thurmond.
34.3.2.9.2 Commercial Computer Software Design Tools

As personal computers grew in power, the manual/graphical design tools were ported to the PC. Among the early computer programs for cluster design were JBL’s CADP, Bose Modeler, Electro-Voice/Altec AcoustaCADD, Thomas McCarthy’s Umbulus, and John Prohs PHD Program.

The cost of maintaining these programs and compiling the necessary database of loudspeakers is high and two commercial software programs have come to dominate the field. The first, EASE, was developed by consultant Dr. Wolfgang Anhert, and is distributed by Renkus-Heinz, Fig. 34-21. The other, Modeler, is a proprietary program developed and distributed by Bose. EASE runs on a Windows-based PC. Modeler runs on an Apple Macintosh or a Windows-based PC.

![Figure 34-21. EASE. Courtesy Renkus-Heinz.](image)

Modeler, while a very capable program, is only usable with Bose loudspeakers. Check with the Bose Corporation for updates to this policy. As a result, EASE, which can be used with any manufacturer’s loudspeakers, is preferred by most designers. Either program has a considerable learning curve and designers must attend one of the available training classes.

Before designing a cluster with either program, the user must enter a detailed room description in three dimensions. This means the user must have accurate and detailed room dimensions and should be familiar with computer aided drafting methods. The programs will import properly prepared computer aided drafting files, such as those produced with AutoCAD.

To use a chosen loudspeaker in either program, the loudspeaker manufacturer must provide compatible data files. Most major loudspeaker manufacturers provide these files but data files for certain loudspeaker models may not be available.

The requirement to enter detailed room data and the lack of availability of some loudspeaker data are limitations that may inhibit a designer from using EASE or Modeler on certain projects. However, the power and versatility of these programs are very high and most designers will want to utilize one of these programs for most projects. Chapters 9 and 35 provide additional details about computer room modeling and auralization.

34.3.2.9.3 Other Software Tools

Additional software tools are available for specialized applications. As an example, Syn-Aud-Con offers a multifunction spreadsheet that calculates many of the equations in this chapter and provides other useful functions.

34.3.2.10 Designing the Complex Cluster

Although programs like EASE and Modeler handle complex clusters well, it’s important for the designer to understand the difficulties behind such a design. In concept, the design of a multiloudspeaker central cluster in a room with complex geometry is no different from the simple rectangular room design discussed in Section 34.3.2. In practice, the complex cluster shown in Fig. 34-22 presents a set of new difficulties.

First, the complex cluster is most often designed for a large public facility. In practically every such situation, the budget will be tight, leaving no room for errors in design. It is simply not economically possible to redesign a large cluster after it has been installed.

Second, many of the approximations used in the simple cluster design method are too gross to be used in the design of a complex cluster. For example, the approximations used for the value of $N$ in the Alcons equation need to be refined for a complex cluster design.

Here, based on the four questions, is a primarily qualitative explanation of some of the refinements needed for the design of a complex cluster. Some quantitative explanations are given, but a full, quantitative analysis of the complex cluster is beyond the scope of this discussion. EASE or Modeler will greatly help in
Chapter 34

1266

While each space has different acoustics, they interact with each other in a complex way further complicating the process of calculating the reverberant field at any listener’s location, Fig. 34-23.

Even in rooms that are fairly well behaved acoustically and have a statistically random reverberant field, the calculation of reverberant field level is not simple. This is because this calculation requires a thorough knowledge of the characteristics of the cluster. Each loudspeaker adds an amount to the reverberant field that depends on the electrical power applied to the loudspeaker and its efficiency. While few manufacturers provide direct data on the efficiency of their loudspeakers, this can be calculated from a knowledge of the on-axis sensitivity and the $Q$.

Finally, all the factors involved in the reverberant field calculation vary with frequency so that, for full precision, a new set of calculations must be performed for each frequency of interest.

34.3.2.10.2 Simplifying the Complex Cluster Design Process

Before the advent of EASE, Modeler and the earlier software design tools, these complexities were so overwhelming that few designers made any attempt to deal with them directly. Instead, they used simplifications such as the $D_c$ Modifier approach. This approach involves calculating a value of $N$ for the cluster.

A simple estimate of $N$ is the total number of loudspeakers producing the same acoustic power as the loudspeaker pointed at any given listener. For example, if there are three loudspeakers in the system, all producing the same acoustic power, and only one loudspeaker is pointed at the listener, then $N$ equals 3. If there are four loudspeakers, two of which are pointed at the listener, the situation is the same as having two loudspeakers with one pointed at the listener. Therefore, $N$ would equal 2.

It’s possible to extend this simple estimate in a logical manner resulting in a value of $N$ for almost any cluster. However, the process itself is complex and it depends on estimates for the acoustic power output of each loudspeaker calculated from the loudspeaker’s published $Q$ and $L_s$, both of which are compromise values that vary with frequency.

A better way is to rely on a software evaluation of the complex cluster performed by EASE or Modeler or one of the other software design tools. The detailed loudspeaker data required by these software tools enables them to calculate the acoustic power output of each loudspeaker and, thus, its contribution to the rever-

Figure 34-22. A large, complex cluster. Courtesy JBL Professional.

the design of a complex cluster, but only when all room and loudspeaker data is accurate. In any case, the complexity of the design process and the economic consequences of errors are significant enough that the services of an experienced, qualified acoustical consultant are highly recommended.

34.3.2.10.1 The Fundamental Complexity

When a cluster involves more than perhaps two or three loudspeakers, its operation becomes complex. The calculation of $Alcons$ for a far-throw loudspeaker, for example, cannot ignore the reverberant field contributions from the other loudspeakers in the cluster. A qualitative method of dealing with the problem is straightforward. The direct sound level at each listener can be calculated via the inverse-square law, Eq. 34-1, from a knowledge of which loudspeaker or loudspeakers are aimed at the listener. The total reverberant field sound pressure level can be calculated by adding the total acoustic power output of all the loudspeakers and placing this value into a modified form of the room reverberation equation. Answering the four questions becomes a matter of using either the direct sound, the direct plus reverberant sound, or a direct/reverberant ratio.$^5$.$^6$

Calculating the reverberant field level in the room requires a detailed knowledge of the room’s acoustic parameters, however, and in many rooms, the acoustic parameters change from position to position in the room. A religious facility in the shape of a cross (cruciform church), with balconies in each wing, for example, may have several totally acoustically different spaces that can be covered from the same cluster location.
34.3.2.10.3 The Four Questions for the Complex Cluster

34.3.2.10.4 Question 1: Is the System Loud Enough?

For the complex cluster, a new approach is indicated. That approach is to find the total direct sound level at the listener’s position, and to add them to get the overall total sound level at that position. Comparing and adjusting this overall level with the desired $L_P$ (i.e., is it at least 15 dB above ambient noise?) will provide the required EPR. It is also possible to use the original indoor EPR equation (Eq. 34-16) by calculating a value for the $D_c$ modifier $N$ and using this value of $N$ in the critical distance portion of the EPR calculations.

