Most automatic mixers are unsuitable for mixing musical material. However, most can be used effectively for voice mixing of footlight microphones in a theater, and some automatic mixers may find use in submixing of instruments or vocals in an entertainment-oriented system. In all cases, the ability of the mixer to sense in-use microphones and attenuate (or to turn off) other microphones is a valuable aid in reducing unwanted noise pickup. In addition, the ability to help reduce the possibility of feedback (the NOM function) is welcome in any system.
34.4.3.3 Mix-Minus and Matrix Mixing

The automatic mixer in Fig. 34-40 includes a matrix output. This enables a mix-minus system for conference rooms or other multimicrophone systems, Fig. 34-41. Each talker at this conference table has his or her own microphone and loudspeaker. The signal from a given talker’s microphone is amplified to a greater degree in loudspeakers that are farther away from the talker. This is a natural way to make the talker’s voice heard well at any point around the conference table. In addition, this system helps control feedback because the talker’s voice is not amplified into his or her local loudspeaker and only slightly into nearby loudspeakers. In combination with normal automatic mixer functions, the mix-minus approach can make effective sound reinforcement possible in a large conference room. This approach is also valuable for audio or video teleconferencing systems.

A mix-minus system is complex but the calculations are simple if taken one microphone at a time. Consider a single talker and microphone. Assume that the listener seated next to this talker can hear the talker unaided by the sound system. Now, use inverse-square law, Eq. 34-1, to calculate the loss from this nearby listener to the farthest listener. Amplify the signal to this farthest listener (using the loudspeaker nearest to that listener) to make up for the loss. Do the same for each remaining listener. Now, repeat the process for the second talker and so on. A spreadsheet is a useful tool for keeping track of these calculations and the required settings in the matrix.

34.4.3.4 Problems in Automatic Mixing

Despite sophisticated circuitry, ambient noise may still turn a microphone channel on at the wrong time. Another problem is coherent input signals, that is, signals that are in-phase and have similar waveshape, which may fool the mixer and allow it to raise its gain to a feedback condition. Nearly coherent signals may arrive at the microphones from a slammed door, for example.

An obvious problem with all automatic mixers is that they do not know when a new talker approaches the microphone. Thus, the mixer cannot readjust a microphone level for a loud-versus-quiet-voiced talker. A compressor or AGC (automatic gain control) circuit could be added to the mixer to adjust the level to compensate but this would defeat the number of open microphones (NOM) function and could cause the system to go into feedback. An experienced human operator is the best solution to this problem.

Despite their problems, automatic mixers are extremely useful, and a well-designed system with an automatic mixer is more likely than ever before to be audibly transparent to an audience.

34.4.4 Signal-Processing Components

Most signal-processing functions are now performed by software modules in a DSP device. However, it is still possible to purchase individual signal-processing devices and the functions are the same whether they are performed by a separate hardware device or a software module in a DSP. For reasons of clarity, this section considers separate hardware signal-processing components. However, as discussed, the functions can be performed equally well by multifunction DSP devices.
34.4.4.1 Compressors and Limiters

Compressors and limiters are devices that control a system’s dynamic range (dynamic range is the difference in dB, between the highest and lowest $L_P$ levels in any audio program). A limiter reduces the signal level when the level rises above a preset threshold. In this manner, a limiter helps minimize system damage from dropped microphones or other transients, Fig. 34-42.

A true compressor reduces too-high signal levels but it also increases very low signal levels to keep them above the ambient noise. Compression ratio is the ratio of output level change to input level change in dB.

Although true compressors are used in broadcast and recording applications, sound reinforcement systems seldom use true compressors. Perhaps for this reason the terms compressor and limiter are often used interchangeably in sound reinforcement literature.

34.4.4.1.1 Sound System Applications for a Compressor/Limiter

In a paging system, a true compressor can keep the average level of the voices of different announcers more constant so that paging can reach noisy areas of a factory or airport more consistently. In addition, because of reduced dynamic range, peaks are lowered, reducing the chance of clipping distortion.

In a large sound reinforcement system, such as a concert tour sound system, a limiter can reduce the chance of peak clipping and can thus help avoid amplifier or speaker damage from large turnon/turnoff transients or from sudden, loud feedback.

34.4.4.1.2 Problems with Compressor/Limiters

While useful, compressors/limiters are not cure-all devices. The compressor makes its decision to begin compressing by continuously monitoring the program level. Unfortunately, the highest levels are usually low bass notes. Thus, the compressor/lIMITER may compress the high frequencies needlessly when it detects a bass note that is too loud. One solution to this problem is to use a compressor on each output of an electronic crossover on a biamplified or triamplified system so that the compressor acts only on the frequencies in each band. Another solution is to use a separate compressor on each mixer input that may receive excessive program levels. Perhaps the best solution, for quality-conscious systems, is to use the limiter just to limit peaks. Set up the limiter with a high compression ratio and a high threshold so that it begins limiting only on potentially dangerous peaks and then limits them hard. With this setup, the limiter should be inaudible at normal program levels.

34.4.4.2 Equalizers

An equalizer is a device that controls the frequency response of a system or an individual source. An equalizer could be considered to be a large number of tone controls, operating at different frequencies, all in one device. Chapter 23 provides details of equalizers and their design.

There are two types of equalizer commonly used in sound reinforcement, the graphic equalizer and the parametric equalizer, Figs. 34-43 and 34-44.

34.4.4.2.1 Graphic Equalizers

Graphic equalizers usually have a series of slider-type controls that boost or cut each frequency. When the controls are adjusted up or down they resemble a graph of the unit’s frequency response, hence the name graphic equalizer. Graphic equalizers are commonly available in 1 octave types or in $1/3$-octave types. An octave-band equalizer has controls that are spaced 1 octave apart. A $1/3$-octave-band equalizer has controls that are spaced $1/3$ of an octave apart. Some manufacturers offer $1/6$-octave spacing for part of the frequency range.

Octave-band equalizers are useful for adjusting the frequency response of an individual source. For example, to mellow the sound of a nasal-voice singer, use an octave-band equalizer connected to the insert points on the mixing console’s input channel.
For overall sound system equalization, as described in Section 34.5.2.2, an octave-band equalizer may be acceptable for simple systems in rooms with well-behaved acoustics. Most sound systems, however, need the greater precision of a $\frac{1}{3}$-octave band equalizer or parametric equalizer as described below.

34.4.4.2.2 Boost-and-Cut Equalizers Versus Cut-Only Equalizers

Early equalizers were made from passive components and, thus, could not amplify a signal. These were cut-only equalizers. When active models were developed, however, they included electronic amplifiers for the purpose of buffering the impedance of the filters and, in some cases, of allowing the frequency response to be boosted as well as cut at any given frequency.

Either type of equalizer is suitable for sound reinforcement system equalization. However, choose a high-quality equalizer and when equalizing a sound system avoid boosting any frequency more than about +3 dB to maintain good system head room.

34.4.4.2.3 Constant Q versus Variable Q Equalizers

$Q$ for a filter is the ratio between the filter’s center frequency and its bandwidth. Early passive equalizers used variable $Q$ filters. The $Q$ of these filters was low at low insertion (small fader movement) and increased at high insertion. Some active equalizers have constant $Q$ filters whose $Q$ does not vary with insertion. Both types of filters can be combining filters. A good quality equalizer of either type is suitable for system equalization.

34.4.4.3 Parametric Equalizers

Parametric equalizers have fewer filters than graphic equalizers but the parameters of each filter are highly variable, hence the name, parametric equalizer. Typically, each filter of a parametric equalizer has variable insertion, variable $Q$ and variable center frequency. Some mixing consoles include parametric equalization on each input. Others include quasi-parametric equalization where the insertion and center frequency, but not the $Q$, are variable.

Because of their flexibility, parametric equalizers with only three or four filter sections can approximate almost any curve needed for sound reinforcement equalization. For this reason, some designers favor them over graphic equalizers for sound system equalization.

34.4.4.4 Digital and DSP Equalizers

Most modern systems will have their equalization functions performed by some kind of multifunction DSP device where the equalization is simply a software module. Commonly, these DSP devices are controlled by a computer and the settings of an equalizer module are accessible via a user interface or GUI that resembles an analog equalizer of the same type. It may be possible to change many of the settings so the system designer can choose a graphic or parametric equalizer and control $Q$, center frequency, insertion depth and even filter design type. Usually the default settings are acceptable but it’s a good idea to review all of these settings before using the device.
34.4.4.5 High-Pass and Low-Pass Filters

High-pass filters, also called low-cut filters, pass high frequencies and attenuate low frequencies. Low-pass filters, also called high-cut filters, pass low frequencies and attenuate high frequencies. A high-pass filter and low-pass filter with the same -3 dB frequency make a simple crossover network, Fig. 34-45.

Most sound reinforcement systems should include a 40 Hz, 18 dB/octave high-pass filter to reduce subsonic frequencies that might otherwise damage loudspeakers. For systems that include subwoofers, use a 20 Hz, 18 dB/octave (or steeper) high-pass filter in the subwoofer circuit and a 40 Hz high-pass filter (or higher) in the main loudspeaker circuit. Many graphic equalizers, and virtually all multifunction DSP devices, include a variable high-pass filter for this purpose.

34.4.4.6 Delay

Delay units are also called signal delay or digital delay. The term time delay is inappropriate since the signal is being delayed, not the time. Delay is useful in many sound reinforcement applications as detailed in Section 34.5.2.1. The most common example is a combination cluster and under-balcony loudspeaker system. The signal to the under-balcony loudspeakers is delayed to allow the sound from the cluster to catch up and avoid an artificial echo. Delay can also be used to line up the wavefronts from the high- and low-frequency components of a packaged loudspeaker system or to line up the wavefronts of the multiple loudspeakers in a cluster.

For sound reinforcement, choose a high-quality delay unit with dynamic range of 96 dB or greater and adjustment increments of 20 μs or shorter. For delaying the components of a packaged loudspeaker or a cluster, choose a delay with 10 μs or shorter increments.

Delay is a normal module of a multifunction DSP device. Most have varying increments of delay and a total delay limited only by system memory.

34.4.4.7 Electronic Crossovers

A crossover network routes high frequencies to the high-frequency loudspeakers (tweeters) and low frequencies to the low-frequency loudspeakers (woofers). The use of crossover networks is discussed in Section 34.3.4. Electronic crossovers should conform to the general specifications presented in Section 34.4.1 and are often included in multifunction DSP devices.

34.4.5 Digital Signal Processing

Most audio signal processing now takes place in the digital domain. Common DSP devices can be programmed to emulate a group of their analog counterparts arranged in a configuration chosen by the sound system designer. Some include mixing and output signal routing. There are two general types of digital signal-processing devices now in use in professional and commercial audio systems. (Also see Chapter 31.)

34.4.5.1 Multifunction DSP

The multi-function digital signal-processing system, typified by Peavey’s Media Matrix, Biamp’s Audia, or the BSS Soundweb, can become an entire sound system up to the power amplifiers and loudspeakers. This type of DSP device includes mixing and automatic mixing capabilities, output signal routing, and all types of signal processing (compression, limiting, equalization, delay, crossover), Fig. 34-46.

34.4.5.2 Power Amplifier DSP

Power amplifier DSP performs most of the same functions as all-in-one DSP. However the DSP devices are attached to the individual channels of a power amplifier. Because of this location, amplifier DSP is not suitable for mixing or output signal routing. However, it can perform all signal-processing functions and can also supervise and control the amplifier channel. Some power amplifier DSP devices are optional. Others are included with the amplifier and located inside the amplifier chassis, Figs. 34-47 and 34-48.

34.4.5.3 Loudspeaker Processing DSP

Most DSP functions needed by a loudspeaker can be performed by a multifunction or amplifier DSP. However, some manufacturers offer special-purpose DSP devices designed to perform loudspeaker optimization functions not available in these other devices. For
example, the loudspeaker processor could maintain a table of specific loudspeaker models with crossover, equalization, and delay settings for each model. Offloading this function from the multifunction DSP frees valuable outputs and software resources and may even reduce overall system cost, Fig. 34-49.

34.4.5.4 Multifunction DSP in Sound Reinforcement System Design

DSP does more than simply replace traditional analog devices in a system design. DSP gives the system designer two important new capabilities.

First, DSP is programmable. That means the designer can set up more than one system design and give the user the ability to switch between “designs.” For example, the system could be equalized for both a full house and an empty house with a button push to switch between these curves. Or, the system at a religious facility could be optimized for a wedding or funeral or typical religious service with a button push to
select the appropriate configuration. This configuration can include equalization but it can also include mixing and output signal routing.

Second, DSP allows multiple signal-processing devices at reduced cost. This opens up opportunities that were previously available only in high-cost systems. For example, consider a religious facility with distributed column loudspeakers mounted on pillars down each side of the main auditorium. DSP can provide separate delay for each pair of loudspeakers, and it can even provide separate equalization. This can be valuable when the first pair is near the platform, the last pair is near a balcony, and the others are in yet a different acoustical environment.

### 34.4.6 Digital Audio Networking

More and more audio processing is done in the digital domain. Thus, it seems natural that audio signals should be transferred between devices in digital form. In some cases, this is a simple matter of connecting the digital output of one device to the digital input of another device. Audio devices with AES/EBU inputs and outputs are set up for this kind of connection.

In some systems, it may be useful to route multiple channels of audio from one location to another. For example in a performing arts center, it’s commonly necessary to transfer multiple channels of audio from the stage to the mixing location and from there to the system rack room. If most processing is done in the digital domain it makes sense to keep the signals in digital form during these routing functions.

Although proprietary systems exist, most digital audio networking systems are based on Ethernet computer standards. The best known of these is CobraNet, developed by Peak Audio, a division of Cirrus Logic. CobraNet is licensed to a number of other manufacturers who have incorporated it into their products.

CobraNet and other digital audio networking systems enable multichannel digital audio transmission over CAT5 or fiber optic lines. They may also enable channel routing and patching functions, a sort of digital patch bay. Also, these transmission systems often include channels for system control signals and system monitoring information.

See Chapter 39 for a detailed discussion of digital audio networking.

### 34.4.7 Power Amplifiers

Power amplifiers for sound reinforcement should conform to the general specifications presented in Section 34.4.1. In addition, they must be able to drive professional loudspeaker loads and long loudspeaker lines. For this reason, a typical home entertainment power amplifier, while it may be a very high-quality product, is not suitable for professional or commercial usage, Figs. 24-50.

![Figure 34-49. Loudspeaker DSP processor. Courtesy BSS.](image)

![Figure 34-50. A two-channel professional power amplifier. Courtesy Crown International.](image)

Most professional power amplifiers are two-channel, or multichannel solid state, analog devices with rack ears and cooling fans. Some include 70 V output transformers for use with distributed systems. Some have optional DSP modules as described in Section 34.4.5. Some have switching power suppliers to reduce their size and weight.

Power amplifiers should include an output relay or other method of uncoupling the loudspeakers from the power amplifier during turn on and turn off to avoid turn-on/turn-off transients from mixers and signal-processing devices. Also, the output relay disconnects the loudspeakers in the event of amplifier failure.

Some manufacturers offer multichannel power amplifiers with several power amplifiers in one chassis, Fig. 34-51. These power amplifiers can often be combined to form higher-power amplifiers or 70 V outputs. For multichannel systems, this type of power amplifier can often reduce costs.

![Figure 34-51. A multi-channel professional power amplifier. Courtesy QSC.](image)
34.4.8 Pads and Transformers

A pad is a resistor circuit that reduces the output level from a source device to make it level compatible with a load device (also see Chapter 23). In the past, external pads were used to reduce the level from high-output microphones to make them compatible with normal microphone input circuits. Now, most mixers include “trim” controls to compensate for low- or high-level microphones.

Pads were also used to convert older high-level devices to be compatible with low-level devices. Today, most professional equipment has +4 dBu compatible input and output levels. In addition, passive components, like passive equalizers, are no longer in common usage. As a result, pads are usually only needed for the occasional connection of a professional device into a semipro or hi-fi device.

Transformers (also see Chapter 13) are devices that can be used to connect devices with unlike impedances and levels. For example, a hi-Z to lo-Z microphone transformer converts the high (voltage) level and high impedance of a high-impedance microphone to the low (voltage) level and low impedance of a low-impedance microphone input. Transformers can also be used to connect an unbalanced source to a balanced line. For example, a transformer could convert the unbalanced output of a consumer CD player to a balanced line for connection to a professional mixing console.

Loudspeaker transformers are used for 70 V loudspeakers as described in Section 34.4.8. Power amplifiers sometimes include transformers to convert the output of a conventional power amplifier to 70 V usage.

Transformers are level and impedance sensitive. That is, a microphone hi-Z to lo-Z transformer cannot be used for line-level impedance conversion. (It would distort.) Neither can a line-level transformer be used for microphone-level conversions. (It would also distort, although in a different manner.) Thus, when selecting transformers, needs must be defined in terms of both the impedance ratio desired and the level of the devices that will be connected to the transformer.

34.4.9 70.7 Volt /100 Volt System Design

A 70.7 V (referred to as 70 V) or 100 V loudspeaker system, as shown in Fig. 34-52, allows relatively long loudspeaker lines while minimizing $F/R$ line losses. 70 V or 100 V distribution also allows multiple loudspeakers to be connected to a single power amplifier without the need for complex series-parallel connections. For these reasons, 70 V or 100 V systems are commonly used for distributed ceiling loudspeaker systems and for any system where loudspeaker lines must be relatively long, 75 to 100 ft or more. Variations on this concept include 25 V distribution, which is sometimes used for school intercom systems, and 140 V distribution, which is sometimes used outside the United States. For brevity, the remainder of this discussion will use the term 70 V to refer to all of these systems. With the exception of local electrical codes, which may limit usage, design principles are the same for any of these systems.

![Figure 34-52. A 70.7 volt loudspeaker system. Courtesy Rane.](image)

34.4.9.1 70 V Transformers

Fig. 34-53 shows a typical 70 V loudspeaker transformer. Choose a transformer that supports the impedance of the selected loudspeaker and has appropriate power taps for the application. Also choose a transformer with performance specifications that are appropriate for the application. In particular, pay attention to the transformer’s frequency response, its distortion, and its dB loss figure. Low-cost 70 V transformers will have poor low-frequency performance, higher distortion (especially at low frequencies), and a dB loss of 1.5 dB or more. These specifications may be suitable for low-level paging and background music. Higher-cost 70 V transformers will have improved low-frequency response, reduced distortion at low frequencies and a dB loss of less than 1.5 dB. Use these for higher-performance applications.

Note that the dB loss specification is usually given in such a way that the transformer delivers its rated power to the loudspeaker but draws slightly more from the power amplifier. As an example, consider a high-quality
70 V transformer with a 0.5 dB loss. When this transformer delivers 10 W to the loudspeaker, it draws 11.1 W from the power amplifier. This is very important in selecting the correct amplifier size.

Choose the power level fed to the loudspeaker by connecting the appropriate primary winding to the 70 V line. Connect the loudspeaker to the appropriate impedance tap on the transformer secondary. Some manufacturers offer packages that include a ceiling loudspeaker with transformer preinstalled.

34.4.9.2 Designing a 70 V System

Choose the system loudspeakers and transformers. Calculate the power required per loudspeaker as described in Section 34.3.3.7.1. Then, choose an appropriate 70 V transformer. Next, calculate the power required by all of the system loudspeakers (the sum) and choose a power amplifier that’s big enough to supply this power plus the amount needed to overcome the loss in the transformers. Here is an equation to help in this final calculation.

\[
P_A = P_L \times 10^{LT/10}
\]

where,

- \(P_A\) is the required power amplifier size (minimum size in watts),
- \(P_L\) is the total power required by all of the loudspeakers (the sum),
- \(LT\) is the loss of an individual 70 V transformer in dB (a positive number).

34.5 System Installation and Commissioning

34.5.1 What Is Commissioning?

After the system has been installed, it must be commissioned. Commissioning involves three general steps. These are outlined below and followed by a detailed discussion of selected commissioning topics.

34.5.1.1 Step 1—Test All Components

Test and confirm that all electronic components and all connections, including microphone and loudspeaker connectors and patch bays, are correctly wired and in proper working order. Pay special attention to polarity and other potential wiring errors.

34.5.1.2 Step 2—Adjust the Electronics

Set up system DSP to its final configuration. Do not adjust DSP delay, limiter or equalizer settings at this time. Next, set any loudspeaker DSP to its final configuration. If the loudspeaker DSP includes optimization for specific models of loudspeaker, implement this optimization at this time. Finally, adjust system gains and losses to minimize hum and noise and optimize head room.

34.5.1.3 Step 3—System Adjustments and Equalization

One at a time, adjust the system power amplifiers to produce the designed \(L_p\) in each audience area. Next, adjust any digital delays for satellite clusters or under-balcony loudspeakers. Finally, equalize the system as discussed in Section 34.5.2.2.

34.5.1.4 Connectors and Cabling

As simple a subject as this may seem, faulty connectors and cabling are the source of a majority of sound system problems. Well-made cabling, of the proper type, with the right connectors for the job, on the other hand, will keep a system operating at maximum efficiency with a minimum of noise pickup.

34.5.1.4.1 General Notes on Cable

A cable is a group of two or more wires, usually in a single outer (insulating) sheath, designed for a particular function.

Cables for portable audio systems should always be made from stranded, not solid, wire. Solid wire cables
will break after the repeated flexing of portable usage. Shields should be braided wire, not foil, for the same reason. Cable for permanently installed systems, on the other hand, can utilize foil shields. In addition, while a tough, rubberized outer sheath is desirable for portable cable (like microphone cable), a smooth vinyl-type sheath will benefit the permanent system installer, since it pulls through conduit more easily.

34.5.1.4.2 General Notes on Connectors

There are only a few types of connectors in general use in commercial and professional sound systems, as shown in Figs. 34-54 and 34-55. The most common of these are discussed here.

34.5.1.4.3 XLR-Type Connection

The term XLR was first used by the Cannon Company but has almost become a generic label for these high-quality audio connectors, now made not only by Cannon but also by Switchcraft, Neutrik, ADC, and others. XLRs are the connector of choice for microphones and any balanced low-level or line-level audio signal as well as AES/EBU digital connections.

34.5.1.4.4 Phone Plugs

The term phone comes from the telephone industry, which normally used a type of phone plug in its early, nonautomated switchboards. Recording studio and other patch bays are close relatives of these telephone switchboards and often use a three-conductor variety of phone plug. The most common type of phone plug used in pro audio has a ¼ inch diameter shank and comes in two-wire (known as tip/sleeve, or T/S) and three-wire (known as tip/ring/sleeve, or T/R/S) versions. The ¼ inch phone plugs are commonly used for instrument amplifiers and hi-Z microphones and sometimes for portable loudspeaker connectors. Unlike XLRs, which are almost invariably high quality, the quality of commercially available phone plugs can vary widely.

34.5.1.4.5 RCA-Type Phono Plugs

Note the term phono not phone, indicating that these plugs got their start on phonographs manufactured by the original RCA company. Phono plugs, or RCAs, are used primarily on hi-fi equipment but may be used to adapt a hi-fi tuner or cassette machine, for example, to an input of a professional mixer. Phono plugs, however, are fragile and do not make good general-purpose pro-audio connectors. Higher-quality phono plugs are used as the coaxial digital audio connectors on consumer equipment.

34.5.1.4.6 Barrier Block Connectors

Professional audio products continue to get smaller while simultaneously adding more inputs and outputs. Manufacturers have responded by adopting miniature barrier block connectors, often called Phoenix connectors or Euro-Block connectors, for inputs and outputs. These connectors use a screw to capture individual bare wires in a small terminal hole.

34.5.1.4.7 CAT 5 Connectors

CAT5 connectors, also known as RJ45 connectors, are used for Ethernet networking and related digital audio connectors, Fig. 34-56.
34.5.1.4.8 Cable and Connectors for Microphones and Other Low-Level Devices

Lo-Z balanced microphones use shielded, two-wire cable and XLR-type connectors. Hi-Z (unbalanced) microphones usually use a ¼ inch phone plug connector. Exposed (portable) microphone cable should have a flexible, tough outer sheath; a braided shield; and stranded inner wires.
The XLR-type connector is an industry standard for lo-Z balanced microphones. Unfortunately, in the past, the wiring of these connectors was not completely standardized. Although pin 1 on the connector was almost always connected to the cable shield, some manufacturers used pin 2 as high or + and other manufacturers used pin 3 as high or + (with the remaining pin low or –). Today, most manufacturers use pin 2 as +. However, older microphones may still use pin 3 as +. Use of two microphones with different polarity to mic the same instrument or voice can result in undesirable phase cancellations. For this reason, it’s wise to check the polarity of older products.

34.5.1.4.9 Microphone Snake Cables

A snake cable is actually a group of microphone or line-level cables all in one outer sheath. These cables use foil shields to reduce their overall diameter to a reasonable size. Because of the fragility of the foil shields in a snake cable (and because of the high cost per foot), extra care must be taken in their handling.

34.5.1.4.10 Cable and Connectors for Line-Level Devices

Line-level devices normally use the same type of cable and connectors as microphones and other low-level devices. That is, balanced line-level devices normally use XLR-type connectors and unbalanced line-level devices normally use ¼ inch phone plug connectors or RCA-type phono connectors. Some balanced line-level devices use three-conductor, ¼ inch tip/ring/sleeve (T/R/S) connectors.

Like older microphones, the polarity of XLR connectors on older line-level devices was, unfortunately, not standardized. Either pin 2 or pin 3 may be the + pin (pin 1 will almost always be the shield).

34.5.1.4.11 Cable and Connectors for Loudspeakers

Loudspeaker cable carries much higher levels of electrical power than either microphone or line-level cable. For this reason, loudspeaker cables use larger gauge wire. Typical loudspeaker cable uses anywhere from number 18 gauge wire to as large as number 10 wire (or even larger). Number 18 gauge wire is suitable only for low-level loudspeakers (like the hi-fi loudspeakers in your den). Number 16 gauge wire is suitable for short runs (less than 25 ft) of low- to medium-level pro-audio loudspeakers. Number 14 gauge wire is suitable for most pro-audio work unless loudspeaker runs are longer than about 75 ft. In that case, number 12 gauge wire should be used. For very long runs of high-power loudspeaker cable, use number 10 (or even number 8) wire. A better way to handle long loudspeaker cable runs, however, is to move the power amplifier closer to the loudspeakers and run line-level signals over the long distance. Alternatively, use a 70 V (or 100 V) distribution system.

One apparent way to reduce loudspeaker cable requirements is to use powered loudspeakers that do not require any loudspeaker cable (only signal cable and ac power). However, unless ac power already exists at each loudspeaker location, the ac cable and conduit requirements may be more expensive than loudspeaker cable for nonpowered loudspeakers.

A connector developed by the Neutrik company, known as the Speakon, has become a de facto standard among most loudspeaker manufacturers. The Speakon connector, Fig. 34-57 is, in many ways, an ideal loudspeaker connector. It is a high-current twist-lock connector that is unlikely to fall out of its socket. It is self-wiping to keep its contacts clean. It is easy to assemble and is made from tough, lightweight plastic. In addition, it is relatively inexpensive in comparison to high-current metal connectors.