Many designers believe that, although the reverberant energy in a room can aid the perception of useful loudness, it is the direct sound level that is most important. The $L_{P_d}$ can, of course, always be calculated via the inverse-square law, Eq. 34-1. If a listener is in the direct field of more than one loudspeaker, the direct sound from all such loudspeakers can be added to obtain the total $L_{P_d}$ at the listener. If the $L_{P_d}$ level at the listener is high enough, the $L_{P_t}$ will also be high enough, thus, answering Question 1 satisfactorily.

34.3.2.10.5 Question 2: Can Everybody Hear?

For a complex cluster, the answer to Question 2 can be obtained manually. However, given accurate data, software tools like EASE and Modeler provide a detailed and accurate answer that makes these tools the best way to answer Question 2.

34.3.2.10.6 Question 3: Can Everybody Understand?

The $Alcons$ equation, like the EPR equation, may be used for a complex cluster by calculating a value of $N$ as discussed in Section 34.3.2.10.

Another method is to calculate the direct field and the reverberant field at each listener’s position of interest and perform a direct/reverberant comparison. Since the $Alcons$ concept is based on the direct/reverberant ratio, a knowledge of the actual numeric direct/reverberant ratio is equivalent to a knowledge of the numeric value of $Alcons$. However, the $Alcons$ equation assumes a 25 dB SNR. In rooms with a higher level of ambient noise, use Eq. 34-20. EASE and Modeler also provide good estimates of intelligibility at each listener’s position.

34.3.2.10.7 Question 4: Will It Feed Back?

This question can be answered by calculating the total sound level (direct plus reverberant) reaching the microphone from the cluster. If this level is equal to or greater than the level expected from the talker at the micro-
phone, then the system will almost certainly feed back. If the total direct plus reverberant level at the microphone is at least −6 dB below the expected level from the talker, the system will probably be stable.

Reference 6 provides a method, if complicated, for calculating the total reverberant level at the microphone from a complex cluster. The PAG and NAG equations may be used with a value of N, calculated as discussed in Section 34.3.2.10 for the complex cluster, although the direct plus reverberant approach will probably give a more accurate result. EASE and Modeler also provide this capability.

The actual feedback process also involves reflections from near the microphone, since these reflections can increase the sound level at the microphone by as much as 6 dB (for a reflection from a hard surface that is in phase with the source sound and, therefore, adds coherently with the source sound). Thus, such a reflection could cause a system to feed back even when calculations would show a 6 dB feedback stability margin.

Addition of more than one microphone to the complex cluster system will not automatically lower the gain before feedback by 3 dB as indicated in the PAG equation. That is because each microphone may receive a different amount of direct sound from the cluster and may be subjected to different nearby reflections. Assuming similar microphone locations, however, simplifies the calculation, and a 3 dB reduction in gain before feedback is a reasonable assumption in most systems. This means that the total sound level from the cluster reaching either microphone must be about −9 dB below the expected talker level at that microphone to achieve the 6 dB feedback stability margin. This also, of course, assumes that the gain (volume control setting) of each microphone is similar.

Signal alignment can work well when the audience is concentrated in a small area. However, it is very difficult to design a cluster to be properly signal aligned for a larger audience area. Aligning the cluster for one listener may make matters worse for another listener. Also, correct signal alignment can vary with frequency. As a result of these and other problems, signal alignment is best for very simple clusters or for clusters that have been specifically designed for signal alignment.

Another solution to the problem of signal alignment is to purposely misalign the loudspeakers in such a way as to simulate beneficial reflections (see Section 34.2.3.1.2). This concept relies on the idea that a delayed signal arriving between approximately 20 ms and 50 ms after the original signal is beneficial to both Lp and intelligibility.

Purposeful misalignment ideas can be used to advantage in designing an exploded cluster. Following this concept, it is acceptable for a listener to hear two clusters at once if the signal from the second cluster arrives between 20 ms and 50 ms after the signal from the first cluster. Some designers use DSP signal delay on alternate clusters in an exploded cluster to achieve this goal.

It is even possible to combine the concepts of signal alignment and purposeful misalignment by carefully aligning a small cluster and purposely misaligning that cluster with another, nearby cluster. However, there is as much art as science in the implementation of either signal alignment or purposeful misalignment. For this reason, the designer is cautioned to rely on traditional cluster design principles and to not depend on signal alignment or purposeful misalignment for the success of a design.

34.3.3 The Distributed Loudspeaker System

There are several types of distributed loudspeaker systems but all share a common theme. In contrast to a central cluster where the loudspeakers are all concentrated in one location, the loudspeakers in a distributed system are distributed throughout the audience area in such a way as to cover the area evenly.

Because every listener is more or less the same distance from a loudspeaker, coverage can be very uniform from a distributed system. In addition, if the system is carefully designed, the potential for feedback should be very low, and because every listener is relatively near a loudspeaker, the direct/reverberant ratio is high and intelligibility is often very good.

Thus, in the ideal case, a well-designed distributed system can work very well. One problem with even the ideal distributed system, however, is that the listeners
will hear the sound coming from over their heads. That is, the natural localization provided by a central cluster is not provided by a distributed system. This problem is usually minor and can be minimized by using an electronic signal delay in combination with a localizer loudspeaker, a subject covered in Section 34.3.3.8.1.

Sometimes, a distributed system will be installed in a very large room with a high reverberation time. A convention hall exhibit room or high-ceiling airport terminal is a good example. This type of system will probably be used for paging and perhaps for background music. Thus, the localization of a central cluster is not needed. The high reverberation and high noise present in rooms like this, however, present problems to the system designer. These problems can be at least partially overcome by a dense enough layout and careful equalization. In these areas $N \alpha$ also plays an important role. The distributed system has an additional advantage over the central cluster in this case because it effectively reduces the value of $D_2$ (the distance from the loudspeaker to the farthest listener) and, thus, improves the SNR and the direct/reverberant ratio.