Figure 34-57. The Neutrik Speakon, a four or eight wire, high-current, twist lock loudspeaker connector. Courtesy Neutrik USA, Inc.

Except for very high-quality types, ¼ inch phone plugs are not suitable for the high-current use they get in pro audio. Thus, ¼ inch phone plugs are only suitable for low- and medium-level loudspeakers (perhaps up to 200 W or so per loudspeaker). Some power amplifier outputs use dual banana connectors, also called five-way binding posts. XLR connectors are sometimes used for loudspeaker connectors, but their current capacity, like the capacity of a phone plug, is limited, and they should not be used for higher-power capacity systems.
34.5.1.5 Cable and Connectors for Digital Audio Devices

Cable and connectors for digital audio devices are derived from computer cabling and are often exactly the same. For example, many digital audio devices utilize Ethernet-style CAT5 cabling and connectors or USB cable and connectors. As a rule, these computer-derived connectors and cabling are not rugged enough for portable sound system usage. For this reason, some audio cabling companies have introduced specialty connectors designed for portable usage such as the one shown in Fig. 34-58.

![Figure 34-58. An ethernet-style connector designed for portable audio systems. Courtesy Neutrik USA, Inc.](image)

The AES/EBU digital audio standard utilizes conventional XLR connectors. The digital audio output coaxial connector found on home-theater receivers is a high-quality RCA-type connector. As with all computer connections, digital audio connections should use high-quality cable and connectors of the right impedance and length. Consult the device manufacturer for recommended cable specifications.

Fiber optic cable and connectors may be used in large installed audio systems because of their ability to carry multiple channels of digital information (audio, video, control, and other) on a single cable and because of their relative immunity from hum and noise pickup. Fiber optic suppliers often provide seminars to teach designers and installers how to specify, design, and install fiber optic cabling systems.

See Chapter 15 for a detailed discussion of fiber optic cabling systems. See Chapter 39 for a detailed discussion of digital audio networking and the associated connections.

34.5.1.6 Understanding Balanced and Unbalanced Lines

Every audio signal requires at least two wires. In an unbalanced line, the shield (outer conductor) is also one of the audio signal wires. Thus, an unbalanced line, Fig. 34-59A, needs only the shield and one additional wire (a total of two wires). In a balanced line, the shield does not carry audio signals. Thus, a balanced line, Fig. 34-59B, requires the shield and two additional wires to carry the audio signal (for a total of three wires). Also see Chapter 37 for a more detailed discussion of balanced and unbalanced circuits.

![Figure 34-59. Balanced and unbalanced lines. Courtesy Fender Musical Instruments.](image)

The primary advantage of a balanced line is that it is much less likely to pick up external electronic noises (hum, buzzing, static, radio stations, etc.) than an unbalanced line.

34.5.1.7 Impedance and Level Watching

While some passive devices require impedance matching, most active audio devices do not require matched impedances. What they do require is impedance compatibility. In addition, all audio devices require signal level compatibility. Thus, impedance and level watching means establishing and maintaining required impedance and level compatibility (as will be discussed).

34.5.1.7.1 Terms: Source, Input, Output, Load

In Fig. 34-60, the source is the microphone, the input is the input to the mixer/amplifier, the output is the output from the mixer/amplifier, and the load is the loudspeaker, but these four terms are relative. For example, the input to the mixer-amplifier can be called a load from the viewpoint of the microphone. And, the mixer-amplifier output can be called a source from the viewpoint of the loudspeaker.

Thus, the input impedance of the mixer/amplifier can be called the load impedance for the microphone, and
the output impedance of the mixer/amplifier can be called the source impedance for the loudspeaker.

These four terms—source, input, output, and load—and their relative nature are important to an understanding of impedance and level watching. As an example, consider a microphone whose impedance is 200Ω. That impedance is actually the internal impedance of the microphone and should be called the source or output impedance of the microphone. (The microphone is a source from the viewpoint of the mixer/amplifier.)

That same microphone should probably be loaded with an impedance of 2 kΩ or higher. That load impedance is actually the input impedance of the mixer/amplifier (the input of the mixer/amplifier is a load to the microphone).

### 34.5.1.7.2 Impedance Compatibility

Impedance watching just means making sure that when two devices are connected, they are compatible from an impedance viewpoint, Fig. 34-61. Here are some rules to help watch impedances.

### 34.5.1.7.3 Passive Devices

In the special case of a passive filter, like a loudspeaker crossover network or a passive graphic equalizer, input and output impedances must be matched. These devices are the origin of the familiar term impedance matching. Impedance matching means that if the device is a loudspeaker crossover network and it has an 8 Ω low-frequency output impedance and an 8 Ω high-frequency output impedance, then it must be connected to an 8 Ω low-frequency loudspeaker and an 8 Ω high-frequency loudspeaker. Any other impedance, either higher or lower, will degrade the performance of the crossover network. (The input to a modern loudspeaker crossover network is designed for the very low actual output impedance of a modern power amplifier.)

An older passive device such as a passive graphic equalizer has similar requirements. If such a device has a 600 Ω input impedance, then it must be connected to a source impedance of exactly 600 Ω. The same goes for the output. If the passive graphic has a 600 Ω output impedance, then it must be connected to a load impedance of exactly 600 Ω to insure proper operation of the graphic equalizer. In many cases, build-out and termination resistors must be added to match these impedances (see Chapter 23).

### 34.5.1.7.4 Passive Sources

Impedance matching for a passive source, like a dynamic microphone or guitar pickup, simply means supplying a compatible load impedance for that device. The device specifications should be a reasonably accurate guide to the proper load impedance. A good rule of thumb for dynamic microphones is that the microphone load impedance (which is probably the input impedance of a mixer or preamplifier) should be at least five to ten times the microphone’s rated source impedance. Thus, for a 150 Ω (source impedance) microphone, the optimum load impedance would be 750–1500 Ω or higher. This requirement is satisfied by the input of almost all low-impedance mixer inputs. Note that the
load impedance required by a high-impedance microphone is many times higher than the load impedance required by a low-impedance microphone. High-impedance microphones, therefore, can only be used with mixers having special inputs designed for these high impedances.

34.5.1.7.5 Active Devices

An active device is one that uses batteries or ac power and has one or more tubes, transistors, or ICs. Impedance watching for an active device means not overloading its output, that is, not connecting too low a load impedance to the output of the active device. A too-low impedance is an overload because the lower the impedance, the closer it is to a short circuit.

It’s usually very easy to follow this rule because almost every active device comes with a set of specifications that indicates the value in ohms of the lowest allowable load impedance. This is usually called the rated or minimum load impedance. Incidentally, in almost every case, it’s acceptable to connect a higher than rated load impedance to any active device.

For many modern solid state power amplifiers, for example, the minimum load impedance is 4 Ω. That means any impedance down to 4 Ω may be connected to this power amplifier. Since an 8 Ω loudspeaker is greater than 4 Ω, it is an acceptable load; a 16 Ω loudspeaker is also acceptable. Two 8 Ω loudspeakers in parallel equals a 4 Ω load so this arrangement is also acceptable. Four 4 Ω loudspeakers in parallel equal a 1 Ω load; this is definitely not acceptable. Connecting a too-low load impedance to a power amplifier will cause the protection circuits of the power amplifier to operate, which increases distortion, and may, in extreme cases, cause damage to the power amplifier or loudspeakers.

For a line-level active device, like a limiter, the same rule applies. If the limiter has a rated minimum load impedance of 600 Ω, the output of the limiter may be connected to the input of any device whose input impedance is 600 Ω or higher. (The input impedance of most active devices is considerably higher than 600 Ω.)

Some professional power amplifiers, on the other hand, have input impedances of 5 kΩ or lower. Connecting a hi-fi-type tuner, with a 10 kΩ minimum load impedance to the professional power amplifier, with its 5 kΩ input impedance would reduce the output level from the tuner and might also cause an increase in distortion.

34.5.1.7.6 Active Sources

Active sources like battery or phantom-powered condenser microphones should receive the same treatment as any other active device although most battery or phantom-powered microphones are designed to act like conventional low-Z dynamic microphones from the point of view of their desired load impedance.

34.5.1.7.7 Impedance and Cable Length

One more aspect of impedance watching involves the effect of cable length on the frequency response of high-impedance microphones. From the following information, we can see that a too-long cable on a high-impedance microphone will cause a loss in high-frequency response; that is, the sound from the microphone will be dull, and voices will lack intelligibility. This results from the interaction between the capacitance in the cable and the high impedance of the microphone, which form a low-pass filter. The lower impedance of a low-impedance microphone also interacts with the capacitance of the cable, but the effect is noticeable only at very high frequencies (out of the audio range). A good rule of thumb is to avoid cables longer than 15 ft with a high-impedance microphone (some high-impedance microphones will tolerate cable lengths up to about 25 ft). A low-impedance microphone, on the other hand, will perform properly with cables as long as 200 ft or more.

This same cable length consideration applies to line-level devices. The hi-fi tuner mentioned previously, for example, should not be used with a cable longer than about 15 ft. (The cable should be shorter if possible.)

34.5.1.7.8 Signal-Level Compatibility

Achieving level compatibility between devices means two things: avoiding too-high levels, which cause clipping distortion, and avoiding too-low levels, which allow electronic noises (usually hiss), as shown in Figs. 34-62A and 34-62B.

There are three basic classifications of level in analog professional audio devices, Fig.34-63:

1. Low-level devices (microphones, pickups, and so on).
2. Line-level devices (limiters, graphic equalizers, and so on).
3. High-level devices (the output from a power amplifier).
The first rule of level compatibility is to avoid connecting devices from different classifications unless they are specifically designed for each other.

For example, don’t connect a microphone directly to a power amplifier because the output of the microphone is too low. This connection wouldn’t damage anything but would result in very low sound level, and the noise from the power amplifier might be almost as high as the wanted sound.

As an obvious example, don’t connect the output from a power amplifier to the input of a mixer. The power amplifier output level is far too high for the input of the mixer. This connection would almost certainly result in severe clipping distortion (the mixer might even be damaged).

Many devices, however, have an input that is compatible with one level and an output that is compatible with the next higher level. For example, the input channels of most professional mixers are compatible with low-level devices like microphones, although their outputs are designed for both mic-level and low- and high-level line loads. A power amplifier, as another example, has a line-level input and a loudspeaker-level output. Thus, the output of a limiter or graphic equalizer can usually be connected directly to the input of a professional power amplifier. (Impedance must be considered, too, but the input impedance of most professional power amplifiers is high enough to be impedance compatible with the output of almost any professional line-level device.)

The situation is complicated somewhat by variations in the level of devices in a given category. For example, a typical condenser microphone has a higher output than a typical dynamic microphone. One solution to this problem is to design the mixer for the lower-level microphone and provide a pad for the higher-level microphone. A more common solution on professional mixers is to include either a built-in (adjustable) pad or a preamplifier gain adjustment or both. By properly adjusting these controls, the mixer’s input channel can be optimized for either a dynamic or condenser microphone (and, with some mixers, for a line-level input).

The same kind of level-compatibility problems show up in line-level devices. Some line-level devices, mostly special effects devices, are designed for input and output voltages as low as −20 dBu. Others, including some tape machines, are designed for input and output voltages of −10 dBu. Most professional line-level equipment, however, is designed for input and output voltages of +4 dBu.

The level in dBu is found from

\[
\text{dBu} = 20\log \frac{V}{0.7745}
\]

where,

\[
dBu \text{ is the voltage level in dBu,}
\]

\[
V \text{ is the voltage level in volts,}
\]

\[
0.7745 \text{ is the reference level for dBu in volts.}
\]

dBu specifications are only used for voltage output ratings and are not the same as dBm ratings. Many manufacturers are now rating the input and output levels of their products in dBu, however, so it is useful to understand this specification.

The process of achieving compatibility with these line-level devices is similar to the process for low-level devices (e.g., the microphones discussed earlier). Whenever possible, connect the output of a −20 dBu device to the input of another −20 dBu device (the same applies to −10 dBu devices and +4 dBu devices).

If this isn’t possible and the source device has a higher output level than the load device, use a pad to attenuate the level of the source device. For example, if the source is a +4 dBu limiter, and the load is the input to a −10 dBu tape machine, a 14 dB pad is needed to achieve level compatibility. To design a proper pad, impedances must be taken into account (see Chapter 23). Without the pad, there is a risk of clipping distortion. Just turning down the output of the source device probably won’t solve the problem, either. This may result in that other level-compatibility problem—electronic hiss noise.
If the source device has a lower output level than the load device, a line-level preamplifier could be connected between them to give the required amount of gain. In many cases, however, simply connecting these two devices will prove satisfactory. The worst that can happen here is additional hiss, which may be tolerable.

### 34.5.1.7.9 The dBV Specification

All professional equipment uses a dBu or dBm reference for any “+4” input or output. Some professional microphones and consumer type equipment, however, may have outputs that are rated in dB using a dBV reference. When in doubt about the dB reference, consult the owner’s manual for the equipment or, measure the output with a known signal.

The level in dBV is found from

$$dBV = 20\log \frac{V}{1}$$

(34-35)

where,

- $dBV$ is the voltage level in dBV,
- $V$ is the voltage level in volts,
- $1$ is the reference level for $dBV$ in volts.

### 34.5.1.7.10 Impedance and Power Transfer

To understand what happens to the power output of an amplifier when different impedances are connected to it, find the rated power output of the amplifier and its rated load impedance. That rated load impedance is usually the minimum acceptable load impedance of the amplifier.

In addition, find the true minimum impedance of the loudspeaker as well as its rated or nominal impedance. Normally, the nominal impedance of the loudspeaker will be used to make impedance-matching calculations like those described in the next paragraph. The minimum impedance of a loudspeaker, however, can fall significantly below its nominal impedance, and a loudspeaker with an extremely low minimum impedance could even overload a power amplifier whose rated load impedance was acceptable for rated nominal impedance of the loudspeaker.

Some professional power amplifiers are designed to accept impedances as low as 2 Ω because of the very low minimum impedance of some loudspeakers. Many 8 Ω loudspeakers (8 Ω is the rated or nominal impedance), for example, have minimum impedances of 6 Ω or even as low as 5 Ω. Two of these loudspeakers in parallel would have a minimum impedance of 2.5 Ω,
which would still be within the safe limits for these power amplifiers.

The easiest way to describe the change in power output with different load impedances is to take an example, such as is shown in Fig. 34-64. One manufacturer’s professional power amplifier is rated at 440 W per channel into a 4 Ω load. It has a minimum load impedance of 2 Ω even though its 440 W power rating is at 4 Ω, and 440 W into 4 Ω means exactly that. Connect a 4 Ω loudspeaker to one channel of this power amplifier, and the amplifier will produce as much as 440 W into that loudspeaker. Connecting two 8 Ω loudspeakers (in parallel) to one channel of this power amplifier will, again, result in as much as 440 W into the resulting total impedance of 4 Ω. Each 8 Ω loudspeaker in this example will receive exactly one-half of the total power, or a maximum of 220 W.

Connect a single 8 Ω loudspeaker to one channel of this power amplifier, and that loudspeaker will still only receive a maximum of about 220 W. (The actual power will be slightly higher.) Connect a single 16 Ω loudspeaker, and it will receive a maximum of about 110 W. In other words, doubling the load impedance halves the power output of a power amplifier. Conversely, halving the load impedance doubles the power output of the amplifier. Remembering this simple relationship can help insure that a loudspeaker and power amplifier will be compatible in terms of impedance and power levels.

34.5.1.8 Digital Audio Level and Impedance Watching

Since most digital audio connections and cabling are based on computer standards, an audio system designer or installer may confidently use properly rated computer cable and connectors to connect digital audio devices. Pay attention to maximum cable length and, for portable applications, use connectors and cabling designed for portable usage. For proprietary or noncomputer-related digital audio connectors, such as the AES/EBU connection, consult the device manufacturer for cable and connector recommendations. Also see Chapter 39 for a detailed discussion of digital audio networking and connections.

34.5.1.9 Grounding and Shielding (also see Chapter 32)

Caution: In any audio system installation, governmental and insurance underwriters’ electrical codes must be observed. These codes are based on safety and may vary in different localities. In all cases, local codes take precedence over any suggestions contained in the Handbook for Sound Engineers.

Note that the ac power discussions in this section apply specifically to the United States only. The general discussions of grounding and shielding, however, should be applicable to audio systems used in any location. Always obey local and national fire and electrical safety regulations.
There are two primary reasons for careful grounding and shielding in an audio system. The first reason is safety. A poorly grounded system, especially outdoors, may be a shock hazard. The second reason is to reduce pickup of external noise. That external noise expresses itself in the form of hums and buzzes and other noises including radio station pickup.

34.5.1.9.1 Grounding for Safety

In U.S. electrical systems, the third (round) prong on the ac cable of any piece of audio equipment is the ac safety ground. When plugged into a properly wired ac receptacle, the third prong of the ac cable connects the chassis of the audio device to the ac ground through the third prong of the ac receptacle.

This is the ideal situation from a safety viewpoint. Under these conditions, there is almost no combination of events that could cause a shock hazard from a single audio device by itself. It is unfortunate (from a safety viewpoint) that any audio device is seldom used by itself; there are always other pieces of equipment involved, and most of the time, these are also ac powered. In addition, one or both of the following may be encountered:

1. Older audio equipment (in particular, guitar amplifiers) with two-wire ac plugs and ground or hum switches.
2. Older, two-wire ac receptacles or improperly wired three-wire ac receptacles.

34.5.1.9.2 Improperly Wired ac Receptacles

An improperly wired outlet, Fig. 34-65, may have its two ac wires reversed (polarity reversal), or it may have a disconnected ground. Any fault in the wiring of the ac receptacle is potentially hazardous, and, thus, the best, and perhaps the only safe way to deal with an improperly wired ac receptacle is to simply refuse to use it until it has been properly repaired by a licensed electrician.

A simple three-prong outlet tester can indicate many of these problems and is a useful addition to any audio technician’s tool kit. Note that the three-prong outlet tester cannot detect a ground-neutral swap. Neither can it detect a high-impedance ground. Both of these are hazardous conditions.

Another worthwhile measurement is the actual ac receptacle voltage, especially in an unfamiliar facility. Voltages that are too high or too low could cause improper operation, or even damage the equipment; too-high voltages could also pose a shock hazard. Most audio equipment will work fine on an ac outlet with voltages as low as about 110 Vac and as high as about 120 Vac. Newer equipment may be designed to automatically adjust for voltages as low as 100 Vac and as high as 240 Vac. Check the specifications for the equipment if there is any doubt.

34.5.1.9.3 Two-Wire ac Receptacles

All new ac installations in the United States use modern three-wire ac receptacles with a third ground prong. The problem with two-wire ac receptacles is that they don’t have that important third ground prong. Thus, to use one of these two-wire receptacles, it’s necessary to adapt it to the three-wire ac plug on a more modern piece of audio equipment using a two-wire to three-wire ac adapter. When the two-wire ac outlet is wired properly and a low-impedance grounded screw is available, these adapters can maintain a safe ground for the three-wire audio equipment.

To make this two-wire adapter work properly, connect the loose (ground) wire with a connector or the ground lug of the adapter to a grounded screw on the two-wire ac receptacle. To check the safety of the two-wire to three-wire connection, first, connect the loose wire on the adapter to the screw on the two-wire receptacle; then plug the two-wire adapter into the two-wire receptacle. Next, plug a three-wire ac outlet tester into the adapter. If the screw is grounded, the ac outlet tester will so indicate. (Most three-wire ac outlet testers either have a “good” light or they don’t light at all on a good receptacle.) If the screw is not grounded, the outlet tester will so indicate. In this case, connect the loose wire from the adapter to some other grounded screw in order to maintain a safe ground. If the outlet tester shows a good ground but reversed polarity on the two-wire to three-wire adapter, simply reverse the adapter in the receptacle.

Remember that the three-prong outlet tester cannot detect a ground-neutral swap, a hazardous condition. Also, it is possible for the three-prong outlet tester to indicate a good ground when the ground connection is actually a high-impedance ground (poor connection). For these reasons, it is strongly recommended that, whenever you are connecting any three-wire ac-powered equipment to any two-wire ac receptacle, you use a portable GFI (ground fault interruption) device to protect the equipment and the users.
34.5.1.9.4 Older Two-Wire Audio Equipment

Some newer equipment, especially consumer-type equipment, may come with a two-wire ac cable. This newer equipment may be as safe as if it had a three-wire (grounded) ac cable. A good example of such a piece of (nonaudio) equipment with a two-wire ac cable is a double-insulated power tool (drills, saws, and so on). One way to judge the safety of a piece of audio equipment with a two-wire ac cable is to look for a UL (Underwriter’s Laboratories) sticker. Listings from other recognized safety agencies may also be used to judge the safety of a piece of equipment.

It’s the older, two-wire audio equipment, however, that can be potentially hazardous. The details of how a shock hazard can develop are complex, but dealing with this problem in an audio system is straightforward. The shock hazard, if there is one, will probably develop between the chassis of an older, two-wire guitar amplifier and the chassis of a microphone.

The chassis of the microphone is connected to the chassis of the microphone-preamplifier-mixer through the shield of the connecting cable. Thus, if the mixer is properly grounded, the chassis of the microphone is properly grounded, too, and neither the microphone nor the mixer will present any safety hazard. The guitar amplifier (or other two-wire equipment), however, is, potentially, not properly grounded. That means that a hazardous ac voltage could be present on the chassis of the guitar amp or on the strings of a guitar, which are connected to the chassis of the amplifier through the shield of the guitar cord.

Although it is possible to test for this problem, it’s also important to protect the user with a portable GFI (ground fault interruption) device on the guitar amplifier.

34.5.1.9.5 Grounding for Safety Outdoors

The most common safety problems outdoors are improperly wired portable ac outlets and wet ground or wet portable stages (and, of course, rain). Check the wiring carefully, using the same techniques as if the system were indoors. Consider canceling a performance if rain begins. If a performance must proceed on wet ground or in the rain, the best way to avoid shock hazards to the performers is to use wireless microphones and wireless instrument transmitters. These same outdoor problems, of course, can develop indoors on a damp floor. Portable GFI (ground fault interruption) devices are strongly recommended for any equipment used in an outdoor or damp indoor situation.
34.5.1.9.6 Grounding to Reduce External Noise Pickup

After safety, the second reason to pay attention to grounding is that, although proper grounding won’t always reduce external noise pickup, poor grounding can unquestionably increase external noise pickup.

One myth about grounding is that a piece of equipment must be earth grounded to avoid noise pickup. Anyone who owns a portable MP3 player or CD player knows that this isn’t true. Good grounding practice is primarily a matter of proper connections between devices, avoiding ground loops and using equipment that does not have the “Pin 1 Problem.”

34.5.1.9.7 Definitions: Ground, Earth, Common

A common connection in an audio system is some point where a group of circuits (usually shields or other zero-signal circuit lines) connect. Ground in an audio system is the primary zero signal reference for the system. In a typical system, there may be a common connection of all audio signal shields and a separate common connection of all power-supply negative terminals. At some physical point in the system, these commons are connected together. That point becomes the system ground and is called the zero signal reference potential because that is the place where a voltmeter reference lead is placed. An earth connection is a connection directly to the earth often made via a copper rod driven into moist, salted soil. The system ground is physically connected to the earth at this copper rod. These terms are not fixed in meaning, however, and the term ground, for example, is often used in place of either of the other two terms, or grounding may be used as a general term to describe the practice of external noise reduction. In addition, outside the United States, the term earth is often used in place of the term ground to indicate the system zero signal reference potential.

34.5.1.9.8 Ground Loops in Unbalanced Systems

A couple of examples will help explain what ground loops are and how to avoid them (also see Chapter 32). In Figs. 34-66, 34-67, and 34-68, the loop is between two audio cables that connect a line-level device to a power amplifier with unbalanced inputs. These are examples of unavoidable ground loops. The best way to deal with this type of ground loop is to keep the cables as short as possible and bundle them physically as close together as possible (lace or tape them together if the setup will allow it). This reduces the area enclosed by the loop, which will reduce the pickup of external noise. Alternately, use an appropriate transformer to balance the connection and allow a telescoping shield to interrupt the ground loop (see the next section).

34.5.1.9.9 Ground Loops in Balanced Systems and Using the Telescoping Shield Connection

By using balanced connections between two pieces of audio equipment, the shield at the receiving end can be lifted (disconnected) to interrupt one type of ground loop, Fig. 34-69A. This lifted ground results in what is known as a telescoping shield. Since, in a balanced line, the shield does not carry audio signal, it can be disconnected at one end without interrupting the audio signal (and without disrupting the effectiveness of the shield). Unfortunately, this is not a very practical solution to the problem in a portable audio system because it would require special cables that have the shield disconnected on one end (also see Chapter 32).

In Fig. 34-69B the ground loop occurs between a microphone splitter and the two mixers. Even though...
there is only one audio cable connecting the two devices, a second ground connection, through the ac cables of the devices, makes the return connection and forms a ground loop. Using a telescoping shield breaks the ground loop and thus helps prevent pickup of magnetically coupled and common-impedance coupled noise. In Fig. 34-69C a ground-lift switch has been installed so that, when opened, the ground connection through the shield will be interrupted. Never lift the ac ground on a power amplifier or otherwise defeat the ac safety ground on any piece of equipment.

34.5.1.9.10 The Pin 1 Problem

Unfortunately, not all professional audio equipment is properly grounded internally. In some equipment, noise from the shield of a connecting cable is coupled via common impedance into the internal signal path through improper grounding of pin 1 of an XLR connector. Noise caused by this problem will frustrate the best efforts of an experienced installer because the problem is inside the equipment and it cannot be solved externally. The only solution for this problem is to substitute a different piece of equipment with proper internal grounding. Chapter 32 has a more detailed description of this problem.

34.5.1.9.11 Transformers versus Active Balanced Inputs and Outputs

All attempts to solve hum and noise problems can be frustrated if even one piece of system electronics has poor rejection of hum and noise. To avoid this problem, all system electronics should have balanced inputs and outputs (except, of course, for the outputs of system power amplifiers unless they are 70.7 V systems). In addition, the internal circuit design of each piece of audio equipment should be optimized in terms of good grounding and shielding performance.
Both transformer-coupled and active-balanced equipment can provide excellent hum and noise rejection. As a general rule, however, high-quality transformer-coupled inputs and outputs will outperform all but the best active-balanced designs in terms of hum and noise rejection. In addition, transformers offer the benefit of protection against stray dc.

The choice should be made based on a careful examination of the device’s specifications, especially the noise rejection performance of the input stages. In addition, remember that lower-quality transformers and simple-circuit, low-performance active balanced inputs and outputs will probably not provide the expected level of hum- and noise-rejection or of audio performance.

34.5.1.9.12 Using Proper Shielding to Reduce Noise Pickup

Proper grounding helps prevent pickup of noise that is transmitted magnetically and noise that is coupled through a common impedance. Magnetically transmitted noise most often comes from motors or, more commonly in audio, from large ac power transformers (either building transformers or the power transformers in a power amplifier or other piece of audio equipment). Proper shielding, on the other hand, helps prevent pickup of noise that is transmitted capacitively. Capacitively transmitted noise may be in the form of radio waves from a radio station or citizens band radio, or it may be in the form of static from certain types of motors or lighting dimmers. Noise from lighting dimmers may also come through the ac lines.

Proper shielding, except in severe noise situations, is straightforward. Use high-quality shielded cables on all microphones and on all line-level equipment, and, if at all possible, install the electronics in a metal equipment rack (preferably steel since this also provides some protection against magnetically coupled noise). Some very low-cost audio cables including guitar cables have poor quality shields. Watch for these potential sources of noise pickup, Fig. 34-70.

It is seldom necessary to use shielded cable for loudspeakers, since they operate at a very high level and a very low impedance. The noise picked up by a loudspeaker cable is actually at the same level as the noise picked up by a microphone cable. However, because the loudspeaker operates at a much higher level than the microphone, the SNR is vastly better, and the noise is seldom a problem.

34.5.1.9.13 Reducing Noise Pickup from ac Lines

Some types of noise, notably noise from lighting dimmers, enter audio equipment from the ac power lines. There are four ways to reduce this problem (see Chapter 32). A licensed electrician must perform this troubleshooting and any needed modifications.

1. Install filters on the dimmer circuits (filters at the audio equipment won’t help as much and probably will cost a lot more).
2. Make sure the dimmer circuits are properly loaded. In other words, if the dimmers are rated for 1500 W loads, make sure they have 1500 W worth of lighting connected to them. (Or add a suitable dummy load to simulate a full-rated load on the dimmer.) The reason for doing this is that the noise filters (if there are any) will only work properly when the dimmer is loaded properly (this is an example of impedance matching).
3. Be sure the lighting circuits are properly grounded (improper grounding can increase noise levels at the source as well as at the audio equipment).
4. Use a different ac circuit.

34.5.1.9.14 More Tips on Reducing Noise Pickup

Rack Mount the Equipment. Rack mounting, especially when the rack mount rails are made of metal, connects the chassis of all the equipment into a unitized shield. Perhaps more important, rack mounting allows the use of shorter connecting cables and keeps them closer together. When rack mounting large power amplifiers, however, do not place sensitive, low-level equipment right next to them in the rack. The power transformer in a large power amplifier can produce a large alternating magnetic field that can induce hum in low-level equipment.
Keep the Cables Short. Rack mounting can help here, as can simple neatness.

Keep Cables of the Same Type Close Together. Group cables that carry the same signal level. Especially when they form an unavoidable ground loop, keeping cables close together will help reduce noise pickup.

Keep Cables of Different Types as Far Apart as Possible. This means keep the microphone cables away from loudspeaker cables. And keep all audio cables away from the ac power cables. On long cable runs, keep line-level cables and microphone cables separated. It’s a common, but risky, procedure to run microphones through a snake (a multimicrophone cable) to a mixer and then run the outputs from the mixer back to the power amplifier through the same snake. This mixing of levels, in a long cable run (greater than about 25 ft) can cause a form of electronic feedback that could cause harmful oscillations in the system mixer.

Keep the Wiring Neat. Carefully made cables, of the proper length (not too long), that are carefully laid out on a stage or in an installation are probably the best way of all to reduce external noise pickup, Fig. 34-71.

34.5.2 Testing and Adjusting

34.5.2.1 Signal Delay in Sound Reinforcement

There are two uses for signal delay in sound reinforcement. The first is to delay one loudspeaker system to allow the sound from a remote loudspeaker system to catch up. This avoids the creation of an artificial echo. The second purpose of signal delay in sound reinforcement is to line up the wave fronts from the components in a packaged loudspeaker system or, similarly, to line up the wave fronts of the various loudspeakers in a loudspeaker cluster.

34.5.2.1.1 Signal Delay for Loudspeaker Clusters

To calculate the delay for a rear cluster in a two-cluster system, choose a typical listener in the coverage pattern of the second cluster who can still hear the first cluster. Calculate the distance from this listener to the first cluster and subtract the distance from this listener to the second cluster. Perform this calculation for several listeners in the coverage of the second cluster who can also hear the first cluster. Choose an average value, biased toward those listeners who can hear the first cluster best. Multiply this average value times 1.13 for distances in feet or 3.71 for distances in meters, to obtain the starting point for delay in milliseconds. Add 6 to 20 ms (the exact amount is best determined on site by listening) to take advantage of the localization known as the Haas effect.

34.5.2.1.2 Signal Delay for an Under-Balcony Distributed System

Choose a listener near the front of the area under the balcony, one who can hear both the central cluster and the under-balcony distributed system. Then, follow the instructions in Section 34.5.2.1.1 above.

34.5.2.1.3 Signal Delay for a Loudspeaker or Loudspeaker Cluster

See Section 34.3.2.11 for a discussion of this topic.

34.5.2.2 Equalization

34.5.2.2.1 The Concept of Equalization

Sound system equalization is a process of adjusting the electronic frequency response of a system to compensate for uneven loudspeaker response and room acoustics. The goals of equalization are to provide a natural-sounding system with good intelligibility and to minimize feedback that might be caused by peaks in the frequency
response. In entertainment sound reinforcement systems, equalization may also be used to enhance the sound quality of, for example, a nasal-sounding performer’s voice. This use of equalization is very different from the other uses and, in general, it is better to avoid using the same equalizer to both equalize the overall system and provide enhancement of an individual performer.

34.5.2.2.2 What Equalization Can and Cannot Do

Equalization can make a well-designed system sound subjectively better. It can improve intelligibility by smoothing the frequency response or by deliberately peaking response in the intelligibility frequencies (approximately 1500–5000 Hz). Equalization can also help minimize feedback caused by frequency-response irregularities.

Equalization cannot make a poorly designed system sound good. Equalization cannot significantly improve the sound quality of poor-quality loudspeakers. Equalization cannot affect the reverberation time in a room in any way.

Equalization cannot significantly improve a feedback problem in a room where the PAG (potential acoustic gain) is unacceptable. And equalization cannot solve system response problems when those problems are caused by signal alignment irregularities.

34.5.2.2.3 System Design Criteria for Equalization

Equalization should be the icing on the cake for a well-designed system. A system to be equalized should be designed using high-quality, low-distortion loudspeakers and electronics with adequate head room. In a multiloudspeaker system, solve any signal-alignment problems before attempting to equalize the system (see Section 34.3.2.11).

34.5.2.2.4 System Equipment

The system to be equalized must have an equalizer permanently installed in its signal chain. The equalizer must remain in the system after the equalization process has been performed and thus should be a high-quality device with low distortion, low noise, and balanced input and output. Filters should combine smoothly between sections. For a parametric, this can be accomplished by using as broad a bandwidth as possible during equalization and overlapping the bandwidth of adjacent filters just enough to keep the electrical response smooth.

Commonly, the equalizer will be a module in a DSP. Choose the module to meet the above criteria.

34.5.2.2.5 Test Equipment

Test equipment should include a calibrated, flat-response microphone, a ½-octave real-time audio spectrum analyzer, Fig. 34-72, (often called a real-time), and a pink-noise generator. All equipment should be high quality and properly calibrated. If available, a sound level meter, with a flat response position, is useful. Some meters have a line-level output and can thus be used as the system test microphone, Fig. 34-73. Note that newer, computer-based test instruments, such as SIA Software’s SMAART system, Fig. 34-74, offer a real-time analyzer function and may thus be used in the equalization process.

Often, a house microphone is substituted for the calibrated microphone in the equalization process. This allows the system response to be adjusted to compensate for the response of the microphone as well as the loudspeakers and the room acoustics. The house microphone, however, should only be used when there is only one type of microphone in the system (and all such microphones have manufacturers’ response curves that are very similar to each other).

If more than one type of microphone is used in the system, either a separate equalizer must be used for each type of microphone (indicating a separate mixer) or the calibrated microphone should be used for the
equalization process and mixer tone controls used to adjust for different microphone types (a more reasonable approach).

34.5.2.2.6 The Test Setup

Connect the pink-noise generator to a typical microphone input (use a pad if necessary to connect a line-level pink-noise generator to a microphone input). Set all system tone controls to their flat positions, and set the equalizer controls to flat. Place the real-time analyzer near the equalizer and place the test microphone in a typical listening position. Avoid placing the microphone directly on-axis of any individual loudspeaker, Fig. 34-75.

Figure 34-75. Equalization test setup diagram.

Turn on the system and the pink-noise generator, and using the sound-level meter in its flat and slow response positions, set the system gain for the design level. That is, if the system was designed for 90 dB with 10 dB of head room, increase the system gain until the meter reads 90 dB. If the system produces the proper output, reduce the signal at least 10 dB so the system will not go into clipping in any octave.

Turn on the real-time analyzer and observe the response. Note any significant peaks or dips. Move the test microphone to several different locations and note the changes. If the analyzer has memories, these can be used in comparing microphone positions. If the system response changes radically from position to position or has significant peaks or dips at any position, attend to these problems before beginning the equalization process.

34.5.2.2.7 The Equalization Process

To equalize the system, first adjust the high-frequency and low-frequency power amplifiers (in a biamplified system) for the flattest response as indicated on the real-time analyzer. Begin the process of adjusting the equalizer by observing the real-time analyzer and choosing a frequency area that peaks above the rest of the response curve. Using the equalizer, reduce the response in this frequency area. In the beginning of the process, avoid cutting or boosting any frequency more than about 3 dB since later adjustments of adjacent filters may affect the earlier adjustment. Do the same at any other significant peaking areas. If the system equalizer includes boost capabilities, boost carefully between system peaks if you desire, being sure that you are not
trying to boost a diaphragmatic absorber (again, no more than about 3 dB at first) to help smooth system response. At this point, a smooth, not flat, response is the goal.

In many two-way, central-cluster systems, response peaks will come in the neighborhood of 200–2000 Hz. These frequencies include the efficiency peaks of the low- and high-frequency loudspeakers and reflect the normal midrange deficiency of many two-way systems. These peaks are, therefore, the first place to make system adjustments, again, working for smooth response at first.

34.5.2.2.8 The Desired System Response Curve

Once the system response is reasonably smooth, begin adjustments toward the desired system response curve, as shown in Fig. 34-76. For a speech-only system, the final curve should be relatively flat from its low-frequency limit (about 50–80 Hz) up to about 1000 Hz. At 1000 Hz, the response should begin a roll-off of about 3 dB/octave to about 8–10 kHz. Response above this frequency should roll-off more rapidly (use a system low-pass filter if available). For a music or music and voice system, begin the roll-off at about 2000 Hz and allow the response to follow this roll-off to 12.5 kHz or higher with rapid roll-off above the desired maximum frequency.

This high-frequency roll-off is a guideline and should be modified for each individual system on the basis of subjective sound quality. The purpose of the roll-off is to improve the system sound quality, since a perfectly flat system response, as displayed on the real-time analyzer, will sound overly crisp, and vocal sibilants (high-frequency breath sounds) will be overly emphasized.

The final equalization curve will probably not follow these rolloff curves perfectly. A final system curve within ±2 dB of the desired curve is, in most cases, more than adequate. Avoid filter settings more than a 6 dB boost or cut whenever possible, remembering that a 6 dB boost requires four times the amplifier power output and four times the loudspeaker power capacity. For this reason, a final equalization curve that requires only a ±3 dB setting on any individual filter but is within only ±3 dB of the desired curve may sound better than a final curve that is within ±1 dB of the desired curve but required ±6 dB of equalization at several filter positions (and, therefore, reduced system head room and increased system noise).

34.5.2.2.9 Why High-Frequency Roll-Off Is Required in Equalization

The reverberant field in most rooms is dominated by the low frequencies. When the equalization microphone is placed in the reverberant field (past the $D_c$, critical distance from the cluster), the frequency response shown on a real-time analyzer will also be dominated by the low frequencies. From another point of view, the low frequencies don’t attenuate much past $D_c$ because they are supported by the reverberant field. The high frequencies, however, continue to attenuate past $D_c$ since they are not supported as strongly by the reverberant field. For this reason, the real-time analyzer will show a frequency response that is dominated by the low frequencies (bass heavy).

If equalization is then performed using this real-time analyzer display, which is low-frequency dominated, most people will tend to boost the high-frequency response of the system (or cut the low-frequency response) to make the analyzer display a more flat response. This, however, causes the direct sound from the loudspeaker system to be dominated by the high frequencies and our perception of the sound quality will then be that it is too sibilant or too harsh or lacking in bass. The rolloff curves shown in Fig. 34-76 were developed to avoid this problem.

The experience of those engineers who have experimented with direct-sound-only equalization using TEF analyzers (not real-time analyzers) supports the idea that we judge the response of a system based on the direct sound and not on the direct plus reverberant sound. The discussion of the need for roll-off in the previous paragraphs also supports this concept.

One additional reason to roll off the high-frequency response during equalization is to compensate for the presence boost that exists in many microphones. Listen to the system using the house microphone to see if any additional roll-off is needed for this problem.

34.5.2.2.10 Use of High- and Low-Pass Filters

A 12 or 18 dB/octave high-pass filter, at approximately 50–160 Hz, will enhance the performance of a voice-only system by filtering out unwanted low-frequency transients like dropped microphones and breath pops. For a music or music-plus-voice system, use a high-pass filter at 20 Hz or above. Most music systems are actually improved by a high-pass filter at 40–80 Hz. In addition, a vented-box-type, low-frequency enclosure should be high-passed at a frequency slightly below the
A 12 or 18 dB/octave low-pass filter at 12.5–20 kHz will reduce unwanted RF signals and will help prevent system electronic oscillation. In a music system, a low pass at 16–20 kHz will improve the system for the same reasons. Any system with a high-pass filter should also have a low-pass filter for frequency-response balance (the sound quality will be improved).

High-pass and low-pass filters are often included as part of the system equalizer and are available modules in almost every DSP device.

34.5.2.2.11 Equalization Using TEF or Other Equipment That Measures Direct Sound Response

Some users of Time-Energy-Frequency (TEF) test equipment, and other test equipment that can measure direct sound response, have reported very good success in equalizing the direct sound from the loudspeaker system, ignoring (at least temporarily) the frequency response of the reverberant sound. This tends to support the idea that the primary usefulness of equalization may be to smooth the response of the loudspeakers, not the room.

When equalizing the direct sound using TEF-type equipment, do not follow the high-frequency roll-off curves indicated in Fig. 34-76. Instead, equalize for a relatively flat response. Then, begin a gradual high-frequency roll-off at 10–12 kHz. Finally, adjust the overall response for a subjectively pleasing sound while remembering the goals of smooth response and intelligibility.

34.5.2.2.12 Use of Narrow-Band Filters in Equalization

Very narrow-band filters are sometimes added to an equalized system for the purpose of controlling feedback and the ringing that occurs in a system that is near feedback. Used in a well-designed and carefully equalized system, narrow-band filters can be successful for these purposes. Common filter types include parametric filters tuned to a very narrow bandwidth and active and passive narrow-band or notch filters.

Narrow-band techniques for controlling feedback work best in fixed systems in rooms with constant microphone and loudspeaker positions. Even in a portable system, a skilled operator may be able to readjust a set of narrow-band filters to make them useful for feedback control. As in any attempt at feedback control by filtering or equalization, only two or three feedback
(or ringing) frequencies can usually be eliminated before a point of diminishing returns is reached.

34.5.2.13 Equalization Using Source-Independent Measurement (SIM)

Developed by John Meyer of Meyer Sound Laboratories and Brüel & Kjaer Instruments, the Source Independent Measurement method of equalization uses the sound source, voice or music, as the equalization test signal and an FFT (Fast Fourier Transform) analyzer as the test equipment. While more complex than traditional equalization, the promoted advantages of this equalization method are that it can be used during a concert performance to correct and recorrect changes in system response due to changes in audience size or room humidity.

34.5.2.14 Automatic Equalization

Some manufacturers have offered systems that, when properly set up, could actually equalize themselves. However, most designers believe that equalization is complex enough to require the engineering judgments of an experienced human operator. For this reason, there are few such systems on the market, Fig. 34-77.

34.5.3 Rigging the Cluster

There are three sections to every rigging system:

1. The loudspeakers and their internal hardware.
2. The building structure.
3. Everything between the loudspeakers and the building structure.

The loudspeaker manufacturer must certify that the loudspeaker is designed for suspension. Do not suspend any loudspeaker unless the manufacturer has certified it for suspension. The manufacturer must also specify any limitations on rigging such as the number (or weight) of additional loudspeakers that can be suspended below a single loudspeaker.

For a new facility, the building architect or structural engineer must certify the building structure as being capable of supporting the weight of the cluster with a suitable design factor (safety factor). The system designer must supply the architect or structural engineer with the installed cluster weight. For an existing facility, the owner or system designer should contact the original architect or structural engineer for approval to suspend the cluster in the desired location. If the original architect or structural engineer is no longer available, find another architect or registered professional engineer (PE) to inspect the structure and approve the system suspension in the desired location(s).

The rigging system itself is the responsibility of the system designer and the installing contractor. This includes rigging cables, any suspension grid, and all associated hardware (the loudspeaker manufacturer may supply eyebolts for its loudspeakers). The system designer or installing contractor must present the rigging system design, with associated drawings, to an outside registered architect or professional structural engineer for official approval.

The system must be installed by experienced, professional riggers. Always use hardware that is designed and certified for rigging usage, Fig. 34-78. The system designer should supervise the cluster installation to confirm the aiming points of each loudspeaker.

When finished, the loudspeaker cluster should be inspected for proper loudspeaker aiming and rigging safety. Document the entire installation with as-built drawings.

34.5.4 System Documentation

Here are the most important system documents and their purposes.
Figure 34-78. Certified rigging hardware. Courtesy ATM Hardware.
34.5.4.1 Original Plans and As-Built Drawings

As-built drawings are critical for service technicians and for a designer of any future system expansion. Keep a set of original plans as reference for any changes that were made. Include a final block diagram (one-line or riser diagram) in the as-builds.

34.5.4.2 Equipment Lists and Equipment Owner’s Manuals

Keep an accurate final equipment list. Both the installing contractor and the end user should keep owners’ manuals since these may not be available if equipment becomes obsolete.

34.5.4.3 Software Configurations and Backups

Backup the configuration files for DSP systems. Sound systems may be used for a decade or more before being replaced. For this reason, it’s a good idea to keep copies of the software used to configure/program the DSP since newer versions may not work on older hardware.

34.5.4.4 Approvals and Certifications

Keep rigging drawings and approvals and any other safety agency approvals such as those from a local fire marshall.

34.5.4.5 Additional Documentation

Keep a written record of all system settings such as amplifier-level control settings and equalizer control settings.

34.5.5 Troubleshooting a Sound System

Repairing a sound system may require the skills of a trained technician. Troubleshooting, that is, finding the problem, is something almost anyone can do if they

1. Know the block diagram of their system.
2. Understand what each component in the system is supposed to do.
3. Know where to look for common trouble spots.

34.5.5.1 Know the Block Diagram

A sound system block diagram explains how the various components in the system are connected to each other and what happens to a signal as it flows through the system. Because the block diagram shows the way the sound system operates, it is extremely useful in the troubleshooting process.

As obvious as it may sound, it’s not possible to tell whether a component is working properly or not unless its original function is well understood. Thus, it’s a good idea to keep instruction manuals on all components handy. Some repairs are as simple as repositioning a control knob or throwing a switch that someone has inadvertently changed.

Cables and connectors are by far the most common sources of problems in audio systems. This is the best reason to keep lots of spares, especially of cables that are moved around a lot, such as microphone cables.

Other common trouble spots are fuses and circuit breakers, as well as switches and controls that are in the wrong positions, and problems with house ac power.

34.5.5.2 Logical Troubleshooting

The process of troubleshooting involves logical thought and methodical tracking down of a problem by elimination.

Logical thought processes come into play when a problem first occurs. If a single microphone goes suddenly dead, logic says that the power amplifier probably isn’t at fault. If, on the other hand, an entire system is suddenly quiet, the power amplifier might be at fault, because it’s not likely that all the microphones have failed at once.

A methodical elimination process, as shown in Figs. 34-79 and 34-80, can track down the source of most problems very quickly. The idea is to find out what component (microphone, cable, mixer, amplifier, loudspeaker, etc.) is causing the problem and to replace or repair it. During a live performance, of course, replacing a faulty component is the most likely cure since a repair might take up too much time.

The system mixer is a good place to begin the troubleshooting process because it has the controls for the entire system. A noise in the system, for example, can be traced by looking at the VU meters or listening to a PFL (pre-fade-listen) circuit with headphones. This alone, may indicate that the noise problem is coming from one microphone. Pull down the fader for that input channel. If the noise goes away, check out the microphone, or more likely, the microphone cable.

If the entire system suddenly goes dead, again, check out the VU meters or listen to the PFL. If they are still active, then it is most likely that the system is working through the mixer (it’s still possible that the output circuits of the mixer are at fault). Thus, some compo-
The component farther along in the system is the most likely culprit. Think through the block diagram at this point to find the next suspect component. (One component that may be a problem is the house ac power.)

When possible, patch around suspect components. For example, a limiter can be completely removed from the system, and the system will still operate. Thus, if a limiter is suspect, use a patch cable to bypass it. If the bypass operation causes the system to begin operating again, the limiter is at fault.

When the suspect component is necessary to the operation of the system, try to replace it with some other equivalent component. If a loudspeaker is suspect, for example, try switching it with a similar loudspeaker or even a stage monitor loudspeaker temporarily in place of a main system loudspeaker. If the mixer is suspect, try running a CD player or MP3 player directly into the system power amplifier to make sure that portion of the system is still working.

### 34.5.5.3 DSP Troubleshooting

It’s common for an all-in-one DSP unit to host all of a sound system’s signal processing—everything between the mixer and the power amplifiers. A suspect all-in-one DSP like this can’t be bypassed for troubleshooting. Also, it’s not easy to swap it for another DSP, even if one is available, because the second DSP must be pro-

---

**Figure 34-79.** Troubleshooting Part 1. Assumes that the problem is hum, noise, or oscillation and that block diagram flow is from left to right. Method is to break system (disconnect) at indicated points until the faulty component is located.
grammed and adjusted exactly the same as the first DSP. If you suspect an all-in-one DSP, try patching from the mixer directly into the system power amplifiers. Keep the level down on the mixer and insert the mixer’s input-channel high-pass filters to avoid damaging HF loudspeakers. This is a crude method but should provide some insight into the problem.

A second problem with DSP troubleshooting is that the trouble may be improper DSP programming or adjustment. For example, if a graphic equalizer module has several adjacent filters reduced by several dB, it may be necessary to increase the gain in the following module to compensate. Then, if a high-level signal occurs that’s outside the frequency range of those filters, it may overdrive the following gain stage. It’s not easy to troubleshoot this kind of problem because you can’t insert real test equipment between the DSP modules. However, many DSP units now include meters and signal generator modules that can be patched into system nodes for troubleshooting.

Figure 34-80. Troubleshooting Part 2. Assumes that the problem is distortion or interruption of signal and the block diagram flow is from left to right. Method is use of signal generator and tracer (a tape deck and powered loudspeaker may suffice) to locate the faulty component.
34.5.5.4 Anticipating and Preparing for Problems

These techniques can help troubleshoot DSP problems and other problems but this kind of troubleshooting can take time. Thus, it’s better to anticipate potential problems in the system and prepare to solve them quickly. Keep spare cables, spare components, and troubleshooting equipment nearby. Plan what to do if a critical system component fails. This includes the system mixing console and any all-in-one DSP units. Some facilities with critical sound requirements keep a smaller mixer and a second, programmed DSP ready to swap in case of failure. Finally, when possible design the system to minimize problems resulting from the failure of a single piece of equipment. For example, replace the all-in-one DSP with networked amplifier DSP units. This way, the failure of a single DSP cannot cause the entire sound system to fail.

34.6 Applications

34.6.1 Portable and Tour Sound Systems

Portable systems range from voice-only paging systems, as might be used at a local county fair, up to the giant tour sound systems used for outdoor rock music festivals. The design criteria for a portable system build on the criteria discussed for permanently installed systems, adding to and modifying the system to take into account such obvious considerations as travel and less obvious considerations such as the potential for abuse by an inexperienced operator or an overexcited audience.

34.6.1.1 Packaging

Portable systems must be rugged to survive travel. They must be packaged efficiently in order to fit into as small a travel vehicle as possible and so that setup and tear-down are quick and efficient. Even large tour sound systems are normally designed to fit efficiently into standard-size trucks (48 foot or 52 foot semitrailers in the United States). Efficient packaging leads to lower ownership and operating costs from the ability to use smaller vehicles (or fewer large vehicles) and from the requirement of fewer hours for setup and teardown. Rugged packaging for all components of the system, from loudspeaker systems to electronics to microphones and accessories, also reduces system maintenance costs and improves reliability.

34.6.1.2 Loudspeaker Systems

In the past, a county fair might rent a portable system consisting of a group of 70 V paging horns, matching electronics, and one or more paging microphones. Today, most portable systems use packaged loudspeakers or line arrays and the largest tour sound systems may even use proprietary loudspeaker systems designed and built by the tour sound company itself.

For efficient arraying, most portable packaged loudspeaker systems are trapezoidal in shape. Manufactured packaged loudspeaker systems are usually two-way or three-way designs. Proprietary, tour-sound packaged loudspeaker systems are commonly three-way or even four-way systems.

Although some four-way proprietary tour-sound systems include subwoofers, most popular music applications use separate subwoofers. Separate subwoofers mean the main packaged loudspeaker systems can be smaller. Putting subwoofers on the floor reduces the size of any suspended array.

Smaller portable systems may use a single type of packaged loudspeaker. For example a weekband band may use a two-way or three-way, 90° design and find this fills its needs for nightclubs and smaller dance halls. Larger systems will benefit from more than one type of packaged loudspeaker system. For example, a mid-sized tour sound system might include both 60° and 90° packaged loudspeaker systems along with separate subwoofers.

In the past, tour sound systems used separate components (horns and woofers) in place of today’s packaged loudspeaker systems. While systems using separate components took longer to set up and tear down, they provided increased versatility because the operator could choose from multiple horn patterns and design a custom array for each venue.

A designer of a portable system today could bring back some of this versatility by including both 60° and 90° packaged loudspeaker systems, by using separate subwoofers and by packaging a few component long-throw (40° by 20°) horns to cover the upper seats in an arena or the far rows of an outdoor theater.

Many tour sound companies are now using line array-type systems. These systems utilize specially designed loudspeaker systems and sophisticated DSP electronics to create precisely controlled vertical directivity patterns that can reach the back of an audience with good sound quality while maintaining a reasonable level in the front.

Selected models of line arrays and packaged loudspeaker systems are available in self-powered versions
with internal amplifiers and often with internal DSP signal processing, which may include crossover, delay, limiting, and equalization. If designed for portable use (and suspension), these systems can eliminate the need to carry racks of amplifiers and signal-processing gear. However, they complicate suspended system design because ac cabling must be included in the array.

34.6.1.3 Portable System Rigging

Rigging a portable system is much like rigging a permanently installed system (see Section 34.5.3). Do not suspend any loudspeaker system unless its manufacturer has certified it for suspension. Get the entire rigging system approved by a licensed architect or professional engineer (PE). For each new venue, consult with the building architect or a local PE to confirm that the building structure is capable of supporting the system with adequate design factor (safety factor). Have the system rigging performed by certified rigging professionals.