Another reason for using a distributed system, even in a room that could utilize a central cluster, is that the distributed system allows a more flexible room layout than the central cluster. In some multipurpose rooms, for example, the stage location may be changed from event to event, and some events may not use a stage at all. The distributed system allows almost any location to be used as the stage or primary microphone location without the distraction that would be caused by having a central cluster behind the heads of the audience. In addition, in large, reverberant spaces, like sports arenas, distributed loudspeakers above unused portions of the room can be turned off. This helps intelligibility because it improves the direct/reverberant ratio by lowering the amount of energy uselessly put into the reverberant field.

The primary disadvantage of any distributed system is its (usual) higher cost compared with a central cluster designed for the same space (assuming that a central cluster could work in the space).

### 34.3.3.1 Distributed Ceiling Loudspeaker Systems

Distributed ceiling loudspeaker systems are normally installed in rooms with low ceilings (low compared to the length and width dimensions of the room) where a central cluster or distributed cluster system cannot adequately cover the room. In some situations where a central cluster would work from a design point of view, a distributed system is chosen for its versatility. A distributed system (without delay) does not have the psychoacoustic localization of a central cluster. Thus, microphone locations can be varied without worrying about the effects on localization. Loudspeakers can be turned off above microphone locations making multiple (or varying) microphone locations possible while reducing feedback potential. Loudspeakers can also be turned off in areas not in use to avoid exciting the reverberant field in those areas. Adding variable signal delay makes it possible to provide the psychoacoustic localization of a central cluster from any chosen microphone location, Fig. 34-24.

![Figure 34-24](image)

#### Figure 34-24

Ceiling distributed loudspeaker system with signal delay and localizer loudspeaker. Courtesy Bosch/Electro-Voice.

### 34.3.3.2 Central Cluster Plus Distributed System

In some rooms with central clusters and rear balconies, listeners seated under the balcony are not adequately covered by the central cluster. In this case, a distributed
system, placed under the balcony, with signal delay, can provide coverage for the under-balcony listeners, Fig. 34-25. A good rule of thumb is that every listener under a balcony should have good line of sight to the loudspeaker covering his or her area in order to hear the central cluster well. If any part of the central cluster is shadowed by the balcony, consider a distributed, under-balcony, signal-delayed system.

34.3.3.3 Multicluster System

A multicluster system could be considered a distributed system. Also, in the large arenas and exhibit halls mentioned previously, horn/woofer components more typical of a central cluster may be used in the distributed system simply to produce a higher $L_p$ capability.

34.3.3.4 Distributed Column System

One common variation on the distributed system is called a distributed column system, Fig. 34-26. This type of system is normally installed in a long, narrow religious cathedral where a central cluster cannot be installed for aesthetic reasons. A group of column-type loudspeakers (or some other type of packaged loudspeaker systems with appropriate dispersion) are installed. Electronic signal delay and a localizer loudspeaker may be included. This system can have the same problems as the split cluster described earlier, however, and should be used only in narrow rooms to minimize these problems.

34.3.3.5 Pew-Back Distributed System

Another distributed variation for churches is known as the pew-back system. In this system, pioneered by consultant David Klepper, a large number of small loudspeakers (usually one loudspeaker for every two to three listeners) is placed on the backs of the pews and facing the listeners. Signal delay is required. One problem with a pew-back system is the significant change in $D_2$ and loudspeaker $Q$ when the listeners stand up (the listeners move both farther away from the loudspeaker and more off axis of the loudspeaker). Another problem is the large value of $N$ caused by the large number of active loudspeakers. To partially overcome the $N$ problem, add a latching relay in each enclosure and a “push-to-listen” button. This way, loudspeakers in pews with no listeners will not be turned on, and those loudspeakers will not uselessly add to the reverberant field intensity.

Both the distributed column system and the pew-back system are difficult to design and install properly. As with any difficult design, an experienced acoustical consultant may be the best answer to getting a costly job done right the first time.

34.3.3.6 Loudspeakers for Distributed Systems

34.3.3.6.1 Ceiling Loudspeaker Systems

Typical ceiling loudspeakers are 4 inch or 8 inch cone-type components that often come in a package that includes a round metal enclosure, grille, and 70 V transformer, Fig. 34-27. Those designed for installation in a dropped ceiling may also include an optional T-bar suspension system. Some may be UL listed for fire signaling or fire resistance. This type of ceiling loudspeaker is intended for sound reinforcement, business music, and paging in applications that do not require high SPL levels.

Larger ceiling loudspeakers and enclosures are designed for use in convention centers, arenas, and other applications that may require mid- to high SPL levels and a wide frequency range. These systems typi-
cally use a 12 or 15 inch coaxial loudspeaker component, Fig. 34-28.

34.3.3.7 Designing the Distributed Ceiling System

Skipping Question 2 momentarily, here are discussions of the other three questions for a distributed ceiling system.

34.3.3.7.1 Question 1: Is It Loud Enough?

One of the advantages of a distributed system is that a typical listener is about the same distance from the nearest loudspeaker as any other listener. In addition, these distances are usually short compared to the critical distance $D_c$. Thus, the direct sound, not the reverberant sound, is the primary component of the $L_p$ reaching the listener and the electrical power required (EPR) equation for the simplified system, Eq. 34-6, can be used. Use a single loudspeaker for this calculation for the minimum-overlap configurations (see Question 2, following). For the 50% overlap configurations, subtract 3 dB from the desired sound pressure level for the calculation of EPR to a single loudspeaker, since the equivalent of at least two loudspeakers will be covering each listener. If the room is highly reverberant and/or the ceiling height is sufficient to make the reverberant field a significant component of the sound at the listener’s ears, the indoor EPR equation (Eq. 34-16 or 34-17) may be used. To include the effect of the multiple sources, use a value of $Q = 3/N$, where $N$ is the total number of distributed loudspeakers in the critical distance $D_c$ calculation. The number 3 is a typical $Q$ for a distributed
coaxial loudspeaker (an actual $Q$ should be used if available). The value of $N$ should be divided by two if each listener can hear the direct sound from two nearby loudspeakers and so on. Using the simplified method of Eq. 34-6 will always provide a safe answer to Question 1 since it considers direct sound only.