34.6.1.4 Cabling

The cabling system for a portable system must be every bit as rugged and efficient as the packaging for the loudspeaker systems. Solid-core wire is absolutely out of consideration. High-quality, multistrand wire of a large wire size (low gauge number) is highly recommended.

Loudspeaker connectors must be rugged, high capacity, and easy to connect (but difficult to connect improperly!). While smaller portable systems may utilize high-current phone plugs, most larger systems use a specialty type of twist-lock loudspeaker connector, manufactured by Neutrik and known as the Speakon. Some amplifiers even have Speakon connections.

Microphone connectors are invariably XLR type for good reasons. The XLR connector is rugged yet easy to connect and disconnect. It has ample current capacity for microphone and line-level signals, and it has limited self-wiping (cleaning) of its contacts. Furthermore, pin 1 of the XLR always connects first. This allows the shields of the cables being connected to equalize their static charge before the signal wires are connected and thus helps avoid electrical (static discharge) transients. Snakes with only a few cables are often terminated with a group of individual XLR connectors. Larger snake cables often have elaborate multipin connectors that lead to either a group of XLRs or a metal box with a group of chassis-mounted XLRs. Some tour companies have adapted their mixers to accept a multipin snake cable directly. This simplifies connections but eliminates the ability to repatch the cables (at least at the mixer) for a different stage setup, and it hinders quick troubleshooting.

Digital cabling for sound systems borrows from computer network standards. Unfortunately, computer networking connectors such as RJ45 (Ethernet) and fiber-optic connectors, are not rugged enough for constant portable usage. Some manufacturers now offer ruggedized versions of these connectors, Fig. 34-56, and more such connectors will certainly appear in the future.
34.6.1.5 Electronics

Electronics for portable systems are generally the same as for installed systems. Choose the electronics for ruggedness, however, in addition to performance. The large power transformer on a power amplifier, for example, must be securely fastened to its chassis to avoid physical destruction of the power amplifier during the jolts of traveling over rough roads.

Most portable equipment will be rack mounted. Thus, the equipment must be designed to survive the jolts of travel when mounted in a rack. Experienced tour companies often support the rear of large rack-mounted components to help prevent damage. The racks themselves, of course, must be rugged and travel well, and small racks can mean heat buildup so that extra cooling fans should be considered.

Some manufacturers offer electronic packages specifically designed for traveling. The powered mixer, designed for smaller portable systems, is a good example. Some powered mixers include a full-function mixing console, internal effects, one or more graphic equalizers, compressor/limiters, and one to four power amplifiers. For a small- to medium-sized portable system, these powered mixers are often the only electronics needed.

Mixers and other nonrack-mounted equipment must be carried in padded road cases. Similar cases can be used for microphones, cabling, and system accessories.

34.6.1.6 Multichannel Portable Systems

The primary problem with a multichannel portable sound system is that, ideally, each member of the audience should be able to hear all of the individual channels. That means, ideally, each loudspeaker channel must cover the entire audience. The large system required to make this happen prevents true stereo sound in most portable systems. Stereo-type effects, however, can be achieved with traditional left and right loudspeaker systems, and side and rear loudspeaker systems can be successfully used for fill and special effects.

34.6.1.7 Electrical and SPL Safety in Portable Systems

Electrical safety in portable systems is complicated by the uncertain condition of the ac power system of each building. One excellent way to bypass this problem simply is to carry a portable ac power distribution system, which should be designed and constructed by a qualified, licensed electrician. Have a local licensed electrician connect this portable system to the house ac power.

Often, the portable ac system can be connected directly to the building ac service entrance (a local qualified licensed electrician must perform this connection). This not only bypasses any potential safety problems in the house ac system but also provides a (relatively) clean ac power system for the noise-sensitive sound system electronics.

High \( L_P \) (high sound-pressure-level) hazards are often overlooked but are, nonetheless, dangerous. It is a well-established fact that high \( L_P \), over an extended period of time, can cause permanent hearing damage. Hearing protection is a must, especially when performing high \( L_P \) equalization or other testing or when checking out individual loudspeakers before or during a performance. It is possible to wear concealed ear plugs (the expanding foam type are comfortable and very effective) during a concert performance, even if you are mixing the performance. The human brain adjusts the hearing mechanism to the point where things begin to sound right again after a short period of wearing hearing protection. The situation is similar to wearing sunglasses. After a period, colors begin to look right again. This type of hearing protection is important especially for the extremely high \( L_P \) encountered during stage monitor mixing. When in doubt about whether or not you need hearing protection, listen to the ringing in your ears after a performance. This ringing, known as tinnitus, is the human body’s way of telling us that the sound level is too high. Prolonged exposure to these levels, of course, will almost certainly lead to permanent hearing loss.

34.6.1.8 Performance Criteria

Any system for entertainment must be designed to accept and reinforce an \( L_P \) of 100–120 dB. These levels represent amplifier power output and loudspeaker power handling in the neighborhood of 1000 times that of a speech-only system. Microphone input levels are such that electrical output from a high-sensitivity microphone may be as high as 0 dBu on peaks. Thus, mixers must have high-input capabilities and lots of head room.

Ideally, system head room should be as high as 20 dB, although, economically, this may be unobtainable. Extensive use of compressor/limiters can make a 10 dB head room system sound almost as good as one with 20 dB of head room (and the loudspeaker and power amplifier costs are lower).

The frequency response of a system designed for popular music must extend down to at least 40 Hz (or lower) and at least as high as 12–16 kHz. One way to
approach the design of this type of system is to design a vocal system with response from about 80 Hz to about 8 kHz and add supertweeters and subwoofers for the very low and very high frequencies. The subwoofers and supertweeters can be considered special effects for this type of system.

34.6.1.9 Stage Monitor Systems

Stage monitors are as important as the house loudspeakers for an entertainment sound system for the simple reason that they aid the entertainers and thus help encourage a better performance.

Stage monitor loudspeakers must be unobtrusive yet high performance. One way to accomplish this is to keep the low frequencies out of the stage-monitoring system so that enclosure size can be minimized. Another way is to place full-range stage monitors on the sides of the stage and limited-range monitors at the performer locations.

Whenever possible, treat the stage monitor system as a completely separate system. Split microphone lines on stage, and send one signal to the house mixer and another to a separate monitor mixer. Use a splitter transformer if possible so that grounding isolation can be maintained. Mix, equalize, and power the monitors separately, with the monitor mixer somewhere in the vicinity of the performers, perhaps at one side of the stage so that the operator can hear the results of mixing actions.

Multiple outputs are needed and useful on a monitor mixing system, since each performer may want his or her own mix. For this reason, several manufacturers offer mixers specially designed for the task of monitor mixing.

Equalization of a monitor mixing system is primarily for the purpose of avoiding feedback. Thus, multiband parametric and notch-type filters may be superior to the more common graphic equalizers.

Newer wireless in-the-ear monitoring systems have become a popular alternative to stage monitor loudspeakers. These systems, which operate on wireless microphone frequencies, allow each performer to receive a custom monitor mix and eliminate the need for monitor loudspeakers on the stage.

34.6.1.10 The Entertainment System as a Musical Instrument

Consider that many of the individual instruments used in modern music cannot exist apart from their electronics and loudspeakers. Add a sound system with multiple loudspeakers and, most likely, multiple phasing problems. Close mic the vocals to pick up breath noises not heard in normal conversation. Choose a microphone with lots of proximity effect so that performers can change the quality of their voices by the way they hold the mic. Close mic even the acoustic musical instruments so that feedback can be avoided but so that normal acoustic mixing of the complex acoustic sources in a musical instrument is eliminated. Mix the signals in a way that has little in common with the acoustic mixing that comes from the geographic layout of an orchestra. Add artificial equalization, reverberation, recorded segments, purposeful harmonic distortion, and other special effects. The result, when the sound system operator is as good an artist as the stage performers, is popular music! And, again, that popular music could not exist without the electronics, including the sound system. Finally, more and more, the sound system used in entertainment bears little resemblance to and cannot rightfully be called a sound reinforcement system. It certainly reinforces, but it also enhances, and, to a very great extent, it creates. Thus, there is ample justification for considering the entertainment sound system to be a musical instrument in its own right.

The significance of this, for traditional sound system designers, is that many of the rules of good sound system design can, and in fact, must, be modified for the design of an entertainment sound system. Perhaps more significant, a very well-designed and operated entertainment sound system can be extremely effective in performing its design goal, that of helping a group of artists to entertain an audience. A nontechnical member of that audience may believe that the particular type of sound system would be the answer to some sound reinforcement problem at a local facility. Technical and nontechnical people, then, should understand that the entertainment sound system is, in actuality, a musical instrument, designed for modern popular music, and only for that purpose. Place the same system in another facility and use it for reinforcement of speech or classical music, and it may be entirely unsuitable.

34.6.2 Systems for Religious Facilities

The primary challenges in designing a sound system for a religious facility are the user interface (many users will be volunteers who are unfamiliar with sound system operation), the aesthetic design (most religious facilities will want the loudspeakers hidden), and the acoustic environment (many religious facilities are, like the typical cathedral, highly reverberant).
34.6.2.1 User Interface

Many users in a religious facility are nontechnical and unfamiliar with sound system operation outside of, perhaps, a home theater system. There are two exceptions: the facility lucky enough to have a trained operator on staff and those facilities that have services that include popular religious music, dramatic presentations, and so on, and make full use of the capabilities of an entertainment-type sound system. These exceptions should receive a system designed with a trained operator in mind.

34.6.2.2 Systems for Inexperienced Operators

It’s a good idea to place all seldom used controls and adjustments (including the system equalizer) behind the locked door of an equipment rack or within the software of a DSP system. Minimize the number of controls seen by the user and minimize the complexity of their function. A typical set of controls might consist of a simple mixer with one set of treble and bass controls and a master volume control.

An automatic mixer can be extremely useful since it takes over most of the caretaker functions of mixing. A system with an automatic mixer may need only one user adjustment—the on-off switch. A compressor/limiter and a feedback detector/gain-reduction device would be valuable additions to such a system.

In any such system, provide needed and useful user interfaces such as an MP3 player, CD, or DVD player, and a volume control for each. It may be possible to integrate these into the automatic mixer so that volume controls on the external devices are all that are needed.

Also keep in mind the possibility that an experienced operator may volunteer, in which case the facility may wish to upgrade to a more complex user interface, probably in the form of a mixing console.

A digital mixing console may seem like an ideal way to provide increased capabilities to a religious facility with inexperienced operators. The designer can set up the console with recallable scenes and the operator simply selects the appropriate scene for each worship service. However, the smallest change in a service may necessitate significant changes in settings that require human judgment. When that happens, the digital mixing console may be more difficult to understand than a conventional analog mixing console. Thus, digital mixing consoles may be best for facilities with experienced operators.

34.6.2.3 System Aesthetics

Many religious organizations have large, architecturally beautiful facilities. In general, they do not wish to alter the architectural lines (which may have religious significance) by adding large loudspeakers. In particular, the central cluster type of loudspeaker system almost always ends up in an aesthetically undesirable location.

Religious organizations and their architects should be encouraged to design new buildings with a sound system in mind and to ask a qualified acoustical consultant to join in the process in the early planning stage. Systems for existing facilities, however, must contend with existing architecture and sight lines.

When a central cluster is the right choice for good coverage, it may be enclosed in a framework covered with grille cloth chosen to match the room decor. In those facilities with an attic space above the auditorium it may be possible to hide the system behind a large (new) opening in the ceiling, again, covered with grille cloth. Enclose the cluster above the ceiling, too, to prevent the loss of valuable heat through the hole in the ceiling. Brace the enclosure and line it with fiberglass or other sound absorbent material to help reduce acoustic problems.

Newer Christian churches in the United States often choose a wide, fan-shaped auditorium. For these churches, an exploded cluster is a good way to cover the space with several, relatively small clusters that are easier to disguise. Note that column-style line arrays on each side are usually not a good choice for this style of space because they cannot adequately cover the center of the seating area near the stage.

In a rectangular room, a small central cluster, augmented by a second cluster on delay, may help solve sight-line problems. Column-style line arrays, placed left and right at the sides of the platform, are another alternative for this type of room, providing good coverage while maintaining a discrete profile.

In deep rectangular rooms, a distributed system may be the best solution. In high-ceiling rooms, a distributed system may consist of column-style line arrays or small packaged loudspeakers installed on building pillars. A small localizer loudspeaker in the front can help maintain a natural directionality.

One oft-suggested approach, placing the loudspeakers in an organ chamber, far to the rear of the system microphones and behind a wooden grille, is almost always unworkable. The position of the loudspeakers aims them directly at the system microphones, which usually results in feedback problems. In addi-
tion, the wood grille work, which may be fine for organ music, can cause severe acoustic problems (both from cancellations and from vibrations) in the sound system loudspeakers.

34.6.2.4 Reverberant Room Problem

It is said that the types of chanting services employed by some religious groups developed in large reverberant cathedrals before sound systems were invented. Chanting helped carry an intelligible message to the congregation. All too many religious organizations still have the problem of reverberation, yet many have given up the chanting type of service and now want intelligible speech in their facilities.

The problem of intelligible speech in a reverberant religious facility is no different than in any other reverberant room, except, perhaps, for the desire to hide the loudspeakers. One other consideration, however, is that pipe organs and much religious choir music depend on high levels of reverberation, a criteria that conflicts with the desire for lower reverberation times for speech. Because even a good compromise may be expensive, the services of a qualified consultant are invaluable when this situation arises.

There is no magic way to design a loudspeaker system for a reverberant room. However, there are two ways to maximize the intelligibility of a sound system in a reverberant room. First, get the loudspeakers as close to the listeners as possible. This maximizes the direct-to-reverberant ratio at the listener’s ears, which improves intelligibility. A distributed system (ceiling type, on building pillars or pew-back) is the easiest way to accomplish this goal. Second, use directional loudspeakers and point them at the listeners and away from walls, ceiling, and other hard surfaces. Sometimes, these two concepts can be combined. For example, in a distributed system on building pillars, use a line-array-type column loudspeaker to direct sound at the listeners.

34.6.3 Sports Stadiums and Other Outdoor Systems

The discussion of outdoor system design presented in Section 34.2.2 was limited to very basic, theoretical considerations. The following discussions include many of the practical aspects of the design of an outdoor system. Also see Chapter 7 for a thorough treatment of sound systems in stadiums and other outdoor venues.

34.6.3.1 Excess Attenuation of High Frequencies in Air

The friction of air molecules rubbing against each other causes attenuation of sound that adds to the loss caused by the inverse-square law. This frictional loss is normally insignificant in indoor systems (except in very large rooms) but can become a problem in large outdoor systems because of the long distances involved. The problem is considerably worse at the high frequencies, which are important for speech intelligibility. This is because the molecules of air are moving faster than at low frequencies. The problem also increases at lower relative humidity as shown in Fig. 34-81.

The problem shows up in outdoor systems with long distances between loudspeakers and listeners. It often cannot be solved with simple equalization or even by adding additional high-frequency horns. The reason is that the attenuation may be 10 to 20 dB or even more, depending on frequency, distance, and relative humidity.

One potential solution is to add additional loudspeakers (or high-frequency horns) at a position nearer to the listeners and, of course, to place these loudspeakers on delay. Since the attenuation of low-frequency information is much less, it is normally unnecessary to add additional low-frequency loud-
speakers just to overcome the loss caused by friction in the air.

In many speech-only systems, the loss is simply tolerated. Intelligible, if somewhat telephone-quality speech, does not require frequencies much above about 3 kHz. Except in extreme situations, adding a few extra high-frequency horns and performing some additional equalization will result in an acceptable system. Obviously, the additional equalization should be performed on the long-throw loudspeakers only since the distance from the short-throw loudspeakers to their listeners will be considerably less than for the long-throw loudspeakers.

34.6.3.2 Using Distributed Systems Outdoors

There are several reasons to consider a distributed system for an outdoor facility. Overcoming excess attenuation of high frequencies is one reason. Avoiding the effects of wind and temperature layers is another reason. Distributed systems may reduce annoying neighborhood leakage.

In some stadiums, there is no desirable location for a central cluster. A round or oval stadium with full round seating is one example. The usual scoreboard location will often be awkward for coverage of nearby seating.

Sometimes existing lighting blocks the only workable cluster location. In these or other similar situations, a distributed cluster type of system may be the solution. The clusters can be placed under balconies (under one seating section to cover the one below) or on lighting poles. It is acceptable to place loudspeakers behind the heads of the spectators if this location does not cause artificial echoes or other problems.

The distributed approach may also work well in small outdoor systems such as a high-school football field system. When the audience sits in one or two relatively small sets of bleachers on either side of the field, it is often easier to place horns on existing lighting poles near the bleachers than to build a large central cluster at one end of the field, Fig.34-82.

In any distributed system, consider sight lines and watch out for potential artificial echoes.

34.6.3.3 Echoes Outdoors, Artificial and Otherwise

Normally, echoes are created by sound from a source, such as a loudspeaker cluster, reflecting off a hard surface and reaching a listener at a time that is delayed enough to be perceived as an echo. About the only way to deal with these echoes, outside of treating (or remov-
ing) the reflecting surface, is to simply aim the loudspeakers away from the offending surface. Narrow coverage angle loudspeakers and constant-directivity horns may help.

Echoes may also be created by the sound system because of poor layout or because of poor use or nonuse of electronic signal delay. Fig. 34-83 shows one example of an artificial echo caused by poor loudspeaker layout.

One other source of artificial echoes, poorly understood by many designers, is related to feedback. Any sound from the loudspeakers that reaches the system microphone may be delayed by relatively long times in an outdoor system. This sound can be picked up by the microphone, reamplified, and emitted from the loudspeakers as an echo that cannot be distinguished from an echo created by a reflecting surface.

There are several ways to help solve this problem. One is to enclose the talker and microphone in a relatively soundproof room. In large outdoor stadiums, this is often the easiest way to avoid the regeneration type of echo. Another potential solution is to use a noise-canceling microphone located close to the talker’s mouth. Close talking any system microphone will help, of course, because it allows reduction of system gain and an equal reduction of the reamplification of an echo. A noise gate set to turn off the microphone quickly after the talker stops talking may also help prevent regeneration echoes. This technique, however, will work well only in a situation where the microphone is relatively close to the talker’s mouth.

The announcer on the field hears an echo that no one else in the stadium hears. That’s because announcers first hear their own voice and then, delayed sometimes by as much as half a second or more, they hear their voice as an echo from the loudspeakers. This can be very confusing to an inexperienced announcer and may be the cause of the failure of many prepared speeches given to graduating classes in a football-field setting.

For the small football field with split bleachers, the distributed system concept may help since the sound is primarily aimed at the bleachers and not at the field. Even if there are some horns aimed at the field, they will normally be closer to the field than the horns on a typical scoreboard cluster. Thus, the signal delay and echo problem will be decreased.

Another partial solution to this problem is to give the announcer a local monitor loudspeaker (or headphones in an announce booth). The sound from this monitor will partially mask the echo from the cluster and may allow even an inexperienced talker to speak comfortably.

34.6.3.4 Dealing with Long Distances

Modular/concert-style line arrays may seem like an ideal way to throw sound over long distances outdoors. However, a typical line array has wide horizontal dispersion which may not be desirable. Also, few line arrays are rated for continuous outdoor exposure.

Thus, when a distributed system is not possible, a component cluster consisting of high-efficiency, high-power handling and narrow-coverage, constant-directivity horns is probably better than either line arrays or packaged loudspeaker systems for long-throw applications, Fig. 34-84.
34.6.3.5 High Noise Outdoors (or Indoors)

How much $L_p$ is required at the listener’s position? The answer depends almost entirely on the expected ambient noise at the listener’s location. Crowd noise in a sports stadium, for example, can easily exceed 90 to 95 dB $L_p$ on the A scale. Noise from aircraft in an airport paging system or noise from race cars in a racetrack paging system may exceed this figure by a considerable margin. At a grand prix race, for example, spectators seated near the racetrack may be subjected to potentially ear-damaging short-term peak $L_p$ levels of as high as 140 dB! In the case of the sports stadium, it may be possible to overcome the crowd noise (budget permitting). In the case of the racetrack, ask the announcer to avoid making announcements when the race cars pass the stands and to repeat announcements whenever possible. Also, put the announcer in an acoustically isolated booth so the announcement microphone does not pick up race noise as the cars pass the booth.

In the indoor system design equations in Section 34.2.3, a 15 dB SNR was assumed. For an outdoor classical music reinforcement system, this 15 dB SNR is still desirable. In many speech reinforcement systems, both indoors and out, a 15 dB SNR is simply not possible, and fortunately, it is not necessary. Except in the rare case where the frequency content of the noise is concentrated in the speech band, a 10 dB SNR will usually result in acceptably intelligible speech reinforcement. It is possible to achieve intelligible speech reinforcement with a SNR of lower than 10 dB but it is difficult to predict the success of such a system prior to its installation. When this type of system is contemplated, use a compressor to keep the voice level as constant as possible. Use a good-quality microphone with a bandpass filter to reduce unneeded low and high frequencies and avoid the use of a telephone handset as a paging microphone. Use equalization to boost the intelligibility frequencies slightly to further improve intelligibility. Use a smooth curve from about 1000 Hz to about 8000 Hz peaking in the 2000–4000 Hz bands.

Training the announcer in speech articulation will help, as will repeating announcements. In a plant or airport paging system with high noise levels, alerting the listener to an impending announcement by using a prepage tone can also help improve the effective intelligibility of a paged announcement.

34.6.3.6 Dealing with Varying Noise Levels

A manufacturing plant may have noise levels that vary widely with time and at different local areas within the building. Dealing with noise that varies in different areas is as simple as varying the quantity, type, and power delivered to the loudspeakers in the different areas. For noise levels that vary with time, there are two primary tools. If the noise varies predictably with time, as for an assembly line that is running or stopped on a predictable schedule, devices are available that vary the audio power fed to a loudspeaker line (usually by varying the input level to a power amplifier) depending on the time of day. Some of these devices will vary several different loudspeaker lines at several different times.

For noise levels that vary unpredictably with time, such as the crowd noise at a sports stadium or the noise of a airplane entering a waiting area at an airport, devices are available to measure the ambient noise level and adjust the paging level accordingly, Fig. 34-85. These devices work quite well, although they may have
some trouble in a system that includes background music (the music may be interpreted as ambient noise or may prevent measurement of the noise), and they usually cannot adjust the paging level during a page.

34.6.3.7 Thermal Layers of Air

Sound travels faster in warmer air. By itself, this fact has little significance for the sound system designer. Often, however, a layer of warm air will lie above or below a layer of cool air, and the difference in the speed of sound in these two layers can cause the sound to curve upward or downward toward the cool layer as shown in Fig. 34-86. This can be a help or a hindrance, depending on whether the cool layer is on the top or the bottom of the warm layer.

For example, in the early morning on a golf course, when the sun first comes up and begins to warm the air, the earth maintains a relatively cool layer near the ground. Thus, a sound wave will curve toward the ground, effectively hugging the ground, and can travel a great distance with seemingly little attenuation. Golfers at relatively great distances from each other can speak and be understood almost as if they were just a few feet apart. The same effect occurs over a quiet lake, even in the afternoon sun, since the lake will maintain a cool layer of air all day long. A wind, of course, will mix the layers of air and add noise so that the effect of thermal layers is lost.

In the early evening, when the sun begins to go down, the opposite situation occurs on a hot parking lot. The cool layer is now on top with a warm layer, maintained by the parking lot, on the bottom. The sound effectively curves upward toward the cool air and sound attenuation near the ground is effectively increased.

These phenomena can cause a paging system to work erratically, depending on the time of day. Large-area paging systems, over an airport runway, for example, are sometimes designed to overcome the changes caused by thermal layers. Elaborate systems can be designed to measure the temperature near the ground and above the ground and adjust the electrical input to each component of a vertical array of horns (or even mechanically re-aim the horns) to compensate for the effective curving upward or downward of the sound. In many smaller systems, however, the only necessary action is to test the system for satisfactory operation under worst-case conditions, which will probably be in the late afternoon on a hot day.

34.6.3.8 The Effect of Wind

Sound travels faster in the direction of the wind. Wind above the ground tends to be faster moving than wind near the ground. These factors combine to make the sound waves bend downward for a listener who is downwind from a sound source. Similarly, the sound waves will bend upward for a listener who is upwind from a sound source. Because this situation can vary unpredictably, wind can cause unpredictable changes in sound level and quality.

For outdoor concert systems with two stacks of loudspeakers (one on either side of the stage), a crosswind can cause very perceivable changes in phase cancellations at a given listener’s position. In addition, because high-frequency horns are often very directional at higher frequencies, a small change in the direction of the sound can dramatically change the apparent high-frequency response to a listener.

While there are no permanent solutions to these problems, outdoor theater designers should be aware of them and should choose a site with as little wind as possible. Sound system designers may want to consider a distributed system approach to move the sound source closer to the listeners.
34.6.3.9 Dealing with Weather-Caused Deterioration

The outdoor environment is considerably more hazardous to the life span of a sound system than an artificially lighted, temperature-, and humidity-controlled indoor environment. Wind, rain, snow, ice, lightning, direct sun, widely varying temperature, salt air near the ocean, birds, squirrels, vandals, and pollution are just a few of the hazards faced by an outdoor sound system. Most of these hazards, of course, are felt by the loudspeaker system since the remainder of the sound system will usually be installed in a relatively safe indoor environment. However, avoid placing system electronics in a small room (equipment shack) that is exposed to direct sun and/or has poor ventilation. Also, protect or remove microphones, mixers, and so on that may be used in an exposed announcer’s booth.

Use an effective lightning arrester above any system that might be exposed to lightning. Earth ground any metal gridwork and the metal chassis of loudspeakers to prevent static charge buildup, which can ultimately lead to arcing from the loudspeaker frame to the voice coil. Provide some type of static charge bleed to ground on any balanced, transformer-coupled loudspeaker line for to arcing from the loudspeaker frame to the voice coil. Prevent static charge buildup, which can ultimately lead to arcing from the loudspeaker frame to the voice coil. Provide some type of static charge bleed to ground on any balanced, transformer-coupled loudspeaker line for the same reason. A pair of 1 MΩ resistors, one from each side of the line to ground, works well.

Choose a loudspeaker system intended for outdoor use. Outdoor loudspeaker enclosures and component horns should be coated with some type of weather-resistant finish such as epoxy paint, fiberglass, or the new specialty polyurethane coating now used by several loudspeaker manufacturers. Although a black or gray color is traditional, a white or other reflective color will help prevent heat buildup in hot sunlight. Fiberglass horns and enclosures should be painted white since the fiberglass resin will eventually evaporate in hot, direct sunlight if allowed to absorb heat.

Paper cone loudspeakers should be treated to resist damage from high humidity (this is a good idea in humid indoor environments, such as swimming pools, too). Simply spraying the cone with a waterproofing such as Scotchguard™ will help considerably and does not affect the performance significantly. The diaphragms of high-frequency drivers should either be made of a phenolic-type material or should be treated by the manufacturer to resist damage from humidity (most are). These treatments will also help prevent damage from pollution.

To protect against actual rain, install loudspeakers and horns pointing slightly downward if at all possible. If a horn must be pointed upward, use a curved adapter throat (available from the manufacturer) to point the driver downward. The adapter throat should have a weep hole in the bottom of the curve to allow water to drain out.

For additional protection against driving rain, some manufacturers use a layer of weather-resistant reticulated foam between two layers of grille cloth. Using a horn-loaded enclosure helps by recessing the loudspeaker cone. A layer of hardware cloth, or perforated aluminum, in addition to the grille cloth, can help prevent birds and squirrels from nesting in the enclosures and can help prevent damage from vandals throwing rocks, bottles, and so on. The hardware cloth can often be placed over the mouth of a horn, too.

Salt air can be extremely corrosive to metallic portions of loudspeakers, including metallic high-frequency driver diaphragms and metal horns. Use fiberglass or weather-resistant plastic horns, and coat low-frequency enclosures with epoxy paint or fiberglass. Consult with the manufacturer to choose low-frequency loudspeakers and high-frequency drivers that will resist damage from the salt air.

Especially when using a packaged loudspeaker system outdoors, consider the durability of the connectors. Conventional ¼ inch phone plugs, XLRs, or other indoor-type loudspeaker connectors will deteriorate outdoors from exposure to moisture and dust. Neutrik Speakon connectors are better but are not suitable for long-term outdoor exposure. The best solution is to eliminate the connector altogether and provide a direct cable connection into the loudspeaker system.

No matter how much care is taken in protecting outdoor loudspeaker systems, they will deteriorate faster than similar indoor systems. Thus, the system design should provide for easy access and repair, Fig. 34-87.

34.6.3.10 Simulating the Indoor Environment Outdoors

Many orchestras perform a yearly series of summer concerts in an outdoor amphitheater. Patrons enjoy picnics and music in an informal atmosphere. They may, however, notice that the orchestra’s sound is not quite as rich or full as it would be during an indoor concert. The problem, of course, has nothing to do with the musicians and everything to do with the lack of beneficial reflections in the outdoor environment.

While the outdoor environment can probably never be as good for orchestral music as a great concert hall, steps can be taken to improve the richness of the sound.

Perhaps the most common approach is to reinforce the orchestra through a stage/shell-area loudspeaker system in conjunction with a series of remote loudspeakers (or small clusters) positioned to provide simu-
1328 Chapter 34

lation of the reflections that would occur in a concert hall. Microphone usage and placement are similar to what would be used in the concert hall. An artificial reverberation device is used through the mixing console’s effect send and return. The output of the mixer is fed to a multitap digital delay. The delay taps are selected carefully and fed to the individual loudspeaker systems to simulate the reflections that would be found in a concert hall.

Another approach is to use one or more semicircular rings of small loudspeakers at increasing radii into the audience. The rings may be divided into segments. Feed the rings from the output of the digital delay.

The process is not as straightforward as that of designing a simple sound reinforcement system and may take some experimenting. Nevertheless, it can significantly improve the sound of an outdoor orchestra and, thus, enhance the enjoyment of the audience.

34.6.4 Artificial Ambience

Large, multipurpose facilities designed for good speech intelligibility may not be desirable for musical performances because they do not have good early reflections and do not have a well-developed reverberant field.

Some acoustical consultants now design such rooms with artificial ambience systems designed to add the early reflections and reverberation that are lacking in the natural acoustics.

Such systems consist of many microphones and loudspeakers and very sophisticated amplification, signal-processing, and control systems. These systems are complex and expensive but make it possible to hold a variety of events in a space and optimize the acoustics for each type of event. The services of a consultant, experienced in this type of system, are highly recommended.

34.6.5 Conference and Boardroom Systems

A conference room sound system has special problems because of the large number of open microphones, their proximity to loudspeakers, and the frequent added problems of ambient noise and uncooperative system users.

Some conference rooms are private; that is, they are designed exclusively for the use of the conferees. Other conference rooms include facilities for nonparticipating or infrequently participating observers, such as the stockholders, the press, or the public. Examples of the former are the conference rooms of privately held companies. Examples of the latter are the conference rooms of publicly held companies, unions, school boards, and governmental and other organizations. The sound systems installed in courtrooms are similar to those in conference rooms that include observers.

The primary difference between the two types of systems is in the additional loudspeakers (and roving microphones) needed for the second type of system. Both systems, of course, often include audio recording and playback capabilities and may include video playback and recording, audio or audio and video conferencing capabilities, computer graphics display capabilities, and so on.

34.6.5.1 Local Sound Reinforcement in a Conference Room

Microphone choice is important to the success of a conference room system. One school of thought favors boundary microphones placed on the table in front of each participant. A boundary mic is inconspicuous and does a good job of picking up the direct sound from the talker’s voice. Because the boundary mic element is less than a millimeter from the table surface, it does not pick up reflections from the table in the frequency range of interest. Thus, technically, this is a good choice.
The problem with boundary mics is the users. If the mics are loose, the users will push them out of the way or turn them around. If they are fixed in position, users will lay paperwork or books on top of them, spill water or coffee on them, and otherwise abuse the microphones. Boundary mics also do a very good job of picking up the noise of paper shuffling on the table.

Thus, another school of thought suggests installing gooseneck mics at each talker’s position. The gooseneck mic puts the mic element up near the talker’s mouth so it does a good job of picking up the direct sound. Unfortunately, the first reflection from the table also enters the gooseneck mic causing undesirable comb filtering. Also, it’s easy for the user to push the gooseneck mic out of the way.

Fortunately, gooseneck mics seem to attract users who often pull them close and talk directly into the microphone. When this happens, the direct sound is much louder than the first reflection from the table so the reflection is of little consequence. Thus, the gooseneck mic may work better than the boundary mic even though it is technically inferior (because of the reflection from the table).

In some conference rooms, the designer may need to try both microphone types to see how the users react. It may also be a good idea to give each user a lighted mute button for private conversations with nearby conferees.

Conference room loudspeaker systems are normally laid out in a distributed fashion. To help avoid feedback from multiple open microphones and to help avoid pickup of paper shuffling and other ambient noises, an automatic mixer is commonly used (see Section 34.4.3). Often, the chair position is given an automatic priority switch so that when the person at the chair position speaks, all other microphones are turned off (this may also be accomplished by a manual priority switch).

Another way to help avoid feedback is to use the logic outputs on the back of many automatic mixers to switch off the loudspeaker directly above the head of the person talking. This approach, however, can hinder the kind of back-and-forth conversation where more than one person talks at the same time and there are frequent interruptions. It should be noted that, in a conference room, this kind of conversation is difficult with any system.

A better way to reduce feedback is to use a mix-minus system as discussed in Section 34.4.3.3. To make this work for a large conference table, design the system so that each loudspeaker receives its own customized mix including all microphones except the one nearest the loudspeaker. Taper the mix for microphones located farther away from the local microphone as shown in Fig. 34-41. Loudspeakers for inactive participants can be on all the time unless a roving microphone is being passed around. In this case, the level to the local loudspeakers may need to be reduced somewhat, and, of course, the feed from the roving microphone to the conference table should be fed to all loudspeakers at equal levels.

34.6.5.2 Recording a Conference

The multiple-microphone setup of a conference can be a problem for recording. All microphones can simply be mixed and fed to a single channel of an audio recorder, but the multiple microphones may add unwanted ambient noise. Using the output of the automatic mixer helps avoid this problem. Use one of the matrix outputs when designing a mix-minus system. A courtroom-style, multichannel, logging recorder may also be used to record a number of individual microphones on separate channels. This is especially useful when a transcript of the conference must be made later. In some systems, the chair is given a switch to pause the recording for off-the-record conversations.

34.6.5.3 Audio and Video Teleconferencing

Although speaker-phone conferences over normal telephone lines are still commonplace, most video/audio teleconferencing now takes place over the Internet or dedicated wide area network (WAN). Whatever method is used, the characteristics of the transmission path must be considered. In particular, it is possible for feedback and echoes to occur over a complex path including the transmission line, the local microphone(s) and loudspeakers and the remote microphone(s) and loudspeakers.

A digital echo canceller is built in to every modern video/audio teleconferencing system. These devices help solve the problems of echoes and feedback in a teleconference. To optimize the echo canceller, however, the local audio systems in both rooms must be properly designed.

In most cases, this design is very similar to the design of a conference room designed for local sound reinforcement. Choose microphones carefully as described in Section 34.6.5.1. Lay out a distributed loudspeaker system. Use an automatic mixer with matrix output to create a mix-minus system. Do this in both conference rooms.

In operation, the echo canceller takes some time to adjust itself to the system. After it optimizes its operation, the system should be relatively free of echoes or feedback. The echo canceller must reoptimize itself
when there is any change in the system so try not to move any microphones once a conference has started.

34.6.6 Sound Masking (Noise Masking), Speech Privacy Systems

Sound masking is an electronic system that creates a low-level “masking sound” to improve speech privacy and mask irritating noises in a work space. A well-designed sound masking system provides protection for confidential conversations and creates a more pleasant work environment. A sound masking system may also be called a noise masking or white noise system.

Open-plan offices are the most common application for sound masking. Doctors’ exam rooms, and other facilities that fall under HIPPA privacy regulations, are also good places for sound masking. Sound masking may also be used in courtrooms, law offices and in high-security government or industrial facilities.

34.6.6.1 Criteria for the Environment

A limited range of environments is suitable for sound-masking. The environment must be relatively quiet since the masking sound will need to be louder than the noise to be masked. A general criterion for ambient noise level is about NC-35 (noise criteria curve number 35) or about 45 dB on the A scale. The environment must have a low-reverberation time and as few hard, reflecting surfaces as possible. A well-designed open-plan office will usually meet these criteria.

34.6.6.2 Mechanical Noise Reduction

Noise from computer printer areas, copying machines, and so on should be reduced by mechanical and acoustical means since the sound masking system cannot be expected to overcome these relatively high-level sources. In addition, mechanical barriers in the form of open-plan office-type acoustical dividers are normally installed between offices to help attenuate noises and speech from point to point. Nonreflective ceilings (preferably dropped acoustical tile) and carpeted floors are almost mandatory. Without these mechanical aids, the sound masking system cannot perform its function successfully.

34.6.6.3 Masking Sound

Once higher-level noises have been reduced and an acceptable acoustical environment has been created, low-level noises become more irritating, and speech privacy becomes more important. Masking sound, created by a sound masking, speech-privacy system, can help solve these problems, Fig. 34-88.

Masking sound systems should be located in the vicinity of the listeners, not near offending noise sources. Masking systems must be completely unnoticeable to the listeners. That is, no one should know there is a sound-masking system in operation unless someone turns it off. The reason for this, of course, is that the purpose of the system is to help reduce distracting noises and to aid speech privacy. If the system itself becomes a distraction, one of its primary purposes has been defeated.

The masking sound itself is created by an electronic random-noise generator similar to that used for equalization, and it is fed through an equalizer to a set of power amplifiers and loudspeakers. The loudspeakers are normally hidden in the ceiling plenum, above the acoustic tiles.

34.6.6.4 Criteria for the Loudspeaker System

To meet the primary goals of sound masking and speech privacy and to remain unnoticed by listeners, the loudspeaker system must produce random noise that does not change in level as a listener moves from place to place within the environment. A traditional downward-facing distributed system could achieve this goal, but only with an extremely high density of loudspeakers. Thus, an upward or sideways facing system is more common, Fig. 34-89. The upward and sideways systems use mechanical structure in the ceiling plenum to reflect and help randomize the noise distribution. In a typical open-plan office with a ceiling height of 8–9 ft, the loudspeakers would be spaced in a square or hexagonal pattern with approximately 10–20 ft spacing between individual loudspeakers. Care must be taken to avoid placing a loudspeaker too near a hard reflecting object, such as an airduct, which might cause an audible hot spot in the room below. Various ceiling materials and
baffles are available to help diffuse the masking sound, and several manufacturers produce special loudspeaker-enclosure combinations designed specifically for sound-masking to allow the upward or sideways facing orientation.

34.6.6.5 Criteria for the Amplification System

A standard pink-noise generator, of the type used for sound system equalization, is acceptable provided its output is random enough. Many equalization noise generators utilize digital circuitry, with only pseudorandom noise. Listeners may become aware of this type of generator making it unacceptable. Noise generators specifically designed for sound masking systems are available and are worth any extra cost. The noise generator, like the power amplifier, must be highly reliable. Redundancy can be achieved by mixing two noise generators through a passive mixing network. If one generator fails, the overall noise level will drop about 3 dB, but the system will continue to operate.

34.6.6.6 Criteria for the Equalizer

Because the shape of the final frequency-response curve is critical, and standard masking system curves are specified in ⅛-octave intervals, a ⅛-octave equalizer should be employed. If two, redundant, active equalizers are used, the filter and gain settings on both must be exactly equal.

34.6.6.7 A Second System

A more random (and thus more effective) system design can be achieved by utilizing two separate noise generators feeding two equalizers and two power amplifiers (or banks of power amplifiers in a large system) as shown in Fig. 34-90. Rather than feeding zones of loudspeakers in separate areas, these amplifiers feed adjacent loudspeakers in the same zone in a checkerboard pattern. This plan also produces a higher level of redundancy since failure of one amplifier or noise generator will produce only a 3 dB drop in overall masking level. Thus, this system can be installed with no backup amplifiers if desired. Alternately, a single backup amplifier can be installed in the system rack, ready to replace any single amplifier failure.

34.6.6.8 Masking Plus Paging or Background Music

Background music or paging may be added to a masking system using the same amplifiers and loudspeakers. Intelligibility of the paging may suffer because of the placement of the loudspeakers. (High frequencies will be attenuated.) A separate equalizer should be used for
the paging; if all three functions are to be included, another equalizer should be used for the background music. A multichannel DSP device may be used if the reliability is sufficient. The system power amplifier (and loudspeakers) must be capable of handling simultaneous inputs from all sources with adequate head room. The masking noise must not be turned off or attenuated during a page, since this will cause listeners to become aware of the system, detracting from its effectiveness. It is generally better to separate the masking system from the paging and music system, and design the latter as a standard distributed system.

34.6.6.9 Adjusting the Installed System

Both the level and frequency response of the masking system must be properly adjusted. Perform the adjustments when office workers are not present. Adjust the masking noise level for the degree of speech privacy required keeping the masking sound as low as possible consistent with speech privacy requirements. Ideal levels are between 45 dBA and 48 dBA. When needed, office workers will often tolerate masking-sound levels of as high as 52 dBA, but higher levels will defeat the purpose of the masking system by making it into an irritation itself. If acceptable speech privacy is not achieved at this masking sound level, alternate mechanical and acoustical means should be employed.

The frequency-response curve must also be carefully adjusted to conform to the window curve shown in Fig. 34-91. This curve includes the effects of existing mechanical noise sources such as air-handling systems, and these sources normally contribute the bulk of the noise energy below about 250 Hz. Both frequency response and sound pressure level must be measured at multiple points in the room and variations of more than about ±2 dB can mean degraded system effectiveness.

If other areas of the building, especially on the same floor, will not have a sound masking system, plan the system so that a transition zone can be achieved where the masking sound gradually dies out as a listener moves from one area to another. Adjust this transition zone so that a listener walking from one zone to the other notices only a subjective natural change in sound as might be expected in walking from one area to another.

34.6.6.10 Objective and Subjective Methods for Measuring System Effectiveness

Effective speech privacy is the most important goal of a sound masking/speech-privacy system. Speech privacy is most often specified and evaluated in terms of the Articulation Index (AI) as specified by ANSI Standard S3.5. The Articulation Index measures speech intelligibility as a weighted sum of signal-to-noise ratios in multiple frequency bands. An AI of 1.00 is considered to be excellent intelligibility or no privacy. An AI of 0.00 is considered to be bad intelligibility or confidential privacy. An AI of 0.05 to 0.19 indicates normal privacy. An AI of 0.20 to 0.32 indicates marginal privacy. AI can be evaluated by measuring signal to noise (speech level to background noise level) in the indicated bands, multiplying by the given weighting factors and adding the results. This is normally performed by an acoustical consultant.

A subjective evaluation of system effectiveness should be performed by a jury of at least three listeners. Position each listener (one at a time, independently) on the other side of an acoustic barrier from a talker (this
simulates the normal usage of the office area). Measure the talker’s voices and have them talk louder or quieter until the talker level is about 60–65 dBA. Adjust the masking sound level until the listener agrees that the speech from the talker is audible but not intelligible. Repeat the process for the other two listeners. The final system level should be the highest of the three levels. This minimal privacy level should not be exceeded if at all possible.

34.6.6.11 Conclusion

Sound masking, speech-privacy systems are related to other sound systems only in the fact that they use many of the same components. Their purposes and design are obviously very different from each other. Masking systems are commonly specified for public buildings. Such specifications are drawn up in great detail and requirements for installation and performance documentation are strict. When a design must be performed from scratch, the help of an experienced consultant will be valuable.

34.7 Computers and Software for Sound Reinforcement Systems

34.7.1 Digital Audio Devices

Eventually, most audio products will be based on digital technology. DSP signal-processing systems, as discussed in Section 34.4.5, have already become mainstream products that are extremely useful to the sound system designer. Several manufacturers are now offering fully digital audio mixing consoles. Even analog mixing consoles enjoy important digital features including mute groups and VCA groups.

34.7.2 Audio Signal Transmission via Computer Networks

Cobranet™, developed by Peak Audio, allows transmission of multiple audio signals over a conventional ethernet computer network. Other proprietary digital audio transmission systems are available. Eventually, standards of this type will enable audio signals to remain in digital form from the microphone element to the amplifier input and possibly even to the loudspeaker voice coil.

34.7.3 System Control and Monitoring by Computer

Safety regulations may require that paging systems used for life safety purposes, such as emergency evacuation, be supervised. This usually means a computerized means of monitoring the impedance of the loudspeaker line. If the impedance changes more than a specified amount the computer assumes there is a loudspeaker failure or line short and it signals trouble on the line.

Non-life-safety sound systems may not require computer control and, in many cases, would not benefit from it. Larger, more complex systems, however, can benefit greatly from a central computer set up to monitor and control the system.

Consider a large airport paging system. Paging messages originate in individual gate areas, baggage claim areas, a central paging room, one or more security areas, and even from outside the buildings. Listeners are located in many different areas as well.

Paging messages range from “Mr. Smith, meet your party at Baggage Claim Area 2.” to gate change announcements, flight change announcements, and emergency announcements.

Each message must be routed to the appropriate areas in the appropriate terminals. A priority system must be established for two or more messages that originate at approximately the same time. Emergency priority must be given when needed. In addition, the system equipment may be widely dispersed and must be monitored for possible failures. A computerized system, like that shown in Fig. 34-92, can perform all of these functions and more.

34.7.4 Computer Aided System Design

As discussed in Section 34.3.2.9.2, software programs like EASE and Modeler are extremely valuable system design aids. Less complex software, such as the spreadsheets offered by Syn-Aud-Con can also aid the system designer. Other software, such as Stardraw, helps the designer perform system layout and documentation.
34.7.5 Computer Aided Measurement Systems

As discussed in Chapter 50, computer aided measurement systems like SMAART from SIA Software; TEF from Gold Line; EASERA, an acoustic measurement program offered by the developers of EASE; MLSSA from DRA Laboratories; SIM from Meyer Sound; and others have greatly advanced the state of the art in acoustic and electronic measurements.

Introduction

For more than 2000 years acoustic phenomena have been perceived and manipulated subjectively. Reference can be made in this context to Marcus Vitruvius, the ancient Roman architect who described at this early time the application of acoustic laws in theatrical spaces. But only since the end of the medieval times and particularly during the last century acoustics has developed into an independent science.

Highlights on the way to a scientifically calculated design:

- Roman/Greek times, medieval times: knowledge based on experience and first trial and error reports—e.g., by the Roman architect Vitruvius, 15 BC.
- Since the end of 18th century: Theoretical investigations—e.g., Chladni, 1810, or in 1875, Lord Rayleigh, Professor Helmholtz.
- By 1935: measurement in models and “auralization” in physical models, Professor Spandöck München, Professor Reichardt, Dresden/Germany.
- Since 1965: computer-model investigations, Professor Krokstad, in Trondheim/Norway, afterwards many similar works have been done.
- Since 1995: auralization by means of computer models has been introduced.

A measured sound-field structure in 3D, so-called waterfall form (decay of sound energy as a function of time and frequency) is shown in Fig. 35-1. The sound level is marked on the ordinate, the frequency (range of frequency 63 Hz–8 kHz) on the abscissa, and the time on the third axis (0 ms–direct sound to 3.5 s reverberation).

These sound-field structures are depending on listener locations. In the old days a wanted sound decay for concerts or for speech transmission was generated by changing the primary or secondary structure of a room, see Chapter 7.3.2. Now with sound systems it is possible to generate any sound fields subjectively desired.

Today we can derive the basic items in sound design. Listening comfort and intelligibility are influenced by:

- Reverberation time and volume.
- Early and late reflections.
- Ambient noise level.

Some basic measures of the performance of a sound system are:

- Intelligibility $\text{Alcons, } C_p, \text{RASTI, etc.}$
- Loudness in dB ($\text{SPL}_{\text{tot}}$).
- Direct sound in dB ($\text{SPL}_{\text{dir}}$).
- Frequency response in $\pm$dB from flat.
- Coverage in $\pm$dB from even.

The goal of modern sound design is to calculate in advance the complete sound field structure in a hall or in open spaces by means of Computer-Aided Acoustic Design (CAAD) programs enabling you to prevent any surprises that become evident after a sound system has been installed. You just describe in advance the expected properties of your sound system and the overall acoustic properties of your room using the new sound system.

The following considerations include personal experiences of the authors, especially with the CAAD program EASE, but features of other programs are also explained.

35.1 Sound Design Basics for Acoustic Simulation

Application of physical or computer models for acoustic and sound system design:

Prior to 1965. Physical models since the 1930s and after WWII mainly in selected cases in research centers by means of huge computers.
Since 1970. The programmable pocket computer offered the first algorithms for acoustics. 1980–1985

Since 1981. The PC and PC-XT have been available.

1984: Reverberation time and intelligibility calculations for simple rooms:
CADP / JBL. TEF-10-Analyzer. First coverage plots became reality.

1985: PHD Program. By Prohs/Harris in spring: first version for TEF Analyzer:
1. Room-acoustic calculations like different reverberation times.
2. Loudspeaker cluster design.
3. Power calculation for horn radiators and corresponding drivers.
4. Alcons calculations by Peutz.

1990: EASE. Full-graphic CAD MS-DOS-based program with pop-up menus, Version 1, 1990, by ADA, Germany.

1996: ULYSSES. By IFB/Germany (P. Hallstein).

Room Acoustics Programs

1998: CAESAR. Vorländer/Schmitz/Aachen/Germany, Version 0.12, 2001 Version 0.20.

The programs printed in italics are subject to constant advancement.

35.1.1 Measurement and Planning Methodology with Physical Models of Large Auditoriums
by Hans-Peter Tennhardt

35.1.1.1 Fundamentals

The room impulse response is obtained in a reduced model of the auditorium interior by applying the corresponding scale-model laws based on the constant ratio between the geometrical dimensions \( L \) of the room and of the sound wavelength \( \lambda \) in the model scale (index \( M \)) and in natural scale (index \( N \)):

\[
\frac{L}{\lambda} = \text{Const} = \frac{L_N \times f_N}{c_N} = \frac{L_M \times f_M}{c_M}
\]

(35-1)

where,
\( c \) is the speed of sound,
\( f \) is the frequency.

If the scale-model test is carried out in the same sound propagation medium, then \( c_N = c_M \) and so Eq. 35-1 becomes

\[
p = \frac{L_N}{L_M} = \frac{f_M}{f_N}
\]

(35-2)

i.e., the measurements are carried out in a frequency range that exceeds the original frequency range by the factor \( p \) (reduction scale 1:2).

A favorable compromise regarding model size and accuracy of reproduction is given with a reduction scale of 1:20, but scales between 1:8 and 1:50 are feasible depending on model size or frequency range to be studied. The sound impulse is irradiated from the location of the sound source (e.g., stage, orchestra pit, loudspeaker). The acoustical response of the room to the emitted signal is simultaneously registered at receiving positions (audience area, platform, stage) by special electroacoustic transducers (microphone, dummy head...
with ear simulator). The transfer function between transmitting and receiving locations is calculated from the obtained room impulse response. Very often a spark discharge generator is used as a sound transmitter in air (nowadays electronic MLS scale radiators are also used). With an impulse width in the model of 80 μs, it is possible to resolve path differences equaling 60 cm in the original room. The reproducibility of the maximum sound pressure is below ±0.2 dB.

Special model sound sources enable simulation of a talker or a singer, of an orchestra as nondirectional sound source in the center of the same, of orchestral instrumental groups (see Section 35.1.2.2), and of loudspeaker lines with variable directivity characteristics.

Preferably the registration of the room impulse response is dual-channel by the microphones of the dummy head at listener seats, which are representative for determined seating groups so that the binaural head-related listening parameters of the human auditory organ are optimally reproduced. In a model of scale 1:20 the diameter of this miniature dummy head must be about 11 mm, Fig. 35-2.

![Figure 35-2. Model-size dummy head for measurements at a scale of 1:20.](image)

The investigated frequency range lies between 5 kHz and 200 kHz in the scaled model, which corresponds to 250 Hz to 10 kHz in the original. Structures whose linear dimensions fall below approximately 8 cm in the original room are not reproduced in the model. Also sound absorbers and wall impedances below the studied frequency range are not considered in the model tests.

For better access to the models during the measurements, these should be carried out in air under normal pressure. Owing to the excessive atmospheric absorption occurring at the model frequencies there occurs a faulty momentary value of the sound pressure that is mathematically corrected by a real-time compensation. Without these mathematical corrections the measurements must be carried out in a nitrogen environment instead of air, in which case the drawback consists of bad access to the model.

All physical acoustic phenomena such as diffraction and scattering are represented in a frequency-true fashion.

The obtainable accuracy is presently still superior to that of a computer simulation. The method is capable of providing answers to questions concerning balance investigations in rooms for music performances, see Section 35.1.2.2, the influence of electroacoustical components on room-acoustical parameters, and the directional effect of wall and ceiling structures prepared as scaled models.

By using original sound source simulations (talker, singer, nondirectional sound source, orchestra instrumental groups, loudspeakers) and a dummy head as a receiver unit, the described measuring procedure is applicable also for original rooms.

### 35.1.1.2 Balance Investigations of Music Performances

The scaled-model simulation of an orchestra can in first approximation be realized by a nondirectional sound irradiation from the center of the same. A more detailed simulation is necessary, however, if one wants to have information about the influence of a room on the balance of the different instruments at the listener’s seat. A useful approximation can be obtained by a simulation of orchestra instrumental groups in which their sound spectra are based on the frequency response chiefly reproduced in music presentations. Their directional characteristics are derived from the usual playing posture.²

The simulated orchestra is subdivided into four instrumental groups, in which the percussion instruments, in view of their considerable loudness and adaptable style of playing, may be left out of consideration:

- String instruments (St)
- Woodwind instruments (Wo)
- Brass instruments Bl (Bi)
- Bass instruments Ba (Ba)

To this may be added the electroacoustical model transducer of a singer/talker (S).