34.3.3.7.2 Question 3: Can Everybody Understand?

The Alcons equation (Eq. 34-18) works well for a distributed system. For the value of $N$, divide the total number of distributed loudspeakers in the room by the number of loudspeakers producing direct sound to a listener. Thus, if each listener is in the direct field of two loudspeakers, use a value of $N$ equal to one-half the total number of loudspeakers and so on. Use a value of $Q$ equal to the actual $Q$ of each individual distributed loudspeaker. A good estimate for a coaxial ceiling loudspeaker is $Q = 3$. As with a central cluster system, try to maintain a 15 dB SNR and keep distortion, hum, and so on at a minimum for best intelligibility. In addition, remember that the Alcons equation works best for rooms with reverberation times of at least 1.6 s. In rooms with a lower $RT_{60}$, intelligibility is affected primarily by signal to noise.

34.3.3.7.3 Question 4: Will It Feed Back?

Avoid placing microphones directly under a working loudspeaker. Provide switches to turn off loudspeakers above microphones when microphone positions will vary. Alternately, use an automatic mixer with logic outputs to automatically turn off loudspeakers above the active microphone. For conference rooms and other systems with fixed microphone positions, use an automatic microphone mixer with matrix output to create a mix-minus output signal routing system that always minimizes the signal from any microphone into a nearby loudspeaker (see Section 34.6.5). Use the PAG and NAG equations (Eqs. 34-19 and 34-20) with $Q = 3/N$ (see discussion under Question 1 previously) if the room has a significant reverberant component.

34.3.3.7.4 Question 2: Can Everybody Hear?

There are two basic patterns for laying out a distributed ceiling loudspeaker system. They are the square and hexagonal patterns, as shown in Fig. 34-30. There are at least three variations of each of these two patterns, as shown in Figs. 34-31 and 34-32. The variations are in the spacing between the loudspeakers. An edge-to-edge spacing places the loudspeakers so that their coverage patterns just touch each other. A minimum-overlap spacing overlaps the coverage of the loudspeakers just enough to cover the dead spot in the edge-to-edge pattern. A 50% overlap is just that; each loudspeaker’s coverage pattern overlaps the pattern of its neighbor by 50%. The result is that each loudspeaker is completely overlapped by a group of its neighbors.

The choice of one of these patterns should be made on the basis of the acoustics of the room, the ambient noise, and the type of listeners and talkers. In a difficult situation, such as might be encountered in a reverberant space with significant ambient noise and some listeners with hearing difficulties, a 50% overlap is indicated. For business music (background music) an edge-to-edge pattern may suffice.
In any choice of coverage pattern, room obstacles, microphone locations, and seating area should be considered. There is no reason, for example, to cover wide aisles unless people will frequently be located there. In addition, remember that the coverage pattern should be calculated at about 4 ft above the floor for seated listeners or 5 ft above the floor for standing listeners.

34.3.3.7.5 Equalizing the Distributed Ceiling System

Equalization is discussed in more detail in Section 34.5.2.2. However, in general, the equalization process is the same as for a central cluster system. A typical listener position may be best chosen as in the overlap area of the loudspeakers for a 50% overlap system, or about 20° off-axis of a single loudspeaker for an edge-to-edge or minimum-overlap system. As in the central cluster process, choose several typical positions and equalize for a position that seems to be a good average as far as the before-equalization response. In an acoustically dry room (no significant reverberation field) the equalized response should show more high frequencies than the cluster system guidelines would indicate. This is because there is no low-frequency reverberation to boost the low frequencies artificially and bias the display on the real-time analyzer.

34.3.3.7.6 Distributed Systems in Rooms with Sloped Floors or Ceilings

The traditional approach for a system with sloped floors or ceilings is to divide the room into sections where the ceiling height is relatively constant and design a loudspeaker layout separately for each section. This will result in fewer loudspeakers per unit area in the higher-ceiling portions of the room as shown in Fig. 34-33. Additional power must be allocated to those loudspeakers in the high-ceiling portions.

Another approach to a sloped-ceiling room is to place the loudspeakers as if the ceiling was flat at the lowest height and apply the same power to each loud-
might be used to cover a long, narrow religious facility where a single cluster could not provide acceptable intelligibility in the rear seats. A second ring of clusters may also be installed in a large, fan-shaped room where the main system is an exploded cluster design. In this case, the second ring of clusters is installed on radii from the main clusters.

An examination of the $Alcons$ equation (Eq. 34-18) shows that either increasing $Q$ or decreasing $D_2$ will improve intelligibility. In the case where a loudspeaker with high enough $Q$ will not provide wide enough coverage or where a loudspeaker with high enough $Q$ is simply not available, adding one or more additional clusters that are closer to the far listeners may be the answer since this decreases $D_2$.

Design the first cluster (or exploded clusters) to cover the seating areas out to (and slightly beyond) the position of the second cluster (or second ring of clusters). All other design criteria for the first cluster remain the same as if it were the only cluster. The value of $N$ (the $D_c$ modifier) for either cluster must include the effects of both clusters, however. Design the second cluster to cover the remaining seating area to the farthest listener. In many systems of this type, the second cluster can have a reduced low-frequency section for frequencies below about 200 Hz. This is because the frequencies below 200 Hz do not contribute to intelligibility and because the reverberant field in most rooms requiring a second cluster will carry the low frequencies to the farthest listener with no need for reinforcement from the second cluster.

In calculating $Alcons$ (or $EPR$ or $PAG$ and $NAG$) for either cluster, the value of $N$ must take into account the loudspeakers in both clusters, although the value of $D_2$, of course, will be shorter than it would have been for a single cluster in the same room.

### 34.3.3.8.1 Signal Delay in a Distributed Cluster System

The second cluster in the previous example must receive a signal that is electronically delayed from the signal sent to the first cluster. See Section 34.3.3.8.1 for an example of calculating this delay.

### 34.3.3.8.2 Distributed Clusters with No Delay

In a circular stadium or on long, narrow bleachers such as at a race track, a system of distributed clusters may provide the best coverage and may not require electronic delay because the sound reaching each listener is primarily from one cluster and any nearby cluster is
essentially the same distance from the listener (and thus not acoustically delayed). Design of each cluster in such a system is straightforward. Choose a seating area that can be easily covered by a single cluster. Calculate the difference in distance from a typical listener to adjacent clusters. Avoid wide spacing between clusters that could cause a listener hearing two clusters to hear the second cluster as an echo of the first. Provide sufficient overlap between coverage areas to insure adequate sound pressure level to all listeners but avoid wide overlap areas to prevent the problems inherent in the split cluster discussed in Section 34.3.2.3.