The scaled-model simulation comprises the impulse excitation by a spark-gap generator provided with a shading reflector of defined sound attenuation so as to align it with the directional characteristic of the instru-
mental group in question.\textsuperscript{3,4} The electroacoustical transducers are positioned in the center of the group in question according to the arrangement topography of the orchestra, see the example in Fig. 35-3.

![Diagram](image)

**Figure 35-3.** Typical arrangement of simulated orchestra groups on a concert hall platform.

By evaluating the measured binaural room impulse responses on the basis of the register balance measure (BR, see Section 7.2.2.15); it is possible to infer room-acoustical measures for a required architectural modification of the horizontal and vertical boundary surfaces of the performance zone, and to clarify questions concerning the vertical staggering of the orchestra. The sound intensity-time behavior allows conclusions regarding the sound attack of the individual instrumental groups, and regarding masking effects in the frequency and time domains from which measures for the acoustical formation of the secondary structure of the room can be inferred.

![Image](image)

**Figure 35-4.** Konzerthaus, Berlin.

B. Finished original room.

35.1.2 Building a Computer Model, Entering Room Data

Entering room data into a simulation program must be simple and straightforward. A combination of graphical and numerical entry of the data, planes, and vertex points has to be supported. Entering the room into the program must be efficient in order to make the program work cost effective and intuitive. If the room entry takes too long, the program becomes much less valuable as a real design tool. There are different ways to enter room data:

- By X, Y, Z coordinates.
- By text files.
- By import from professional drawing programs like AutoCAD or SketchUp.
- By use of drawing tools like prototypes or predefined room shapes.

Fig. 35-5A to D shows one example of a model with different view options.

Simpler models that normally should have between 500 and a maximum of 1500 faces may be created based on simple room shapes or prototypes. A manipulation routine should allow one to stretch or shrink dimensions to adapt the prototype to the requirements. This way a simple room model for basic investigations can be created within minutes.

Better would be the possibility of importing DWG or DXF or other similar architecture files directly. But the disadvantage here is that architects in the early design phase do not create 3D models and offer only 2D drawings. These drawings are of less use and so the acoustician has to enter the model vertex by vertex, line by line and area by area. Sometimes 3D models can be built by expanding a 2D plan and by manipulating the result.
35.1.3 Acoustic Sources and Loudspeaker Systems

35.1.3.1 Natural Sources

Sound reinforcement quite often has to deal with reinforcing natural sources like human voices or natural music instruments. Therefore to know the amount of reinforcing required, we have to know the quality of the reference sources and the following aspects:

- Loudness.
- Frequency response.
- Directivity.

Fig. 35-6 shows the level and frequency range of natural sources and instruments perceived by human beings. In this range natural sources develop their sound power and produce level components in the mentioned frequency range. Everything outside this range is on one side masked by noise (lower 30 dB in the midrange) or dangerous for our health—pain threshold $=120$ dB. Frequency components lower than 25 Hz are becoming inaudible as well as frequency parts higher than 15–20 kHz—depending on age and health.

Natural sound sources like human voices or musical instruments do not radiate sound in an omnidirectional way. It comes close in case of a human voice, but the higher the frequencies, the more the head becomes an obstacle to the sound radiation backward. Fig. 35-7A shows the directivity balloon curves of a female voice in the vertical domain. Below 1000 Hz the pattern is almost an omnidirectional radiation pattern, but for higher frequencies the radiation dominates more and more in front of the head. This is also the reason that in such concert halls where the audience is behind the orchestra, people sometimes complain about the singer’s clarity.

The radiation behavior of musical instruments is much more complex. Here a lot of investigations have been done, especially by Meyer. Fig. 35-7B shows the 3D presentation of the directivity balloon of a horn instrument including the player. According to Meyer the shadow effect of the player himself is also considered. We observe with increasing frequencies a reduced radiation into the front domain of the player.

To model all these different natural sources correctly, their radiation behavior has to be known and this not only as single instruments but also in groups. Here a lack of corresponding data is still evident.
35.1.3.2 Loudspeaker Types

We distinguish the following loudspeaker types:

- Point sources.
- Loudspeaker columns.
- Cluster.
- Line arrays.
- Digitally controlled sound columns.

For the use of these different sound radiators, their performance parameters must be known. One will soon note, however, that the performance parameters specified by the manufacturers vary in accuracy and scope. For nearly two decades the Standards Committee of the AES has been trying to update rules and standards for a uniform approach in this respect. When studying the data sheets of diverse manufacturers one will nevertheless note considerable discrepancies allowing the expert to draw conclusions as to the quality of the data given. For this reason we are going to mention the most important data to be specified in loudspeaker design. Let us start with the so-called point sources.

35.1.3.2.1 Point Sources

Point sources do not show automatically omnidirectional radiation behavior. Their directivity behavior is measured on a turntable and all directivity balloon data is referred to the point of rotation, therefore the name point sources.

Transfer Behavior. The nominal load capacity $P_n$ of this loudspeaker type is the rms electrical power specified by the manufacturer according to the design characteristics.

The ratio between the sound pressure $\tilde{p}$ and the voltage $\tilde{u}$ required to attain this capacity at the radiator is called sensitivity $T_s$.

$$T_s = \frac{\tilde{p}}{\tilde{u}}$$  \hspace{1cm} (35-3)

One distinguishes between a free-field sensitivity $T_d$ and a diffuse-field sensitivity $T_r$. The free-field sensitivity is normally indicated for a reference point on the reference axis at a distance of 1 m from the loudspeaker. This can be expressed by

$$T_d = \frac{\tilde{p}_d}{\tilde{u}r_0}$$  \hspace{1cm} (35-4)

The diffuse-field sensitivity has to be ascertained in a diffuse field, for instance in a reverberant chamber. In order to eliminate the room property characterized by the equivalent absorption area of the room, a correction factor has to be used.

![Figure 35-6. Level and frequency range of natural sources and instruments. Courtesy V. O. Knudsen 1932.](image-url)
where,

\[ T_s = \frac{P_d}{u} \quad (35-5) \]

The reference sensitivity \( T_0 \) is preferably 1 Pa/V. If another value is chosen, it has to be indicated.

The sensitivity level, \( G_S \), is defined as the logarithmic quantity of sensitivity:

\[ G_S = 20 \log \frac{T_s}{T_0} \text{ dB} \]

The reference sensitivity \( T_0 \) is preferably 1 Pa/V. If another value is chosen, it has to be indicated.

The graphic representation of the sensitivity level as a function of frequency is called frequency response.

One of the quantities most frequently used in sound reinforcement engineering is the rated or characteristic sensitivity. In combination with the nominal load capacity it serves, among other things, to ascertain the maximum achievable sound pressure in the main reference axis of a loudspeaker or a loudspeaker system. According to the definition given in the Standard DIN 45570, also AES2-1984 (r2003), it is the ratio between the sound pressure \( p_d \) averaged over a determined frequency range (mostly 250–4000 Hz) and measured on the reference axis at a distance of 1 m from the reference point of the radiator—usually the point of rotation during measurements, and the square root of the power supplied. By the standard, this power is referred to the nominal impedance \( Z_n \) of the radiator as
Thus the rated sensitivity is

\[ E_K = \left( \frac{p_d}{u} \right)^2 \frac{r}{Z_n} \]

\[ = \frac{p_d r}{\sqrt{P_s} r_0} \]

where,
\( p_d \) is direct sound pressure,
\( r \) is distance to the loudspeaker on the main axis,
\( r_0 \) is 1 m distance.

Because of its reference to power, this expression is also designated as rated power sensitivity. According to DIN 45570 T1, the logarithmic quantity of this expression is called characteristic sound level \( L_K \), but also sensitivity/dB. It is defined by

\[ L_K = 20\log \frac{E_K}{E_{K0}} \text{ dB} \]

\[ = 20\log E_K \text{ dB} + 94 \text{ dB}. \]

An important parameter for approximating the sound-field conditions in rooms is the front to random factor \( \gamma \). It characterizes the relationship between the acoustic power that would be radiated into the room by an omnidirectional loudspeaker having the same free-field sensitivity as the real loudspeaker to be assessed, and the acoustic power of the real loudspeaker:

\[ \gamma = \frac{\int \tilde{p}_d^2 dS}{\int \tilde{p}^2(\theta) dS} \]

\[ = \frac{S}{\int \tilde{p}^2 dS} \]

where,
\( \tilde{p} \) is sound pressure (\( \tilde{p}_0 \) is measured in the main front direction),
\( S \) is the globe surface around the loudspeaker,
\( \theta \) is the room angle,
for \( \Gamma \) see Eq. 35-17.

A measuring procedure for ascertaining the front to random factor was established in the IEC publication 268-5 (1972):9

\[ \gamma = \left( \frac{p_d r}{p_r r_H} \right)^2 \]

(35-9)

where,
\( p_d \) is direct sound pressure,
\( p_r \) is reverberant sound pressure,
\( r \) is distance to the loudspeaker,
\( r_H \) is the critical distance in the diffuse sound field, see Eqs. 7-10.10

The directivity factor \( Q(\theta) \) is often used for this term, but it is a function of the angle \( \theta \), see Eq. 35-20.

The logarithmic quantity of the front to random factor is the front to random index

\[ C = 10\log \gamma \text{ dB} \]

(35-10)

It corresponds to the difference between the free-field and the diffuse-field sensitivity levels:

\[ C = G_d - G_r \]

(35-11)

where,
\( G_d \) is the sensitivity level in the direct field,
\( G_r \) is the sensitivity level in the diffuse field.

It is also expressed by the sound levels measured at 1 m distance in the direct field of the loudspeaker (\( L_d \)) and in the diffuse field (\( L_r \)) of a room having the reverberation time \( RT_{60} \) and the volume \( V \):

\[ C = L_d - L_r + 10\log \frac{RT_{60}}{V} \text{ dB} + 25 \text{ dB} \]

(35-12)

where,
\( L_d \) is the direct sound level,
\( L_r \) is the diffuse sound level,
\( RT_{60} \) is the reverberation time in seconds,
\( V \) is the volume of the room in m³.

An equal input power \( P_{el} \) is taken for granted.

Because of the dimensions of the radiators, the wavelength of the radiated sound in the lower-frequency range is long compared to the radiating surface. Because of this difference there results only an insignificant directivity. With rising frequency the relationship changes and directivity increases.

For sound reinforcement purposes it has been proven in practice that slight increases of approximately 3 dB/octave of the front to random index of the loudspeaker system is appropriate, because most of the
natural sound sources show a similar increase giving rise to a corresponding timbre change.

For approximate calculations or also measurements of the front to random index, one has to cover at least the range between 500 and 1000 Hz. Many manufacturers are indicating, in the data sheets of their products, the frequency dependence of directivity.

By means of the front to random index $C$ and the nominal power rating $P_n$ it is also possible to describe the characteristic sound level of a loudspeaker system:

$$L_K = L_W + C - 10\log P_n - 11 \text{ dB} \quad (35-13)$$

where, $L_W$ is the sound power level.

The efficiency $\eta$ of a loudspeaker system is determined by the ratio between radiated acoustic power and supplied electric power:

$$\eta = \frac{P_{ak}}{P_{el}}$$

$$= \left(\frac{E_K^2}{\rho_0 c \gamma_L} \times \frac{4\pi r_0^2}{\gamma_L} \right) \times 100\% \quad (35-14)$$

where, $P_{ak}$ is the acoustic sound power, $P_{el}$ is the electrical power applied, $E_K$ is the sensitivity of the loudspeaker, $r_0$ is 1 m distance, $\gamma$ is the front to random factor of the loudspeaker, $\rho_0 c$ is the characteristic acoustic impedance of air = 408 Pa s/m$^3$ at 20°C.

By combining all constants one obtains the following approximation:

$$\eta = 3 \frac{E_K^2}{\gamma_L} \% \quad (35-15)$$

This correlation can be seen in Fig. 35-8. The efficiency of loudspeaker systems lies in reality between 0.1% and 10%. As is the case with the rated sensitivity, the efficiency is often referred to the nominal impedance $Z_n$ of the loudspeaker and designated as nominal efficiency $\eta_n$:

$$\eta_n = \frac{\tilde{p}_d^2 Z_n}{\gamma_L \rho_0^2} \times \frac{4\pi r_0^2}{\rho_0 c} \quad (35-16)$$

where, $\tilde{p}_d$ is the direct sound pressure, $Z_n$ is the nominal impedance, $\gamma_L$ is the front to random factor of the loudspeaker.

**Directional Properties.** All loudspeakers used in real life show a more or less pronounced directional dependence of radiation, which is frequency dependent—just like beaming behaviors. This angular dependence of sound radiation is characterized by three quantities that are going to be considered in detail.

The angular directivity ratio $\Gamma$ for a frequency or a frequency band is the ratio between the sound pressure $p$ radiated at an angle $\theta$ from the reference axis, and the sound pressure $p_0$ generated on the reference axis at equal distance from the selected acoustic reference point (this reference point is selected by the loudspeaker manufacturer and must be published in data sheets; generally it is the center of gravity of the loudspeaker box).\textsuperscript{10}

$$\Gamma(\theta) = \frac{\tilde{p}(\theta)}{p_0} \quad (35-17)$$

In general $\Gamma(\theta) \leq 1$. If the maximum of directional characteristics does not occur at $\theta = 0^\circ$, then $\Gamma(\theta) > 1$.

The logarithmic quantity of the angular directivity ratio is the angular directivity gain

$$D(\theta) = 20\log \Gamma(\theta) \text{ dB} \quad (35-18)$$

Fig. 35-9 shows the directional characteristic of the horn loudspeaker in a polar plot of the directivity gain. One sees the main maximum at $0^\circ$ and several secondary maxima at higher frequencies.
An important parameter for direct sound coverage is the angle of radiation $\Phi$ (beam width angle). It stands for the solid-angle margin within which the directivity gain drops by a maximum of $3\,\text{dB}$ or $6\,\text{dB}$ (or another value to be specified) as against the reference value. The curves of equal directivity gain are marked $\Phi_{-3}$, $\Phi_{-6}$, or generally $\Phi_{-n}$, the higher the directivity the smaller the angle of radiation, Fig. 35-10.

Because of the curves of equal directivity gain and the sound distribution loss, the impact of direct sound of a loudspeaker on a surface may produce elliptic curves that represent a calculated SPL isobar area of the direct sound coverage. These isobar areas are important in the planning of sound reinforcement systems as coverage areas.

For combining the influence of the directional effect as well as that of the distribution between directional and omnidirectional energy, one uses, in acoustics, the directivity deviation ratio:

$$\Gamma^*(9) = \sqrt[3]{\Gamma(9)} \quad (35-19)$$

This quantity is also of high importance to sound reinforcement engineering. It characterizes the reverber-
ation component caused by the loudspeaker in the excited room.

The square of this quantity is the well-known directivity factor $Q$:

$$Q = g(\theta)$$
$$= \gamma \Gamma^2(\theta) \quad (35-20)$$

Especially in the United States, it is common to use just $Q$ for different angles $\theta$. Nevertheless this entity is angle-dependent and therefore should always be referenced along with the corresponding angle. The logarithmic expression of the directivity factor $Q(\theta)$ is the so-called directivity index $DI$ (also angle dependent)

$$DI = H(\theta)$$
$$= 10 \log g(\theta) \text{ dB} \quad (35-21)$$
$$= 10 \log Q(\theta) \text{ dB}$$

where, $H(\theta)$ is the reverberation directional index.

In the German literature one uses for the directivity factor $Q$, the reverberation directional value $g(\theta)$.$^{10}$ By the same token the directivity index, $DI$, is called reverberation directional index $H(\theta)$.

The reader should be aware of the partially contradicting conventions, of which some are using $Q$ and $DI$ only for values of $\theta = 0^\circ$ and others employ $Q$ and $DI$ in an angle-dependent way, sometimes without clearly stating so.

**Transmission Range.** According to several standards, the transmission range of a loudspeaker is the frequency range usable or preferably used for sound transmission. That region of the transmission curve in which the level measured on the reference axis in the free field does not drop below a reference level generally characterizes the transmission range. The reference value is the average over the bandwidth of 1 octave in the region of highest sensitivity (or in a wider region as specified by the manufacturer). In the ascertainment of the upper and lower limits of the transmission range, there are not considered any peaks and dips whose interval is shorter than $1/8$ octave.

This definition implies that loudspeakers have to necessarily be checked as to their transmission range before being used in sound reinforcement systems. With radiators intended for indoor use, it is also necessary to consider the front to random factor—i.e., the influence of the diffuse-field component on the formation of the resulting sound pressure.

For special loudspeaker systems—e.g., studio monitoring equipment—narrower tolerance fields of the free-field sound pressure are indicated for the transmission range. Thus the OIRT Recommendation 55/1 permits for the range from 100 Hz–8 kHz a maximum deviation of $\pm 4$ dB from the average value, whereas below, down to 50 Hz, and above, up to 16 kHz, the tolerance field widens to $-8$ dB and $+4$ dB.$^{11}$

Fig. 35-11 shows exemplary the behavior of free-field sensitivity, diffuse-field sensitivity, and front to random index of a radiator.

Moreover the transmission range is influenced, especially in the lower-frequency range, by the installation conditions or the arrangement of the radiator. Fig. 35-12 shows that the arrangement of the loudspeaker system has a considerable influence on the transmission curve. This is due to the fact that arranging the radiator in front of, below, or above a reflecting surface causes interferences of the direct sound by the strong reflections that give rise to comb-filter-like cancellations, which can be proven by a narrow-band analysis of the resulting signal. These cancellations are particularly pronounced, if the source is in front of a wall, and the radiator has compensating openings in its rear part, or if these reflections come from a distance of about 1.5 m out of a room corner—e.g., between ceiling and wall.

![Figure 35-11. Frequency dependence of the front to random index, as compared with the free-field and the diffuse-field sensitivities.](image-url)

As a rule one can say that the ear normally does not perceive dips and peaks that are not measurable in a $1/3$ octave band filter analysis (unless they show pronounced periodic structures).

A good bass radiation is produced if the radiating plane is embedded in a reflecting surface, for instance, a wall or a ceiling. In this case there may also exist a certain angle between the radiating plane and the surrounding surface.
Types of Loudspeakers. The different tasks of sound reinforcement engineering require different radiator types. These differ as to size and shape of their enclosures, the form of sound conduction, the types of driving systems used, as well as arrangement and combination of the same. In this way one obtains different directional characteristics of sound radiation, sound concentrations, sensitivities, transmission ranges, and dimensions that facilitate solutions for diverse applications or even enable them at all.

Among the simplest radiators are single loudspeakers of smaller dimensions and ratings that are used in decentralized information systems, for instance, for covering large flat rooms or for producing room effects in multipurpose halls. The integration into a wall or an enclosure of these loudspeakers avoids the acoustic short-circuit usually seen with no baffle situations—suppressing the pressure compensation between the front and rear sides of the diaphragm. To this effect a baffle panel or an open or closed box may be used, Fig. 35-13.

With a closed box one has to consider that the oscillating part of the loudspeaker functions in one direction against the relatively stiff air cushion of the box. Loudspeakers for such compact boxes are for this reason provided with an especially soft diaphragm suspension so that they cannot be easily used for other purposes.

Acoustically more favorable are the conditions with vented enclosures, the bass reflex boxes or phase reversal boxes. Such box loudspeakers are nowadays used less as decentralized broadband radiators, but increasingly for high-power large-size loudspeaker arrays.

Another possibility for achieving a determined directional characteristic consists in the arrangement of sound-conducting surfaces in front of the driving loudspeaker system. Given that such arrangements are mostly of hornlike design, they are named horn loudspeakers. Because of the high characteristic sensitivity and the high-directional characteristic, this radiator design is very well suited for sound reinforcement in big auditoriums where the desirable frequency range and different target areas (coverage areas) require the use of different types of radiation patterns.

For technical reasons it is not sensible to construct a broadband horn for the overall transmission range. A better solution is several horn loudspeakers complementing each other.

Bass Horns. Owing to the great dimensions involved, the design of bass horns requires extensive compromises. Practical models of bass horns receive a horn shape, as a rule, only in one dimension, whereas at a right angle to it, sound control is achieved by means of parallel surfaces. The power-handling capacity of such bass horns, which are mainly used in music or concert systems, is about 100–500 VA.

Medium-Frequency Horns. The greatest variety of driver and horn designs is available for horn loudspeakers for the medium-frequency range of about 300 Hz–3 kHz.

The drivers used are mostly dynamic pressure-chamber systems connected to the horn proper by means of a throat, the so-called throat-adapter.

Treble Horns. For the upper frequency range, two main types of horn loudspeakers are produced. These are the horn radiators showing similar design characteristics as the medium-frequency horns that function in the frequency range from 1–10 kHz, and the special treble loudspeakers (calotte horns) used for the frequency range from 3–16 kHz.

35.1.3.3 Loudspeaker Line, Sound Column and Line Arrays with In-Line Arrangement of Radiators

Classical Columns. For many tasks of sound reinforcement engineering, one requires radiators capable of
producing a high sound level at a large distance from their point of installation, while minimally affecting microphones located at close range to them. To have this effect they must show a determined directional characteristic and beaming. A radiator type suitable for this purpose is the loudspeaker array consisting—in the variant required—of a stacked arrangement of in-phase-identical loudspeakers. In the plane orthogonal to this arrangement, there occurs a pressure addition, whereas in the areas above and below this plane, there is a cancellation by interference because of the early-to-late difference between the components stemming from the different loudspeakers, Fig. 35-14. Each of the individual loudspeakers radiates the sound spherically and the sound waves get favorably superposed in the far field, whereas the effect of the individual loudspeaker prevails in the near field. For the far field the following equation was given by Stenzel\textsuperscript{12,13} and Olson\textsuperscript{14} for the angular directivity ratio \( \Gamma \), the so-called polars.

\[
\Gamma = \frac{\sin \left[ \frac{n \pi d \sin a}{\lambda} \right]}{n \sin \left[ \frac{\pi d \sin a}{\lambda} \right]} \tag{35-22}
\]

where,

- \( n \) is the number of individual loudspeakers,
- \( d \) is the spacing of the individual loudspeakers,
- \( a \) is the radiation angle,
- \( \lambda \) is the wavelength of sound,
- \( l = (n - 1) d \), which is the length of the loudspeaker line.

This directional effect of a loudspeaker line according to Fig. 35-15\textsuperscript{15} is shown in Fig. 35-16A—a balloon at 1 kHz, and in Fig. 35-16B—a balloon at 2 kHz. The line consists of nondirectional loudspeakers arranged with a spacing of 25 cm. Secondary maxima occur at frequencies above a critical frequency (wavelength = spacing of the loudspeakers), that is above 1400 Hz in the example. Thus a desirable disc-shaped radiation without secondary maxima can be observed at 1000 Hz, whereas at 2000 Hz lobes (secondary maxima) are already utterly evident.

The drawback of an in-line loudspeaker arrangement consists of the fact that...
The desired directional effect is given only in a range below the critical frequency, whereas above that frequency there occur additional secondary maxima.

The directivity is frequency-dependent—front-to-random factor $\gamma$ of the main maximum $\approx 5.8$ $l/f$ ($l$ is the length of the column in m and $f$ the frequency in kHz).\(^{16}\)

The directivity increase does not only occur in the directivity domain, but also, owing to the distances of the individual loudspeakers, in the scattering domain, so the column is losing directivity at high frequencies.

All these frequency-dependent properties of the loudspeaker lines involve the possibility for timbre changes to occur over the width and depth of the covered auditory. In order to eliminate or limit this drawback, the lines are often subdivided in the upper frequency range. This is mostly accomplished by curving the line “bananalike” or like a so-called J-Array. Alternatively individual elements can be rotated slightly off-axis in the horizontal domain, such as in alternating angles of $\pm 10$ degrees relative to the aiming axis of the system.

**Line Arrays.** Modern line arrays do not consist of a line up of individual cone loudspeakers, but instead of a linear arrangement of wave-guides of the length $l$, which produce a so-called coherent wave front. In contrast to the traditional sound columns, these arrays radiate in their near range so-called cylindrical waves. This near range is frequency dependent and only valid up to the following distances $r$:

$$r = \frac{l^2}{2\lambda}$$  \hspace{1cm} (35-23)

where, array length and wavelength are in meters.

In 1992 Christian Heil was the first to present this new design at the AES in Vienna.\(^{17}\) With the product V-DOSC by L-Acoustics, a new technology was introduced which can now be found with modifications in the product range of more than forty manufacturers (compare Fig. 35-17).

The characteristic feature of these systems is that the sound levels decrease in the near range by only 3 dB with distance doubling, and begin to decrease like those of spherical radiators only beyond the near range. This way it is possible to cover large distances with high sound levels and without having to use delay towers.

**Digitally Controlled Line Arrays.** A way of reducing the frequency dependence of the directional characteristics and beaming of sound lines consists of supplying the sound signal with different phases and levels to the individual loudspeakers in an array.

Duran-Audio was one of the first manufacturers that reduced the length of its Intellivox loudspeaker lines with increasing frequency by electronic means (so-called DDC solution). This solution resulted in loudspeaker lines with pronounced directivity in the vertical domain and constant sound power concentration in the horizontal domain.\(^{18}\) Fig. 35-18 illustrates such a directional effect in 3D representation.

Other manufacturers go similar ways, Renkus-Heinz with the ICONYX loudspeaker,\(^{19}\) Fig. 35-19, the French company ATEIS (Messenger),\(^{20}\) and EAW (DSA series).\(^{21}\)

By changing the firmware control the following features of such columns are possible:

1. Constant SPL versus distance.
   - Midband frequencies.
   - Noncomplex shaped audience areas.

2. The performance is optimized with the following parameters:
• Opening angle.
• Aiming angle.
• Focus distance.
• Mounting height with respect to audience area.

This solution, however, finds its limitations with a complicated audience-area layout. Moreover, certain sound level distributions can be obtained only after several corrections. This gives rise to questions like: “How can a loudspeaker array be controlled so as to create a predefined far and near field response?” One approach was made by Duran Audio with the digital directivity synthesis (DDS). \(^{22}\)

![Figure 35-18. Cluster balloon presentation of Intellivox 2C in EASE.](image)

![Figure 35-19. ICONYX Series from Renkus-Heinz Inc.](image)

Here the directivity pattern of an array is adaptable to audience areas; and uniform SPL distribution also becomes possible in complex-shaped audience areas.
It stands to reason that point sources or line loudspeakers of a certain dimension cannot exhibit this radiation behavior automatically. Here the manufacturer has to supply along with the arrays, not only the electronic driver unit for the same, but also the parameter setup algorithm. By means of attached software this algorithm will then be controlled according to the desired application.

### 35.1.4 Wall Materials

To simulate the radiation behavior of sources in rooms or open spaces we need to construct corresponding models. All boundary walls of these models need to have the corresponding acoustic properties:

- Absorption.
- Scattering.
- Diffraction.

These properties have been discussed in Section 7.3.4, therefore they will not be repeated here. Instead, some specialties important to know when doing computer modeling should be added here.

#### 35.1.4.1 Absorber Data

Absorbing behavior has been known for hundreds of years, but data has been available only for 80 years. We distinguish between data measured in a reverberation chamber (Standard ISO 354) or data that is angle dependent. The latter absorption coefficients are very seldom measured and only available for special applications. For computer simulation, the absorption coefficient measured in the diffuse field will be used. This coefficient is measured by the corresponding manufacturers and published in specification brochures. It is measured in octave or ½-octave bands and starts normally at 63 Hz and goes up to 12 and even 16 kHz. In most simulation programs the low end is skipped because the actual simulation routines do not cover frequency ranges below 100 Hz. The highest-frequency band is quite often only 8 kHz.

All this data is meanwhile published in table form and some simulation programs have more than 2000 materials from different manufacturers on board.

#### 35.1.4.2 Scattering Data

Scattering data is not found in textbooks except for some special scattering materials or samples. Here should be mentioned the products of RPG Diffuser Systems Inc., which produce special modules with sound-scattering surfaces.

On the other hand it is known that the absolute value of the scattering coefficient \( s \) is less important. The fact is that there is almost no material not scattering \( (s = 0) \) or only scattering \( (s = 1) \). The practical values for the scattering coefficients are between 0 and 1. So there are some rules of thumb to define the actual scattering coefficient in simulation software programs. Some programs give some guidance to estimate the coefficients, other programs like EASE 4.2 use special BEM routines (compare to Fig. 7-46) to derive the coefficient in a way as it should be measured according the proposals of Mommertz, see also Standard ISO 17497-1.

A scattering coefficient will never generally be available in tables (except the mentioned special module values), because the way the interior architect uses the materials in a hall affects the scattering behavior. Therefore the scattering behavior of wall parts in a computer model must be determined model specific.

#### 35.1.4.3 Diffraction, Low-Frequency Absorption

As we will see in Section 35.3.2, the computer simulation programs use different ray-tracing algorithms to calculate the impulse responses in model rooms. But these routines of using particle radiation are only valid above a certain frequency determined by

\[
\begin{align*}
  f_1 &= K \sqrt{\frac{RT_{60}}{V}} \\
  \text{where,} & \\
  K & \text{is a constant (2000 in metric units, 11,885 in U.S. units),} \\
  RT_{60} & \text{is the apparent reverberation time in seconds,} \\
  V & \text{is the volume of the room in cubic meters or cubic feet.}
\end{align*}
\]

(35-24)

For lower frequencies and especially in small rooms the particle assumption cannot be applied. Here the wave acoustics routines are applied. An analytical solution is impossible, so numeric routines have been developed. Mainly the finite element method (FEM) and the boundary element method (BEM) are used. First for applying the FEM, the computer model must be subdivided in small volumes (meshes), where the dimensions of the
mesh correspond with the upper frequency handled by the FEM. The higher the frequency, the smaller the dimensions and the longer the calculation time. As an example, to build a mesh in a hall of 10,000 m³ you need a mesh resolution of about 280,000 subvolumes to apply the FEM up to 500 Hz. Fig. 35-20 shows such a mesh grid for a church model. For the BEM only the surface must be meshed accordingly.

After the mesh is ready and that is a quite difficult job in complex room structures, we need to know the impedance behavior of the single wall parts. This is again quite complex because any stiffness or mass values of the majority of the wall materials are not known. So in a first approach the impedance of the wall material can be derived from the known absorption coefficient. Now by applying the well-known algorithm of the FEM, the transfer function at selected receiver places may be calculated. By means of a Fourier transformation you obtain the impulse response in the time domain. By means of this method, transfer functions at receiver places may also be calculated, even if the receiver is shadowed from the sending position and the direct sound was only coming by diffraction to the receiver.

This method can be used very well in small rooms below 300 Hz. A mesh of a control room of 135 m³ consists only of around 1000 subvolumes, if frequencies higher than 300 Hz are neglected. This way very fast calculation results can be expected.

35.1.5 Receivers and Microphone Systems

35.1.5.1 Human Ears

The properties of the human ears are explained in a lot of books about psychoacoustics, including Chapter 3 of this handbook. In simulation programs the acoustic properties of a room or the free-field environment are determined by calculation of the so-called impulse response. This response is calculated using ray-tracing methods. For a single point in space, the so-called monaural response is determined, and the result supplies not only the level at the receiver place, but also the frequency dependence, the angle of incidence for single reflections, and the run-time delay in comparison to the first incoming signal (direct sound). Using so-called head-related transfer functions (HRTF) measured with dummy heads, or using in-ear microphones, Fig. 35-21, the monaural impulse response may be converted into a binaural one used for real-time convolution, see Section 35.3.3.

35.1.5.2 Microphones

The use of microphones in sound reinforcement systems requires observation of a number of conditions. To avoid positive acoustic feedback, it is frequently necessary to keep the microphone at closer distance to the sound source so that often considerably more microphones have to be used. Moreover the live conditions demand very robust microphones.

To simulate the use of microphones, to precalculate the acoustic feedback threshold or to simulate enhancement systems based on electronic processing, an exact knowledge of the properties of the microphone types and their connection technique is needed.

Basic Parameters. The microphone data are laid down in standards. In this context we will consider only this data that is important for computer modeling. For further information especially, regarding the types of microphones, please refer to Chapter 16.

The magnitude of the output voltage of a microphone as a function of the incident sound pressure is described by the microphone sensitivity.

Figure 35-20. Meshed model in EASE 4.2.

Figure 35-21. HRTF balloon of the left ear of a dummy head.
\[ T_E = \frac{\bar{u}}{p} \]  

in V/Pa or its 20-fold common logarithm, the sensitivity level

\[ G_s = 20 \log \frac{T_E}{T_0} \text{ dB} \]  

(35-26)

The reference sensitivity \( T_0 \) is normally specified for 1 V/Pa.

Depending on the test conditions one distinguishes the following sensitivities:

- The pressure open-circuit sensitivity \( T_{E_p} \) as the ratio between the effective output voltage at a certain frequency and the effective sound pressure of a vertically incident sound wave.
- The free-field open-circuit sensitivity \( T_{E_f} \) which considers by special measuring conditions the pressure increase conditioned by the cross-section dimensions of the microphone.
- The diffuse-field sensitivity \( T_{E_r} \), which reflects the diffuse sound incident on the microphone.

**Directivity Behavior.** The dependence of the microphone voltage on the direction of incidence of the exciting sound is called directional effect. The following quantities are used for describing this effect:

- The angular directivity ratio \( \Gamma(\theta) \) is the ratio between the free-field sensitivity \( T_{E_d} \) for a plane sound wave arriving under the angle \( \theta \) to the main microphone axis and the value ascertained in the reference level (incidence angle 0°).

\[ \Gamma(\theta) = \frac{T_{E_d}(\theta)}{T_{E_d}(0)} \]  

(35-27)

- The angular directivity gain \( D \) is the twenty fold common logarithm of the angular directivity ratio.
- The coverage angle is the angular range within which the directivity gain does not drop by more than 3 dB, 6 dB, or 9 dB against the reference axis.

Apart from the quantities describing the ratio between the sensitivities of the microphone with sound incidence from various directions deviating from the main axis, it is also necessary to describe the relationship between the sensitivities with reception of a plane wave and those with diffuse excitation. With these quantities it is then possible to ascertain the suppression of the room-sound components against the direct sound of a source to be transmitted. This energy ratio is described by the following parameters:

- The front to random factor is the ratio between the electric power rendered by the microphone when excited by a plane wave from the direction of the main axis, and the power rendered by the microphone excited in a diffuse field with the same sound level and same exciting signal. If the sensitivity was measured in the direct field as \( T_{E_d} \) and in the diffuse field as \( T_{E_r} \), the front to random factor results as

\[ \gamma_M = \frac{T_{E_d}^2}{T_{E_r}^2}. \]  

(35-28)

- The front to random index is the ten fold common logarithm of the front to random factor.

While the front to random factor of an ideal omnidirectional microphone is 1, that of an ideal cardioid microphone is 3. This means that a cardioid microphone picks up only \( \frac{1}{3} \) of the sound power of a room picked up by a comparable omnidirectional microphone at the same distance from the source. This implies, for instance, that with identical proportion of the sound power, the speaking distance for a cardioid microphone may be three times greater than that of an omnidirectional microphone.

### 35.2 Transducer Data for Acoustic Simulation

To simulate an entire acoustic system, all parts must be taken into account. Besides the room, loudspeakers and natural sound sources as well as microphones and the human hearing system have to be considered. In this section, our main goal is to review existing practice and outline advantages and disadvantages that the user of a software program should be aware of when applying performance data for a particular sound transducer. In this regard, our intention is to talk about the simulation of transducers with respect to the electroacoustic and room-acoustic prediction of the acoustic system as a whole. We will not be concerned with mathematical methods applied in the design process of loudspeakers or microphones. These usually provide a much higher degree of accuracy in some regards, but at the same time often provide insufficient data for other simulation purposes. Specifically, for transducer design utilizing BEM/FEM-based prediction methods we refer the reader to available textbooks and publications.

#### 35.2.1 Simulation of Loudspeakers

In computer aided acoustic design and especially for sound reinforcement applications, the level of accuracy
to which sound sources are modeled plays a crucial role. Accordingly, most simulation software packages have continuously developed their capabilities of describing loudspeakers by measurement data along with the complexity of the loudspeaker systems themselves. At the same pace, the availability and fast development of personal computers had a significant impact on acoustic measurement systems and their accuracy on the one hand and on the computing power available on the other hand.

In this sense, the measurement and simulation of loudspeaker systems can be roughly divided into two periods of time. The first period, until the late 1990s, was characterized by the use of simplified far-field data for almost any sort of loudspeaker and the assumption of a point-source-like behavior. But with the advent of modern line array technology, for both tour sound and speech transmission applications, new concepts had to be developed. These methods include the use of multiple point sources as well as advanced mathematical models to image the complexity of today’s loudspeaker systems. In addition to that, research was further accelerated by the broad availability of DSP platforms and the resulting need to simulate DSP controlled loudspeakers as well as the virtual disappearance of computer-based constraints, such as calculation speed and memory.

### 35.2.1.1 Simulation of Point Sources

**Theoretical Background.** For many years the radiation behavior of sound sources, and loudspeakers in particular, was basically described by a 3D matrix containing magnitude data in a fixed spectral and spatial resolution. Starting with the late 1980s, typical data files contained directivity data for the audible octave bands, such as from 63 Hz to 8 kHz, and for a spherical grid with an angular spacing of 15°. Mostly, data was also assumed to be symmetric in one or two planes. With the need for higher data resolution and the limits of available PC memory and computing power changing at the same time, more advanced data formats developed eventually reaching a nowadays typical resolution of 5° angular increments for 1/3-octave frequency bands. Tables 35-1 and 35-2 show some of these typical loudspeaker data formats and their resolutions.

Now let us look at the background for this development. We express the complex sound pressure \( \hat{p} \) for the time-independent propagation of a spherical wave:\(^{29}\)

\[
\hat{p}_{\text{Sphere}}(\hat{r}, f) = \frac{\hat{A}(\phi, \theta, f)}{|\hat{r}|} \exp(-j\hat{k}\hat{r}) \quad (35-29)
\]

where

\( \hat{r} \) is the receiver location, \( f \) is the frequency, \( \hat{A}(\phi, \theta, f) \) is the complex radiation function of the source depending on angles \( \phi \) and \( \theta \) (both being functions of \( \hat{r}/|\hat{r}| \)) as well as on the frequency, \( \hat{k} \) is the wave vector.

Loudspeaker measurements \( \hat{A} \) happen at discrete angles \( \phi_k, \theta_l \), and frequencies \( f_m \); the simulation software has to interpolate between such data points to obtain a smooth response function:

\[
\hat{p}_{\text{Sim}}(\hat{r}, f_m) = \frac{f_{\text{Int}}(\hat{A}(\phi_k, \theta_l, f_m))}{|\hat{r}|} \exp(-j\hat{k}\hat{r}) \quad (35-29A)
\]

Here the interpolation function is represented by \( f_{\text{Int}} \). The frequency resolution is basically given by the set of available data points of \( f_m \), the angular resolution is given by the density of data points \( \phi_k, \theta_l \).

For a long time, most measurements were made to acquire magnitude data only, \( \hat{A} = |\hat{A}| \) and \( f_{\text{Int}}(\hat{A}) = |f_{\text{Int}}(\hat{A})| \). In such a case, the simulation of interaction between multiple sound sources yields a sound intensity, \( I_{\text{Sum}} \), that is derived either by power summation for incoherent sources \( n \) (located at \( \hat{r}_n \)):

\[
I_{\text{Sum}}(\hat{r}, f_m) = \left[ \sum_n p_n \right]^2 \quad (35-30)
\]

\[= \sum_n \left[ f_{\text{Int}}(\hat{A}_n(\phi_k, \theta_l, f_m)) \right]^2 \left| \hat{r} - \hat{r}_n \right|^2 \]

or by at least considering the run time phase \( \Phi_n = -\hat{k}_n(\hat{r} - \hat{r}_n) \) for coherent sources:

\[
I_{\text{Sum}}(\hat{r}, f_m) = \left[ \sum_n p_n \right]^2 \quad (35-30A)
\]

\[= \left[ \sum_n f_{\text{Int}}(\hat{A}_n(\phi_k, \theta_l, f_m)) \right] \exp[-j\hat{k}_n(\hat{r} - \hat{r}_n)] \left| \hat{r} - \hat{r}_n \right|^2 \]

This simulation model makes some significant assumptions:

1. First, the use of a spherical waveform assumes that both measurement and simulation happen in the far field of the device, that is, at a distance where the sound source (normally a surface) can be considered as a point source \( \hat{p}_{\text{Real}}(\hat{r}, f) \approx \hat{p}_{\text{Sphere}}(\hat{r}, f) \).
2. Second, it is assumed that the density of discrete data points is high enough and the frequency and angular dependency of the directivity characteristics smooth enough so that the true radiation function of the spherical wave can be approximated by \( \hat{A} \approx f_{\text{int}}(A) \).

3. Third, the use of magnitude-only data, assuming that \( \hat{A} \approx f_{\text{int}}(A) \), requires that the point of reference during the measurement of \( A \) is chosen in a way that the true run-time phase, otherwise included with the measurements, can be reconstructed by the run-time phase \( \hat{kr} \) in the model. It requires that the source-inherent phase is negligible as well, \( \text{arg}\hat{A} \approx 0 \).

4. It is assumed that the concerned loudspeaker system is a fixed system that cannot be changed by the user or when its configuration is changed its performance data is not affected. The measurement data is regarded as representative for the whole range of possible applications and configurations.

5. Finally, for the use of such point sources in computations involving geometrical shadowing and ray-tracing calculations, the source is regarded as located at a single point and is either wholly visible (audible) for a receiver or not.

These assumptions have been made especially in the early 1990s in order to obtain and use loudspeaker directivity data in a practical manner. Important factors were the availability and accuracy of measurement platforms and methods, the storage size of the processed measurement data and the PC performance with regard to processor speed available to the average user of the data.

However, these assumptions have a set of drawbacks. That became most evident with the broad use of

large-format touring line arrays and digitally controlled loudspeaker columns but also with the increasing use of inexpensive DSP technology employed for multiway loudspeaker systems. Some of the issues conflicting with above points 1–5 are listed in the following.

- A large line array system of some meters, height cannot be measured adequately in its far field in addition to the fact that a large number of line array applications actually happens to take place mainly in the near field. Therefore the simulation of a whole line array as a point source is not valid within reasonable error ranges.

- Another problem often encountered is insufficient angular resolution. Loudspeaker columns and multiway loudspeakers exhibit significant lobing behavior in the frequency ranges where multiple acoustic sources interact at similar strength. Often too coarse angular measurements fail to capture these fine structures and thus cause erroneous simulation results due to aliasing/sampling errors.

- While in many cases the phase of the sound pressure radiated by a simple loudspeaker is negligible at least if it is considered on-axis and the run-time phase is compensated for, the same is not true for most real-world systems. On the one hand, for multiway systems one cannot generally define a single point where the measured phase response vanishes for all frequencies and angular directions. This is the problem of the so-called acoustic center for a set of sound sources. In such cases the measured phase data will typically show a run-time phase component that depends on angle and frequency, no matter where the point of rotation is. On the other hand, the inherent phase response plays an important role in describing the radiation behavior that is influenced by diffraction about the edges of the loudspeaker case, that is, at angles of 60 degrees and more off-axis.

- Loudspeaker systems become increasingly configurable, so that the user can adapt them to a particular application. Typical examples include almost all touring line arrays where the directional behavior is defined mechanically by the splay angles between adjacent cabinets, and in loudspeaker columns or multiway loudspeakers, where the radiation characteristics can be changed electronically by manipulating the filter settings.

- In advanced computer simulations of sound reinforcement systems in venues, geometrical calculations must be performed. This is required to obtain exact knowledge of which part of the audience might be shadowed by obstacles between the sound sources and the receivers. Geometric considerations are also needed in ray-tracing calculation in order to find reflections and echoes. For both processes, the reduction of a physically large loudspeaker system to a point source can lead to significant errors. Depending on the choice of the reference point for the source, particular reflections might not be found or are exaggerated, or a large fraction of the audience area might be seemingly shadowed by a very small object.

In addition to the above, a set of minor problems is also evident. This includes the definition of maximum power handling capabilities of multi-input systems that are represented by a single point source. The availability of case drawings to help in the mechanical design and the clear indication of the reference point that was used for the measurements are is important.

As a result of the obvious contradictions, a variety of proposed solutions emerged in the later 1990s. This development happened partially by the loudspeaker manufacturers and partially by the creators of simulation software as well. To resolve the problem of large-format loudspeaker systems, a subdivision into smaller elements is required to be able to measure them and use them for prediction purposes. To properly model the coherent interaction between these elements, complex measurement data, including both magnitude and phase data, is needed.

The most prominent solutions can be summarized as follows. Instead of measuring a whole system, so-called far-field cluster balloons were calculated based on the far-field measurement of individual cabinets or groups of loudspeakers. To describe individual sound sources, phase data was introduced in addition to the magnitude-only balloon data. Mathematical models providing phase information implicitly were applied, such as minimum phase or elementary wave approaches as well as 2D sound sources. However, these first approaches lacked generality and thus their implementation into existing simulation software packages was specific, difficult, or even impossible.

The situation was resolved first by the concept of the loudspeaker DLL (dynamic link library), which serves essentially as a programmable plug-in for simulation software. Another concept, namely the GLL (generic loudspeaker library), introduced a new loudspeaker data file format that is significantly more flexible than the conventional data formats, and is designed to resolve most of their apparent contradictions. We will review both approaches in the next section as they have turned out to be a standardized way to model complex loudspeaker systems.
**Practical Considerations.** Improvements that are theoretically desirable must also be practically accomplished. It is clear that only reasonable measurement times can provide reliable data in an efficient manner. In practice, an angular resolution of 5 degrees has proven to be adequate for most needs, sometimes even lower resolutions of 10 degrees can be sufficient. Simulation software packages should be able to handle higher resolutions as well, but only for special cases. This is particularly feasible when measuring durations can be reduced using multiple microphones, like ten or nineteen receivers arranged on an arc. This technique requires some care in the measurement setup since all of the microphones have to be calibrated and normalized relative to each other.

Also the acquisition of both magnitude and phase data requires more care than just the measurement of magnitude-only data. However, modern impulse response acquisition platforms provide a good means to obtain complex data and a sufficient frequency resolution. The representation of a loudspeaker directivity function based on impulse response wave files is thoroughly discussed by the Working Group of the Standards Committee SC04-01 of the AES. As we will present farther below, the utilization of phase data in acoustic modeling has become an important factor. As an illustration, Fig. 35-22A—D show, the magnitude and phase data for a loudspeaker—UPL1 from Meyer Sound Inc.—in high resolution in both MATLAB and EASE.35

Additionally, it is worth mentioning—and we will give some practical guidelines in the next sections—that, in order to obtain acceptable data for a point source approach, measurements have to take place in the far field of that assumed point source. Like indicated previously, this may be difficult for large multi-way cabinets or column loudspeakers.

In general it must be emphasized that the computer model utilizing this loudspeaker data can only be as good as the data of the lowest quality included. Nowadays, the accuracy of the loudspeaker data is often much higher than that of the material data. Absorption and scattering coefficients are usually only known in 1/4 or 1/5 octave bands for random incidence. The user must be aware that although loudspeaker direct field predictions may be very precise, any modeling of the reflections and the diffuse sound field in the room will be limited by the available material data. Furthermore, it is not very likely that there will ever be systematic, large-scale measurements of angle-dependent complex directivity data for the reflection and scattering of sound by wall materials.

To complete this practical perspective another point of concern has to be underlined. Any data set describing the acoustic characteristics of a loudspeaker should also document important measurement parameters and conditions. In particular, the point of rotation used for the sensitivity and balloon measurements must be defined in such a data set and indicated in the case drawing as well, Fig. 35-23. Only when this reference point is known will the end user be able to define precisely the location of the loudspeaker in the computer model and to obtain the right results.

### 35.2.1.2 Simulation of Complex Loudspeakers

#### 35.2.1.2.1 Modeling by Means of a DLL Program Module

In a first step to overcome the variety of issues related to the reduction of complex loudspeakers to simple point sources, the DLL approach was developed. Technically speaking, the MS Windows dynamic link library (DLL) is a program or a set of functions that can be executed and return results. It cannot be run stand-alone but only as a plug-in of another software that accesses it through a predefined interface. The basic idea is to move the complexity of describing a sound source from the acoustic simulation program into a separate module that can be developed independently and that can contain proprietary contents. In this way, a clear cut is made between the creators for simulation software packages and the loudspeaker manufacturers who can develop product-specific DLL modules on their own.

However, acoustic prediction programs have different underlying concepts and therefore, although the DLL concept is a general philosophy, the DLL interfaces are different too. In consequence, a DLL built for one simulation platform cannot be used for another. Nevertheless, all DLL models share a similar approach to resolve the given problems. Because they can be programmed, they are essentially able to handle any kind of data and realize any kind of algorithm. If the mathematical description and/or sufficient measurement data for the loudspeaker system exists, this information can be encoded into a DLL. Given an appropriate theory for how the source radiates sound, the solution can be implemented without much compromise. Practically, the DLL provides the data describing the radiation of sound by a particular loudspeaker and the simulation software employs this data to model the interaction of the source with the room. For an example see Fig. 35-24.
Compared to conventional, tabular data formats this flexibility is unequaled. It is obvious that with a mathematical model of sufficient accuracy many of the previously discussed issues can be resolved. But at the same time, the development of a DLL module requires some programming effort. As an encoded binary file it is also proprietary to the loudspeaker manufacturer, so normally the user of simulation software and DLL plug-ins cannot determine how the loudspeaker system is actually modeled. Unless sufficient information is published by the creator of the DLL, the end user cannot estimate the level of prediction accuracy the model provides.
35.2.1.2.2 Modeling by Means of a GLL Data File

While trying to solve the same problems, technically the GLL concept\textsuperscript{34} takes a different path compared to the DLL philosophy. Based on the experience with many loudspeaker manufacturing companies and the implementation of simulation and measurement software packages, the generic loudspeaker library (GLL) was developed as an object-oriented description language to define the acoustic, mechanical, and electronic properties of loudspeaker systems, Table 35-1. Since for each physical entity the GLL language has a representation in the software domain, there is no need to make artificial assumptions in order to comply with rigid, reduced data structures. Basically, in the GLL philosophy every sound radiating object should be modeled as such and every interaction possible between engineer and loudspeaker in the real world should be imaged in the software domain. In this picture, transducers, filters, cabinets, rigging structures and a whole array or cluster are present in the GLL with their essential properties and parameters, Fig. 35-25.

Typically, the GLL model of a loudspeaker consists of one or multiple sound sources, each with its own location, orientation, directivity, and sensitivity data. These sources can be simple point sources but also spatially extended sources, such as lines, pistons, etc. In addition to that, a complex directivity balloon based on high-resolution impulse response or complex frequency response data on a spherical grid describes the radiation behavior. With the sources representing the acoustic outputs of the loudspeaker on the one hand, the builder of a GLL defines the electronic inputs of the loudspeaker on the other hand. A filter matrix provides the logic to combine inputs and outputs, see the example in Fig. 35-26.

It can include multiple sets of filters, including IIR and FIR filters, crossover, and equalization filters. The loudspeaker box is mechanically characterized by means of a case drawing and data for center of mass calculations. Boxes can be combined into arrays and clusters. Available configurations are predetermined by the loudspeaker manufacturer according to the functions available to the end user. Additional mechanical elements such as frames and connectors allow specifying exactly which configuration possibilities exist.

Once all the data is assembled, the GLL is compiled into a locked, distributable file, Fig. 35-27. In fact, the end user of a compiled GLL can only see the loudspeaker system as he would see it in the real world. The user can apply filters to the electronic inputs of the loudspeaker and he can calculate (= measure) the acoustic output of the loudspeaker. He can look at the loudspeaker case as well. When modeling arrays he may change the arrangement of boxes as allowed by the manufacturer.

It is obvious that the GLL format provides a natural, straightforward way to describe loudspeaker systems. By means of a GLL model any active and passive multi-way loudspeakers, digitally controlled column loudspeakers, line arrays, or loudspeaker clusters can be accurately represented with regard to their acoustic, electronic, and mechanical properties. Nonetheless the GLL model will fail due to its very nature, when artificial algorithms are to be implemented that do not have a counterpart in the real world.

35.2.1.3 Background of Simulation and Measurement

This section reviews simulation methods and measurement requirements as well as their theoretical basis with respect to both DLL and GLL modeling approaches.
35.2.1.3.1 Resolving the Far-Field Problem

One of the primary points to address in the simulation of the acoustic sources is the correct application of the data for the near field and far field. In the previous section we have emphasized that many loudspeakers and loudspeaker systems employed in the field today are actually used mainly in their near field, that is, at distances where the system cannot be approximated by a single point source with a distance-independent directivity pattern. Because of their size these systems can hardly be measured as a whole in their far field. However, measurements at a near-field distance are only valid for use at that distance and not beyond, see Eq. 35-23.

Principally, there are two solutions to that. On the one hand, one can try to model the system as what it is, namely a spatially extended source. It could be characterized mathematically by an ideal straight or curved line source with some correction factors derived from measurements. On the other hand, already for the purposes of practical assembly, transport, and maintenance, almost all large-format loudspeakers are composed of individual elements. For example, a touring line array is built of multiple cabinets each of which in turn house multiple transducers. Thus it seems natural that the line array is described primarily by its components and its overall radiation characteristics are derived from that. In consequence, representing the significantly smaller elements individually as point sources, now the measurement and the simulation only have to happen in the far field of the respective element. Coherent superposition of the sound waves radiated by these elements will then yield the correct behavior of the entire system for both near and far field.

35.2.1.3.2 Acquisition and Interpolation of Complex Data

Data. The issue of using complex data instead of magnitude-only data is closely related to finding an accurate way to interpolate data points over angle and frequency properly for both magnitude and phase data. In return, using complex data on the level of individual elements eliminates the need for higher precision when measuring and interpolating data on the level of the loudspeaker system as a whole.

Critical Frequency.