This same approach applies to smaller loudspeakers distributed around the concourse in an arena or along the sidewalk leading to a theme park attraction.

34.3.3.8.3 Equalizing the Distributed Cluster System

Equalization is discussed in more detail in Section 34.5.2.2. However, if all clusters in a distributed cluster system are the same and are covering areas with similar acoustics, equalization may be performed for a single cluster and duplicated for the other clusters. Check the response of the other areas to confirm the equalized curve is similar. If clusters are covering acoustically different areas or if they are designed for different loudspeakers, each type of area or loudspeaker must receive separate equalization (the central cluster plus under-balcony distributed system, for example).

34.3.4 Crossover Networks and Biampification

Loudspeaker crossover networks are also discussed in Chapter 17.

34.3.4.1 Definitions

Crossover Network. A crossover network is a filter network that routes high frequencies to a high-frequency loudspeaker and low frequencies to a low-frequency loudspeaker. If the crossover network is part of a biampified system, it will do its frequency division prior to the power amplifiers. Three-way and four-way crossovers perform the same function but divide the frequencies into more sections.

Passive Device. A passive device uses no active components (tubes, transistors, ICs) and needs no power supply (ac, dc, battery). The crossover network in a typical packaged loudspeaker system is a passive device.

Active Device. An active device uses one or more active components and requires some type of power supply. An electronic crossover, used in a biampified system, is an active device.

Biamplified System. A biampified system uses an electronic crossover (commonly a module in a DSP) and it uses separate power amplifiers for the high- and low-frequency loudspeakers, Fig. 34-34. A triamplified system is a three-way loudspeaker system with a three-way electronic crossover and separate power amplifiers for the low-, mid-, and high-frequency loudspeakers. To simplify, we often speak of triamplified and multiamplified systems as being biampified.

![Diagram of Crossover Networks](image)

Figure 34-34. Biamplified and nonbiamplified systems.

Head Room. Headroom is the difference, in decibels, between the peak and rms levels in the program material.

34.3.4.2 Advantages of a Biamplified System

One advantage of a biamplified system is that it can actually provide more head room per watt of amplifier power than a system with a traditional (loudspeaker level) passive crossover.

The reason this happens is that most music, especially popular music, is bass heavy; that is, there is much more energy at low frequencies than at high frequencies. When both high and low frequencies are present in a program, the high-energy bass frequencies will dominate the output of the system power amplifier.
leaving little or no power for the high frequencies. The result can be severe amplifier clipping (distortion) of the high-frequency material. By biamping the system, with an electronic crossover, the high-frequency material can be routed to its own power amplifier avoiding the clipping problem. This results in an effective increase in head room that is greater than that which would be obtained by simply using a single power amplifier of equal power output.

Another advantage of biamplification is that it does not absorb amplifier power as a loudspeaker-level passive crossover does. Biamplification, by removing this loudspeaker-level crossover, improves the overall system efficiency.

Improved damping factor is another advantage of biamplification. The damping factor of a power amplifier is a number found by dividing its load impedance (the impedance of the loudspeakers) by the actual output impedance of the amplifier, which will be very low for a modern solid state power amplifier. An amplifier with a high damping factor can exert a greater control over the motions of a loudspeaker cone than an amplifier with a low damping factor. Thus, a high damping factor may improve the sound quality of a system. A loudspeaker-level passive crossover lowers the damping factor by inserting its impedance between the amplifier and the loudspeakers. Removing the loudspeaker-level passive crossover, and biamplifying the system, can thus improve the damping factor.

Biamplification can lower distortion by increasing head room as explained previously. However, if clipping distortion occurs anyway, it may be less audible in a biamplified system. In a conventional, nonbiamplified system, the high-frequency harmonics generated by clipping of a low-frequency transient are passed through the loudspeaker-level crossover to the high-frequency loudspeaker where they will be quite audible. In a biamplified system, there is no crossover and no high-frequency loudspeaker after the low-frequency power amplifier. Thus, the clipped low-frequency signals and their harmonics are restricted to the low-frequency loudspeaker and, due to its poor high-frequency response, the low-frequency loudspeaker attenuates the audibility of these unwanted harmonics.

### 34.3.4.4 Signal Alignment in a Loudspeaker Crossover Network

In the crossover frequency range the output from the loudspeaker system includes output from both the high- and low-frequency components. If the arrival time, at the listener’s ears, of the signal from the high-frequency component differs from the arrival time of the signal from the low-frequency component, significant frequency response degradation can result near the crossover frequency.

The solution to this problem is to physically or electronically align the low- and high-frequency components so that their signal arrivals coincide at the listener’s ears.

### 34.3.5 Protecting the Loudspeakers

#### 34.3.5.1 Loudspeaker Failure Modes

The discussions in this section apply equally to both low-frequency cone-type loudspeakers and high-frequency compression drivers.

Discounting manufacturing defects that may cause random failures, loudspeakers normally fail from either excessive average power or from excessive peak power at low frequencies. Loudspeakers may also fail due to materials aging, physical damage, weather-related deterioration or damage from insects or other pests.

Excessive average power causes voice coil heating and eventually voice coil failure (or failure of other components in the voice coil area). Excessive low-frequency peak power causes mechanical failure of the loudspeaker due to overexcursion. The voice coil may separate from the rest of the loudspeaker or the loudspeaker cone (or driver diaphragm) may tear or shatter. Protecting a loudspeaker, then, is primarily a
manner of preventing these two failure modes and protecting it from weather, physical damage, and pests.

34.3.5.1.1 Choosing Power Amplifiers to Prevent Excessive Average Power

It is possible to destroy a loudspeaker by using a power amplifier that is too large (one whose power output exceeds the power capacity of the loudspeaker by some margin). It is also possible, under some conditions, to destroy a loudspeaker by using a too-small amplifier.

The too-small amplifier is one that does not have enough power output to meet the requirements of both the needed $L_P$ at the farthest listener and the system head room (from the electrical power required equation). Attempting to reach the system requirements will exceed output capabilities of the amplifier, which will cause the amplifier to clip, turning sine waves into semisquare waves and vastly increasing distortion levels.

This clipping causes two problems. First, the square wave can actually draw twice the power output from the power amplifier. That is, if the amplifier is rated at 100 W, a full-voltage square wave can cause the amplifier to deliver as much as 200 W, depending on power-supply limitations and the internal protection circuits of the amplifier. This double power output can be a threat to the loudspeaker all by itself. Second, the square wave causes the loudspeaker cone/diaphragm to move outward (or inward) and stay there for awhile, then move in the other direction and stay there for awhile. When the loudspeaker cone/diaphragm is not moving (at the top and bottom of the square wave), the energy supplied to the voice coil is being entirely converted into heat, with obvious consequences.

Thus, one way to prevent loudspeaker damage is to use a power amplifier that has enough output to reach the maximum $L_P$ requirement and the system head room requirement. Fortunately, in most sound reinforcement systems, actual electrical power required is small, and therefore the problem of a too-small power amplifier shows up primarily in large sound reinforcement systems or in popular music-oriented entertainment systems.

Loudspeaker power capacity is usually rated using some type of noise with a specified head room factor. For example, a loudspeaker may be rated at 100 W continuous pink-noise, with a 10 dB crest factor from 50–1000 Hz. That crest factor is the difference between the average and peak power in the pink-noise signal. The crest factor concept is similar to head room in the sound reinforcement system. Thus, in theory, this loudspeaker can be fed 100 W of pink-noise, band limited from 50–1000 Hz, and with peaks that reach 1000 W. The 100 W loudspeaker is, theoretically, safe with a 1000 W amplifier if system head room is kept at 10 dB or above. In practice, of course, it is very risky to power a 100 W loudspeaker from a 1000 W amplifier. The reasons are many but include the operator who will push the system past its design limits, ignoring distortion and the possibility of sustained feedback that can draw full power from the power amplifier for an extended period.

What then is a safe power amplifier size for a 100 W loudspeaker? In most systems, about twice the rated power capacity of the loudspeaker will be safe provided other potential problems are considered, as discussed in Section 34.3.5.1. In addition, the amplifier should, as previously discussed, be at least capable of supplying enough power to meet the system maximum $L_P$ and head room needs. Full-power, sustained feedback can still, of course, destroy the loudspeaker, but at only twice the rated power capacity of the loudspeaker, the system will likely sound very distorted before the loudspeaker is in danger. This should prompt the system operator to turn down the level, preventing damage.

34.3.5.1.2 Loudspeaker Power Capacity Specifications

Besides pink-noise power capacity, manufacturers commonly use several other power capacity rating methods. Variations on the concept of program power are used in an attempt to define the loudspeaker’s power capacity when the source is normal program material. The interpretation of normal program material, of course, depends on the manufacturer and it is common for this power capacity rating to be significantly higher than other ratings.

Rms power is another common rating method. Mathematically, there is no such thing as rms power. rms power is calculated from rms voltage and load resistance. The correct term should be average power. However, an rms power rating for a loudspeaker is usually similar to a pink-noise rating.

The EIA (Electronic Industries Association) has a loudspeaker power capacity standard using shaped noise that is similar to a pink-noise rating with low- and high-frequency roll-off. This standard, known as EIA RS-426A, is a reasonably reliable indication of the loudspeaker’s thermal power capacity and is similar to a pink-noise power capacity.

There are other methods of rating loudspeaker power capacity (see Chapter 17), but because of the complexity of the subject, all require some interpreta-
tion. It may be that a single number is simply not sufficient to fully describe a loudspeaker’s power capacity.

### 34.3.5.2 Protecting against Excessive Low-Frequency Peak Power

The cone/diaphragm excursion of a loudspeaker increases at low frequencies. The exact amount of increase depends partly on the enclosure or horn the loudspeaker (or high-frequency driver) is used with. Nevertheless, there is some frequency below which each loudspeaker/enclosure or driver/horn should not be used. This low-frequency limit is normally given in the manufacturer’s specifications or, for a vented enclosure design, may be estimated as $f_b$ (the vented box resonant frequency). At very low input power, frequencies lower than this limit will not cause damage. At normal to high power inputs, however, low frequencies can cause loudspeaker damage due to overexcursion.

The cure for this overexcursion is simply to prevent these low frequencies from ever reaching the loudspeaker by using some type of high-pass filter. This may be in the form of a system crossover network, which prevents low frequencies from reaching the high-frequency loudspeaker, or in the form of a separate high-pass filter (often part of a graphic equalizer or DSP), which prevents very low frequencies from reaching the low-frequency loudspeaker. One valuable protection device is a series capacitor, used on the high-frequency loudspeaker, which can reduce the effects of any low frequencies that may pass through the power amplifier due to such problems as turnon/turnoff transients.

Significantly, excessive power input to a loudspeaker at frequencies above its rated frequency range can also be dangerous. Since the loudspeaker cannot produce sound from these frequencies, the input power is mostly converted into heat, adding to the potential problem of excessive average power.

### 34.3.5.3 Loudspeaker Protection Devices

Careful system design and operation by an experienced operator are the best protection against loudspeaker failure. The following devices can help, however, and may be used in almost any system design.

#### 34.3.5.3.1 Fuses

Fuses are poor loudspeaker protection devices. Standard fuses may be capable of protecting a loudspeaker against excessive average power, but they are too slow to protect a loudspeaker successfully against sudden peaks. Fast-blow instrumentation fuses, with improved time response, may blow on normal program peaks and needlessly disrupt sound system operation. Slow-blowing fuses, on the other hand, may not blow quickly enough to prevent loudspeaker damage due to voice coil overheating.

Despite these limitations, fuses are sometimes used as loudspeaker protection devices. If fuses are used, fuse each loudspeaker separately so that a single fuse failure will not completely interrupt system operation. Choose a starting fuse size from the following equation:

$$ F = 0.75 \left( \frac{P}{Z} \right) $$

(34-29)

where,

- $F$ is the fuse size in amperes,
- $P$ is the rated power capacity of the loudspeaker,
- $Z$ is the rated impedance of the loudspeaker.

This equation gives a fuse size that will blow when the input power to the loudspeaker reaches 75% of its rated value. Fuse size may be increased if this fuse blows frequently, but avoid fuses larger than about twice this value since they will pass enough current to overpower the loudspeaker.

Early direct-coupled power amplifiers, when they failed, would often pass their full dc supply voltage to the loudspeaker. This voltage can result in loudspeaker/driver voice coils that are described as being “french fried.” A fuse will help protect a loudspeaker against this type of power amplifier failure mode. On high-frequency loudspeakers, however, a capacitor is probably a better protection device against this problem. In addition, most modern power amplifiers have some kind of internal protection (such as an output relay) that should prevent the problem of dc at the output even when the amplifier itself fails.

#### 34.3.5.3.2 Capacitors

A series capacitor (connected electrically in series with the loudspeaker’s positive input lead) can help prevent excessive low-frequency power and can protect the loudspeaker against dc power from a faulty power amplifier. Capacitors can be chosen from

$$ C = \frac{500,000}{\pi f Z} $$

(34-30)

where,

- $C$ is the value of the capacitor in microfarads,
- $Z$ is the rated impedance of the loudspeaker,
A limiter is not normally considered a loudspeaker protection device, but it may be one of the best and most practical. The limiter, Fig. 34-35, can be adjusted to prevent the system power amplifier from exceeding its power output capabilities and can help prevent high-power peaks from reaching the loudspeakers. In systems where sound quality is a primary consideration, adjust the limiter so that its threshold is high and its compression ratio is high. This way, the limiter will not be in operation until a potentially dangerous peak is detected. Then, the high compression ratio of the limiter will clamp the peak and help prevent loudspeaker damage.

34.3.5.3.4 Other Protection Devices

Transformers can help protect loudspeakers because they cannot pass dc. In the past, some transformers included series capacitors to limit the low-frequency energy to a high-frequency driver. Autotransformers, on the other hand, may pass dc to a loudspeaker since they have only a single winding.

Passive crossover networks, because they include one or more series capacitors, provide good protection for high-frequency drivers and some protection for the low-frequency loudspeaker (against excessive high-frequency power levels). The passive crossover networks used in some packaged loudspeaker systems include sophisticated protection circuitry. The manufacturer will normally specify this in its sales literature and instruction manuals.

High-pass and low-pass filters, similar to those often found in a DSP or on a graphic equalizer, are valuable in any system. A high-pass filter helps keep out unwanted low frequencies that could cause overexcursion. A general rule is that, except for subwoofer systems, a 40–160 Hz high-pass filter should be used in all systems. Even for subwoofers, a 10–20 Hz (or higher) high-pass filter can help prevent dangerous overexcursion. High-pass filters are often available on mixer input channels. Using them here can help reduce damage from dropped microphones or other problems. Low-pass filters help prevent heat-producing radio-frequency energy (picked up from outside sources or from faulty system electronics) from reaching the loudspeakers. Low-pass filters also keep out audio frequencies above the loudspeaker’s range (which would also cause unwanted heating).
Special-purpose DSP processors included with some packaged loudspeaker systems often include sophisticated loudspeaker protection including limiters and even sliding high and low-pass filters.

34.3.5.3.5 Protecting against Weather, Physical Damage and Pests

Physical damage may be caused by overexcited fans at a sporting event or by vandalism. When possible, locate the loudspeakers out of the reach of potential vandals. In some facilities, it may be necessary to build protective cages to prevent damage or theft. Some manufacturers offer vandal-resistant loudspeakers for use in correctional facilities and schools.

Weather and pest damage can best be avoided by choosing loudspeakers designed to resist these problems. When possible, locate loudspeakers in protected areas such as under a balcony or awning. Loudspeakers in outdoor summer amphitheaters may be removed and stored for the winter season or covered for protection from winter damage.

34.3.5.3.6 Age-Related Loudspeaker Damage

The foam surrounds on some cone-type loudspeakers will deteriorate and fail after 10–15 years of use. It’s best to choose loudspeakers with long-lasting surround materials, such as impregnated cloth, to avoid this problem. It’s also possible for cones to age and sag after many years, causing the voice coil to rub against the pole piece. When this happens, recone or replace the loudspeaker.

34.4 Electronic Components for Sound Reinforcement

34.4.1 General Specifications for Sound Reinforcement

Electronic devices for professional and commercial sound reinforcement systems should have balanced inputs and outputs. Line level outputs should be +4 dBu nominal with 20 dB head room for a +24 dBu peak output level. Many digital audio devices have a maximum output of +18 dBu, which is acceptable if the system is designed for this maximum level. The devices should be rack mountable except for those intended to mount on desklike mixing consoles. They should utilize high-quality electronics with low levels of hum and noise; wide smooth frequency response; and low distortion. For most applications, the devices should conform to a recognized safety listing such as UL (Underwriter’s Laboratories).

34.4.2 Mixers and Mixing Consoles

See Chapter 25 for a thorough discussion of all kinds of mixing consoles. There are several types of mixers and mixing consoles commonly used in sound reinforcement systems. Simple rack mixers, like the one shown in Fig. 34-36, may be all that’s needed for a college lecture hall or for a religious facility with a spoken worship style. Automatic mixers, as discussed in Section 34.4.3, can reduce the need for an operator in these simple systems.

Choose a desk-type mixing console, like the one in Fig. 34-37, for live theater or for any facility that hosts live entertainment events. Modern religious facilities often include dramatic and musical performances as part of their worship services. These facilities need a desk-type mixing console. The versatility of a desk-type mixing console means the operators must be well trained in the artistic and technical aspects of its operation.

Tour sound systems use desk-type mixing consoles. Larger tour sound systems may also use a special-purpose type of mixing console known as a monitor mixer. A monitor mixer is specifically designed to mix the monitor loudspeakers on a performance stage. For this reason, the stage monitor mixer is normally located at stage left or stage right where the operator can see and hear the monitor loudspeakers.

Digital mixing consoles, like the one shown in Fig. 34-38, perform the same functions as their analog cousins but they have additional features, such as memory scenes and multifunction outputs, that cannot be implemented on analog consoles. A memory scene stores most or all settings on the console in a digital memory location for recall at the touch of a button. A
live theater can use this to set up console settings for each scene during rehearsal and call them up quickly during a performance. A church with traditional and modern services can set up the console for each service and switch between them quickly. This can be a great help when operators are inexperienced. Multifunction outputs can work as group, main, matrix, or monitor outputs depending on configuration. There are many other useful features on digital mixing consoles. However, some digital mixing consoles are so feature-rich that they are confusing to an inexperienced operator. Control functions may change when memory scenes are changed and, unlike an analog mixing console, it's generally not possible to understand the configuration and settings of the console by simply looking at its controls. Thus, digital mixing consoles are best suited to facilities with experienced operators, Fig. 34-38.

34.4.2.1 Mix Groups, Auxiliary Groups and Matrix Mixing

Most mid- to large-mixing consoles have mix groups and auxiliary groups. Larger mixing consoles often have an output matrix mixing section. Experienced operators develop a mixing style that uses all of these features effectively. Here is one common approach, Fig. 34-39.

Start by connecting sources (microphones, musical instruments, etc.) to the inputs in a way that makes it easy to reach the most-used controls. Set up the input gains and losses for minimum noise and maximum head room (see Chapter 28). Then assign similar sources to the various mix groups in a logical manner. In a religious facility, for example, the operator could assign spoken voices to group 1, singing voices to group 2, choir to group 3, instruments to group 4, percussion to group 5, electronic organ to group 6, and so on. This allows the operator to raise or lower the volume of each
group with a single fader. Assign the groups to the master left and right outputs to feed the auditorium loudspeaker systems.

For individual channel special effects, use that channel’s insert feature. For special effects on a group of sources, use an auxiliary group. In the religious facility example, certain spoken voices may benefit from artificial reverberation during a dramatic presentation. Assign these voices to an auxiliary group and feed the aux group output to the reverberation device. Return the output of the reverberation device to an unused input channel or other available input.

For stage monitor mixing, assign selected inputs to an auxiliary group to feed a stage monitor loudspeaker. By using two or more auxiliary groups, the operator can provide customized mixes for different needs on the stage. In the religious facility example, the choir needs to hear the spoken voices and musical instruments, but may not need to hear itself in the monitor mix. In contrast, the pastor or a lay reader needs to hear the choir and musical instruments but does not need to hear the spoken voices.

If the mixing console has a matrix output, use this section to feed the various loudspeaker systems. Assign groups (and aux groups) to the matrix outputs to achieve an optimum mix for each loudspeaker system. In the religious facility example, use matrix outputs 1, 2, and 3 to feed the auditorium left, center, and right clusters. Use matrix output 4 to feed the under-balcony loudspeakers. Use matrix output 5 to feed any external overflow rooms, mothers’ rooms, and offices. Use matrix outputs 6 and 7 to feed a stereo recording or live broadcast feed.

By using the matrix outputs in this manner, each loudspeaker system or recording or broadcast feed can have a custom mix. In the religious facility example, the auditorium loudspeaker clusters need all of the groups except the electronic organ, which has its own loudspeaker system in the auditorium. The recording or broadcast feeds, and the overflow room feeds, however, need the organ and perhaps an audience response microphone feed. Custom mixes like this can be set up in the matrix and need very little adjustment during a performance.

34.4.3 Automatic Microphone Mixing

Many of the tasks a human operator performs on a simple mixer are predictable. For example, the human operator turns up the volume controls for microphones that are in use and turns down the volume controls for microphones that are not in use. In addition, an experienced human operator will turn down the master volume control about 3 dB each time the number of in-use microphones doubles to help avoid feedback from the NOM problem discussed in Section 34.2.2.5. An automatic mixer performs these two functions without the aid of an operator, Fig. 34-40.

The first commercially successful automatic mixer was invented and patented by Dan Dugan, a consultant in San Francisco, and marketed by Altec Lansing Corp. The Dugan automatic mixer exclusively used analog
circuitry to perform the automatic mixing process according to

\[ L_{N'} = L_N - [\text{Sum}(L_N) - L_N] \]  \hspace{1cm} (34-32)

where,
- \( L_N \) is the level in an individual mixer channel before the automatic circuitry has attenuated that channel,
- \( L_{N'} \) is the level in the channel after attenuation,
- \( \text{Sum}(L_N) \) is the sum of the levels in all channels before they are attenuated,

all values are in decibel notation.

In effect, the equation says that each individual input channel is attenuated by an amount in decibels equal to the difference in decibels between the level of that channel and the sum of all channel levels.
The significance of this equation is that, while it performs the two functions mentioned previously, it does not mention the word threshold nor the word switch. A Dugan system automatic mixer varies the microphone levels in a continuous manner depending only on the relationship of each individual channel level to the sum of all the channel levels.

A user sets up the Dugan mixer by adjusting each individual volume control to a position suitable for the person talking. That means the volume control for a quiet talker’s microphone will have a higher setting than that for a loud talker. These volume control settings assure that the circuitry treats all microphones equally in the equation. After this initial volume control adjustment, the user ceases interacting with the mixer. New talkers, of course, or significant changes in talker input level, require human intervention. A dummy microphone modification helps keep the mixer’s automatic circuitry from being fooled by ambient noise.

Other automatic mixers switch microphones on (to a volume control level preset by the user) when someone talks into the microphone and off when no one talks into the microphone. They also reduce the master volume control by approximately 3 dB when the number of in use microphones doubles. Most of these mixers incorporate sophisticated digital circuitry to make the decisions about when to turn a microphone on or off and exactly how much to attenuate the master volume control. As a result, a well-designed automatic mixer of either type can be successfully used in a system designed for automatic mixing.

Today, automatic mixers may be digital and automatic mixing functions are often included in multichannel DSP devices.

34.4.3.1 Special Features

A number of additional functions/features are either standard or optional on most automatic mixers. Specific features, of course, depend on the make and model chosen.

For example, on the switching-type mixers, users may have the option of adjusting the threshold setting. The threshold is the \( L_p \) at which the mixer turns on a microphone channel. In very high noise areas, for example, a user could increase the threshold to reduce the problem of microphones turning on from ambient noise input. Another feature available on some mixers is adjustment of the amount of off attenuation. That is, the off state can be redefined from no attenuation at all to infinite attenuation (true off). By selecting no attenuation, the on-off switching feature is defeated, and the mixer functions only as a number of open microphones (NOM) attenuator.

One valuable feature found on most mixers is a logic output. This logic output is a dc voltage output, usually compatible with TTL circuitry levels, and it goes high when the microphone is on and goes low when the microphone is off. This logic output can be used to activate relays for zone paging or to activate complex microphone priority switching in conference systems.

Most automatic mixers also allow the user to defeat the automatic circuitry on an individual input channel. This allows a tape machine or other nonmicrophone input to be added to the mix without affecting (and without being affected by) the automatic mixing of the system microphones.

34.4.3.2 Applications for Automatic Mixing

In systems with undemanding, predictable mixing requirements, the automatic mixer may be able to completely replace the human operator. Examples are conference and courtroom systems and speech-oriented systems in religious facilities. In these systems, the installer sets up the system volume controls and instructs the user simply to turn the entire system on and off since the automatic mixer will take care of everything else.

In actuality, systems like these are rare. More common are systems where the automatic mixer becomes an operator aid rather than completely replacing the human mixer. Any of the previously mentioned systems where different talkers use the same microphone require some human intervention. But the automatic mixer can also aid the human operator in more sophisticated systems including entertainment-oriented systems and dramatic (live) theater presentations.