First, let us review the error that we make when measuring a loudspeaker directivity balloon about a given point of rotation (POR). Problems usually arise from the fact that one or several sources are slightly off-set from the POR and thus the measured data suffers a systematic error. For a given setup, Fig. 35-28, we can estimate the relative error for the magnitude data 

\[
\Delta |\hat{A}| = 1 - \frac{x^2}{2d^2} + \frac{x}{d} \sin \vartheta
\]  

(35-31)

where,

- \(x\) is the distance between the POR and the concerned acoustic source,
- \(d\) is the measurement distance between the POR and the microphone (with \(d \gg x\)),
- \(\vartheta\) is the measurement angle between the microphone and the loudspeaker axis.

The error is maximal for measurements where the connecting line between microphone and POR passes through both POR and acoustic source, in this case, at an angle of \(\vartheta = 90^\circ\). Nevertheless, for all practical cases the error is largely negligible. For example, typical values of \(x = 0.1\) m and \(d = 4\) m yield an error of only 0.2 dB.

When describing loudspeakers by magnitude data only, the phase is neglected completely. To simulate the interaction between coherent sources, often the run-time phase calculated from the time of flight between POR and receiver is used. As stated earlier, this assumes that the inherent phase response of the system is negligible and that there is an approximate so-called acoustic center where the run-time phase vanishes and which must be used as the POR. For this measurement situation the systematic error in the phase data,

\[
\delta \Phi = \delta \arg \hat{A} \text{,can be calculated as well.}  
\]  

For large measuring distances \(d\), see Fig. 35-28, it is given by

\[
\delta \Phi = \frac{2\pi}{\lambda} x [\sin \vartheta]
\]  

(35-32)

for magnitude-only data (\(\arg \hat{A} \approx 0\))

where,

- \(\lambda\) denotes the wavelength.

In contrast, by acquiring phase data in addition to the magnitude data, this offset error can be minimized.
\[ \delta \Phi = \frac{2 \pi x^2}{\lambda 2d} (1 - \sin^2 \phi) \]  
(35-33)

for complex data \((\arg \Phi \neq 0)\)

Hence, by using phase data the error is reduced by an order of magnitude. In practice, it is most useful to define a maximum acceptable phase error, such as

\[ \delta \Phi_{\text{Crit}} = \frac{\pi}{4} \]

and use that to derive an upper (critical) frequency limit based on the measurement setup. Fig. 35-29 shows this critical frequency \(f_{\text{Crit}}\) as a function of the distance between POR and acoustic source.

We emphasize that the use of phase data does not only reduce the error in the directivity data but it also largely eliminates the need to define, find, and use the so-called acoustic center, the imaginary origin of the far-field spherical wave front.

**Local Phase Interpolation.** Once complex directivity data is available for a loudspeaker, the next step is to define an appropriate interpolation function for the discrete set of data points to image the continuous sound field of the source in the real-world \((f_{\text{Int}}(A) \rightarrow \vec{A})\). An algorithm will have to work for both magnitude and phase data in both domains, frequency and space. While averaging, smoothing, and interpolating magnitude data is usually a straightforward task, the same is not true for phase data. Due to the mathematical nature of phase, its data values are located on a circle. Accordingly, when phase is mapped to a linear scale the interpolation has to take wrapping into account. In this regard, a variety of methods have been proposed, such as use of group delay, unwrapped phase, or the so-called continuous phase representation. Although these methods have their advantages, it could be shown that generally none of them is appropriate for full-sphere radiation data of a real loudspeaker.39

Alternatively, a method named local phase interpolation can be applied successfully when some care is taken about the resolution of the underlying data. This method essentially interpolates phase on a local scale rather than globally. For example, let the phase average of two data points \(i\) and \(j\) be defined as

\[ \langle \Phi \rangle = \frac{1}{2} \Phi_i + \frac{1}{2} \Phi_j \]  
(35-34)

Then, it is assumed that the corresponding phase data points are all located within a certain range:

\[ |\Phi_i - \Phi_j| < \frac{\pi}{2} \]  
(35-35)

In this respect, \(i\) and \(j\) may represent two angular data points \(\theta_i\) and \(\theta_j\) or two frequencies \(f_i\) and \(f_j\). Also, the averaging or interpolation function may involve more than two points.

Note that in the above case we have assumed that for calculating the absolute difference the maximum possible difference is \(\pi\). This can always be accomplished by shifting the involved phase values by multiples of \(2\pi\) relative to each other.

From the condition above we can derive requirements directly for the measurement. Assuming that the phase response will be usually dominated by a run-time phase component due to one or several acoustic sources being located away from the POR, conditions for the spatial and spectral density of data points can be computed.39 With respect to frequency one obtains

\[ x_{\text{crit}} \approx \frac{c}{4\Delta f} \]  
(35-36)

where,

\(\Delta f\) denotes the frequency resolution,

\(c\) the speed of sound.

Given these parameters, \(x_{\text{crit}}\) is the maximal distance allowed between the POR and the acoustic source at the given frequency resolution. With regard to angle, one finds analogously

\[ x_{\text{crit}} \approx \frac{c}{4\sin(\Delta \theta)} \]  
(35-37)

where,
As an example, these limits correspond roughly to a measurement setup where the acoustic source is not farther away than ca. 0.15 m from the POR. Phase data points will be close enough up to a frequency of 8 kHz, if the frequency resolution is at least \( \frac{1}{12} \) octave (or 475 Hz) and the angular resolution is at least 5 degrees. Such conditions are well within what is possible with modern measurement platforms.

**Data Acquisition.** Although loudspeaker performance data and directivity patterns have been measured for several decades, no definitive standard has emerged from that practice. Also for some years now, the AES standards committees try to unify the variety of existing methods and concepts to reach some commonly accepted measuring recommendations.

The accurate measurement of loudspeaker polar data is one of the issues of the ongoing discussion. Especially the acquisition of complex frequency response data, which asks for significantly higher accuracy in the measurement setup, and better control of the environment than the measurement of magnitude-only data. To determine the exact phase response of the loudspeaker under test relative to the POR, it is inevitable to measure and compensate the measuring distance as well as the environmental conditions that influence the propagation of sound along that path. For example, to be exact within a quarter of a wavelength at 8 kHz, all distance measurements must be accurate within less than a centimeter of length. Although this is not a trivial task, professional acoustic laboratories have been built at the factories of manufacturers, at universities, and by independent service providers. As a result, today many loudspeaker systems are measured using measurement platforms that can provide high-resolution impulse response or complex frequency response data.

But it is important to note that gathering measurement data as described above only slightly increases the overall effort. To build a measurement setup capable of acquiring complex balloon data means a high initial effort, but with respect to automated polar measurements, the subsequent measuring durations are the same as for magnitude-only data. The measurement of the individual components of a loudspeaker cabinet or array is obviously connected with longer measurement times. However, in many cases the angular resolution for a transducer measurement may be lower than for the full multiway device because its directivity behavior is much smoother. In the same manner, the frequency resolution can be chosen adequately. Finally, the acquisition of phase data also means that the so-called acoustic center does not have to be determined in a time-consuming procedure. Mounting the loudspeaker for a measurement is therefore much simpler. The measurement of different transducers of the same loudspeaker does not require remounting the device anymore, as well. Additionally, as we will show below, loudspeaker designers and manufacturers gain direct benefits from advanced measurement data, such as directivity prediction, crossover design, and verification capabilities.

Figs. 35-30, 35-31, and 35-32 show some of the advantages gained by using complex data for individual components. Fig. 35-30 shows a comparison of measurement versus prediction for a stacked configuration of two two-way loudspeakers, arranged horn to horn (HF-HF). Its vertical directivity pattern at 1 kHz is displayed in Fig. 35-30, measured data (+ curve) and calculation based on complex data (solid curve) are in good agreement. Calculations with magnitude-only data (dashed curve), provide erroneous results. In this case, the port of the loudspeaker (FR) was chosen to be the POR. A similar discrepancy between measurement and prediction using magnitude-only data can be seen in the arrangement of woofer to woofer (LF-LF), Fig. 35-31. To illustrate the sampling problems described before, Fig. 35-32 shows the same configuration at 4 kHz. Here measurements (+ curve) can only be imaged properly by a computation at angular increments of 2.5°. The dashed curve is using individual components measured at 5°. Computations or measurements at a too coarse resolution of 5° (dashed curve) fail completely to describe the properties of the system when being interpolated.

Due to the complexity of establishing an accurate and phase-stable measurement setup, a set of alternative approaches is practiced. This includes, in particular, the modeling of the wave front radiated at the loudspeaker by elementary point sources according to the Huygens principle. Other models are based on the idea of deriving the missing phase response from the magnitude response, such as by the minimum phase assumption. Some of these implementations work quite well for a subset of applications, such as in the vertical domain or within some opening angle relative to the loudspeaker’s axis. But generally these ideal models lack the means to depict the sound radiating properties of the loudspeaker in those domains where it is not so well behaved and analytically treatable.

### 35.2.1.3.3 Configurable Loudspeakers

In the previous sections an overview about the crucial parts of modeling modern loudspeaker systems was given. In turn, the acquisition of complex directivity...
data for individual components creates the basis for another step toward resolving apparent problems on the software side. It allows including system configurability, both electronic and mechanical.

Filter settings of active and passive loudspeakers can now be taken into account in a straightforward way. We can describe the complex radiation function more precisely by including the electronic input $U(f)$ into
the system, the sensitivity of the transducer $\tilde{\eta}(f)$, and the filter configuration $\tilde{h}(f)$ of the system:

$$A(\varphi, \theta, f) = \tilde{\Gamma}(\varphi, \theta, f)\tilde{\eta}(f)\tilde{h}(f)\tilde{U}(f)$$  \hspace{1cm} (35-38)$$

where, $\Gamma(\varphi, \theta, f)$ denotes the angle- and frequency-dependent directivity ratio.

Correspondingly, the coherent pressure sum of several components of a system is expressed by:

$$p_{Sum}(\hat{r}, f) = \sum_n \frac{\tilde{\Gamma}_n(\varphi, \theta, f)\tilde{\eta}_n(f)\tilde{h}_n(f)\tilde{U}_n(f)}{|\hat{r} - \hat{r}_n|} \exp[-jk_n(\hat{r} - \hat{r}_n)]$$  \hspace{1cm} (35-39)$$

This formulation relates principally to Eq. 35-6 with the equalities of $E_k \sim |\tilde{\eta}_n(f)\tilde{h}_n(f)|$ and $P \sim |\tilde{U}_n(f)|^2$. The loudspeaker properties $\tilde{\Gamma}_n(\varphi, \theta, f)$ and $\tilde{\eta}_n(f)$ will normally be measured and the parameters $\tilde{h}_n(f)$ and $\tilde{U}_n(f)$ are defined by the manufacturer or end user. As a result, this concept allows one to model the full response of a multicomponent system under consideration of the given filter settings, may it be a multiway loudspeaker or a digitally steered column. Of course, the effect of changing crossover parameters on the directivity characteristics can be also calculated.\(^\text{41}\)

An example is shown in Fig. 35-33.

A second step can now be taken as well. The mechanical variability of touring line arrays or clusters can be considered by defining $\hat{r}_n$, either directly by its coordinates or indirectly as a function of user-defined parameters, such as the mounting height of the system and the splay angles between individual cabinets.

### 35.2.1.3.4 Shadowing and Ray Tracing

It has been pointed out earlier, that for a large-format loudspeaker system, the use of a single point as the origin for ray tracing- or particle-based methods is not adequate. On the other hand, it is not practical to use all individual acoustic sources as origins for the ray-tracing process, given available computing power and the geometrical accuracy of the model. But that is not necessary anyway, since the ray tracing algorithm can be run for subsets or groups of acoustic sources. Therefore representative points have to be found, so-called virtual center points, that can be used as particle sources, Fig. 35-34.

Typical lower-frequency limits for the particle model and the level of detail in common room models suggest ray tracing sources to be spaced apart by about 0.5 to 1 m. In many cases this corresponds to one ray tracing origin per loudspeaker cabinet. While this method of virtual center points is significantly more accurate than using a single source of rays for the whole array, it is still viable with respect to the required computational performance.

### 35.2.1.3.5 Additional Notes

Some other problems are also automatically resolved by modeling the components of a loudspeaker system separately. For example, the definition of maximum power handling capabilities becomes straightforward. Each component can be described individually by its maximum input level and possibly the frequency response of the test signal. In this respect also the focus of the pro-audio community increasingly shifts from sometimes obscure maximum power values, as defined by the loudspeaker manufacturer, toward the specification of maximum voltage as the entity that is directly measured and applied in modern constant voltage amplifiers.

Finally, one should be aware of the errors made in advanced modeling approaches like the GLL or DLL. It is clear that the acquisition of complex data requires more care and thus engineers will initially see signifi-
cant measuring errors, especially with respect to the repeatability of measurements. By refining the measurement setup, using latest measurement technology, and employing data averaging, as well as symmetry assumptions, the data acquisition can usually be improved by an order of magnitude. In addition, it must be emphasized that the variation between samples of the same loudspeaker model may be larger than the measuring error. However, this depends strongly on the manufacturer and its level of quality control.

From the point of view of the simulation software, the best-known practices should be assumed. There is not much sense in limiting the capabilities of an acoustic simulation package because of the quality of the most inexpensive loudspeaker boxes. Like for the geometrical and acoustic model of room, the “garbage in, garbage out” principle holds true for the sound system part of the room as well and the user must be aware of that.

### 35.2.2 Receiver Simulation

For a complete acoustic model, the acoustic receivers must also be considered. Most important for auralization purposes is to account for the characteristics of the human head and how it influences the sound that reaches the inner ear. Often, simulation software packages also allow utilizing microphone directivity data, in order to be able to image real-world measurement. However, it must be stated that in general the correct implementation of electroacoustic receivers has not nearly received the same level of attention as the sources.

**Figure 35-33.** Directivity optimization with the prediction software EASE SpeakerLab. Left column shows frequency response and vertical beamwidth of a two-way loudspeaker for initial crossover filter settings, right column shows optimized frequency response and vertical beamwidth. LF unit (--), HF unit (- -), full-range (·).
35.2.2.1 Simulation of the Human Head

Central to incorporating the characteristics of the human head into the simulation results and thus preparing them for final auralization purposes is the head-related transfer function. Typically, this is a data set that consists of two directivity balloons, one for the left ear and a second one for the right ear. Each describes, usually by means of complex data, how the human head and the outer part of the ear change the incoming sound waves as they arrive at the ear. It is critical for a satisfactory binaural auralization that the signal for each ear is weighted with an appropriate angle- and frequency-dependent directivity function.

The acquisition of measurement data for the human head is not a trivial matter. Since real human heads cannot be measured directly, a so-called dummy head has to be built or in-ear microphones have to be used, see Section 35.1.5.1 Human Ears. Each ear of a dummy or a real head is equipped with a microphone. Balloon measurements are made similar to loudspeaker balloon measurements, only that the locations of source and receiver are reversed and a stereo set of data files is obtained.27

Recent research has shown that the inclusion of the human torso into the HRTF also has significant effect on the quality of the binaural reproduction. Even more so, auralization results of highest quality can be obtained utilizing a head-tracking system and a set of HRTF balloons, where each pair of balloons describes the transfer function for the left and right ear for a particular angular position of the human head relative to the human body. This data can then be employed to auralize impulse responses of either a measured or simulated environment with speech and music contents.

35.2.2.2 Simulation of Microphones

The need for inclusion of microphones in acoustic simulation software has several reasons. On the one hand, to be able to compare measurements with computational results, the frequency response and the directivity characteristics of the microphone have to be taken into account. On the other hand, the possibility to simulate either recording or reinforcement of a talker or musician is of practical interest too. For example, by varying the location and orientation of the pick-up microphones the coverage can be optimized. Finally, by including microphones, it becomes possible to simulate the entire chain of sound reinforcement, from the source over the microphone to the loudspeaker and back to the microphone. Only this enables the prediction of feedback and to estimate the potential gain before feedback.

However, the acquisition and distribution of microphone data must still be considered in its infancy. Available data consists largely of octave-based magnitude-only data that assumes axial symmetry. Measurement techniques vary significantly among microphone manufacturers and measuring conditions, such as the measurement distance, are not standardized and often not even documented. Therefore most users of simulation programs do not consider implementing microphone data into their models, or if so, they use generic data based on ideal directional behavior, like cardioid or omnidirectional patterns.

There are several more issues that inhibit the widespread acquisition, acceptance, and use of microphone data.

- First, especially the measurement distance is important with respect to the acquisition of the data and its application in the software domain. A lot of microphones exhibit the so-called proximity effect, that is, the property that their frequency response and directivity function change depending on the shape of the incident wave front. This effect is most visible if the acoustic source is within a few meters, range of the microphone and thus the wave front cannot be considered as plane anymore.
- Secondly, we described earlier with respect to loudspeaker data, that it is important to preserve configurability also in the software domain. In this regard, switchable multipattern microphones have to be
taken into account when developing a fully descriptive data model.

- The use of combined microphones is also widespread. In particular, multichannel receivers, such as dummy heads, coincidence recording microphones, or B-format receivers, need to find an appropriate representation in the simulation software.

- Another issue of concern is the acquisition of phase data. The impact of neglecting the phase of the loudspeaker on the simulation of its performance is well known. But not much research has happened in that respect regarding microphones. Nevertheless, it is clear that under special circumstances like in feedback situations or for the electronic combination of microphone signals (e.g., two active microphones on lecterns) phase plays an important role.

- Finally, of course, it must be stated that the usability of microphone data has its limitations depending on the application of the particular model. Compared to installation microphones typical handheld microphones have different properties. The data that is needed and that can be acquired may differ accordingly.

Recently an advanced data model was proposed that is able to resolve many of the issues listed above.43 Basically, it suggests using a similar approach like the loudspeaker description language (GLL) introduced earlier, namely to describe receiver systems in a generalized, object-oriented way. This means especially that:

- Microphone data files should at least include far-field data (plane wave assumption), but can also contain proximity data for various near-field distances.
- A microphone model can consist of multiple receivers, that is, acoustic inputs, and can have multiple channels (electronic outputs).
- A switchable microphone should be represented by a set of corresponding data subsets.
- Impulse response or complex frequency response data should be utilized to describe the sensitivity and the directional properties of the microphone as appropriate.

Fig. 35-35 is an example for an import function in the new EASE Microphone Database software.

**Figure 35-35. Import routine in EASE Microphone Database Software.**

A computer simulation must come close to reality (errors generally equal or less than 30%). Then it becomes possible that the acoustic behavior of a facility can be made audible by so-called auralization. (One will listen to sound events just performed by means of the computer.) The following will give a short introduction of the possibilities of computer simulation today.

### 35.3 Tools of Simulation

#### 35.3.1 Room Acoustic Simulation

**35.3.1.1 Statistical Approach**

Based on simple room data and the associated surface absorption coefficients, a computer program is able to calculate the reverberation time according the Sabine and Norris-Eyring equations, see Section 7.2.1.1. On the other side measured values must be usable directly in such a program. Calculation of the early decay time (EDT) should be possible too.

A comprehensive database of country-specific and international wall materials and their absorption coefficients is part of the program. This database should be accessible to allow the user to import and enter data from other textbook sources or measurements. Because most of the needed scattering coefficients are not available in textbooks a computer program should allow deriving values even by rules of thumb.

A set of frequency-dependent target reverberation times should be available for entering into the simulation program so that the room models, calculated (or real-world measured) $RT_{60}$ times can be compared with the target values. The program should then indicate (for each selected frequency band) the calculated (or measured) Fig. 35-35 time versus the target $RT_{60}$ time and list the number of excess or deficient $RT_{60}$ times for
each band relative to the target values within a range of tolerance, Fig. 35-36.

![Image of RT60 chart with tolerance range.](Figure 35-36. RT60 chart with tolerance range.)

The graph of RT60 times should allow plotting multiple RT60 values within a single graph, so as to show the impact of various audience sizes, proposed and/or alternative room treatments, etc., on the RT60 time. An option must allow plotting a grayed or dashed area as the desirable range of reverberation times for a particular project, against which the measured or calculated RT60 values can be referenced.

### 35.3.2 Ray Tracing or Image Modeling Approach

#### 35.3.2.1 Preliminary Remark

There are several ways to calculate the impulse response of a radiated sound event. The widest-known method is the image-source algorithm. Worth mentioning at this point are also the ray-trace method, which was first known in optics, and other special procedures like cone tracing or pyramid tracing. Nowadays these procedures are more often than not used in a combined form as so-called hybrid procedures.

#### 35.3.2.2 Image Modeling

With image modeling there is a source and a receiving point selected. Then a deterministic search of all image sound sources of different orders is started to compute the impulse response, Fig. 35-37.

![Image of ray calculation with image model algorithm.](Figure 35-37. Ray calculation with image model algorithm.)

In the image modeling method a receiving point is used instead of a counting balloon (in contrast to classical ray tracing). Frequency response and interference effects (including phase investigations) are also easily calculated.

This method is very time consuming and the calculation time is proportional to $N^i$ with: $N =$ number of model walls and $i =$ the order of wall bounces.

---

35.3.1.2 Objective Room-Acoustic Measures

The simplest way to obtain objective measures is to use the direct sound of one or more sources and calculate the reverberation level of the room by means of the reverberation time equations assuming the room follows a statistically even distributed sound decay (homogeneous, isotropic diffuse sound field, that is, the RT60 is constant over the room). From these calculations it is possible to derive the direct sound and the diffuse-sound levels and consequently a range of objective acoustic parameters, see Section 7.1. It goes without saying that this requires the acoustical conditions of the room to show a statistically regular behavior (frequency response of the reverberation time that is independent of the location considered in the room). In practice, however, such behavior will hardly be found. For this reason one tends to qualify such data as having only a preliminary guideline character and to have it confirmed by additional detailed investigations.
So one gets usable results for models with \( N < 50 \) and \( i < +6 \). For larger models and more complicated investigations the next method is more advantageous.

35.3.2.3 Ray Tracing

In contrast to image modeling, here the path of a single sound particle radiated under a random angle into the room along a ray is followed. All surfaces are checked to find the reflection points (with or without absorption or diffusion). The tracing of the single ray is terminated when the remaining sound energy has decreased to a certain level or when the particle hits an appropriately arranged counting balloon with a finite diameter, typically at the location of a listener in the room, Fig. 35-38.

Because of these cones, fast ray calculations can proceed. The fact that the cones do not cover the source “sphere” surface completely turns out to be a disadvantage. It is necessary to overlap adjacent cones and an algorithm is required to avoid multiple detections or to “weight” the energy so that the multiple contributions produce (on average) the correct sound level. Some famous conical beam tracers are known, implementing different techniques to correct this point.44,45,46

35.3.2.5 Pyramid Tracing

This method was introduced by Farina in the program “Ramsete” in 1995.47 Farina demonstrated that the pyramid beams do not suffer from the cone-trace overlap, as adjacent pyramids cover perfectly the source sphere, Fig. 35-40.

Originally a subdivision of the surface in triangles was made by subsequent subdivisions of the 8 octants of the sphere: according to Farina “this way the number
of pyramids generated can be any power of 2, and all of them have almost the same base area, giving a nearly isotropic sound source."

35.3.2.6 Room-Acoustic Analysis Module-(AURA)

To illustrate these methods, as an example the new hybrid ray-tracing algorithm AURA will be explained in more detail in the following.

Based on CAESAR, the AURA algorithm calculates the transfer function of a room for a given receiver point using the active sound sources. For this purpose a hybrid model is employed that uses an exact image source model for early specular reflections and an energy-based ray-tracing model for late and scattered reflections. The transition between the two models is determined by a fixed reflection order.

The ray-tracing model utilizes a probabilistic particle approach and can therefore be understood as a Monte-Carlo model. At first, the sound source emits a particle in a randomly selected direction with a given energy. The particle is then traced through the room until it either hits a boundary or a receiver or its time of flight reaches the user-defined cut-off time. When the particle hits a boundary it is attenuated according to the surface material and its direction is adjusted according to the reflection law. An essential assumption of this Monte-Carlo approach is that attenuation due to air or surface reflections is taken into account as a reduction of particle energy, while the propagation loss over distance is indirectly covered by the reduced detection probability for individual particles with increasing distance and fixed receiver sizes.

Per receiver and simulated frequency, a so-called echogram is created that contains energy bins linearly spaced in time. When a receiver is hit, the energy of the detected particle is added to the bin that corresponds to the time of flight. Also, as a separate step, the contributions from the image source model are included. The particle model accounts for scattering in a probabilistic way. Whenever a particle hits a surface, the material absorption part is subtracted from its energy. Then, a random number is generated and depending on the scattering factor, the particle is either reflected geometrically or it is scattered under a random angle based on a Lambert distribution. After that the particle is traced until it hits a receiver or a wall again.

For room acoustic models brute-force ray tracing, that is, testing all model walls or wall triangles for intersection, is often impractical since computation time scales linearly with the number of triangles. Improved performance is obtained by structuring triangle data such that each ray is tested for intersection only with a subset of triangles. Current methods are based on two main strategies: hierarchical bounding volumes (HBV) and space partitioning. In the former case, a hierarchy of simple bounding volumes (such as spheres) is constructed, where a particular volume may include either a number of smaller child-volumes or actual triangles. A ray is tested for intersection starting at the top of the hierarchy, such that a particular child-volume is only tested if the parent was hit. The cost of ray-bounding volume intersection is small, and the resulting computation scaling with the number of triangles is approximately logarithmic. In space partitioning schemes, the physical space where the triangles reside is partitioned into smaller cells or so-called voxels. Rays are followed through adjacent voxels and tested only against triangles pertaining to those voxels. The partitioning may be uniform or more complex—e.g., hierarchical, adaptive, etc.

Previous studies indicate that no particular ray-tracing acceleration structure is obviously the most efficient, since the total computation cost depends both on algorithm and hardware implementation. Whereas highly refined hierarchical acceleration schemes may require less intersection tests, the associated data structures are nonuniform (i.e., hard to parallelize), involve traversal of nonlocal data structures, and as such are less suitable for cache and vector processing optimizations as available on modern processors and graphics cards. On the other hand, space partitioning methods, in particular those involving simple data structures like uniform grids, are more suitable to efficient implementation on vector processing elements.

In AURA a uniform grid ray-tracing algorithm is implemented similar to Amanatides and Woo. A 3D uniform grid is assigned to the simulation box and each triangle is associated with every cell having a common interior point with it. The grid spacing in every direction is determined automatically via an empirical formula: the number of cells on each axis is proportional to the square root of the total number of triangles, and to the box length along the axis divided by the average box dimension (since in general the triangles form approximately a 2D shell, such a formula matches the average cell dimension to the average triangle dimension). Up to sixty four cells per axis are allowed, in order to limit memory requirements. Given a ray specified by an origin and direction vector, a fast grid traversal algorithm computes the next grid cell intersected by the ray. Each triangle associated with this grid cell is then tested for intersection with the ray. No particular optimization is done to avoid duplicate ray-triangle tests when one
triangle spans multiple voxels. Thus a ray-triangle intersection is only considered if it occurs within the boundaries of the current cell. The grid traversal continues until a hit point is found or the ray exits the simulation box.

The software implementation in AURA was carefully designed to facilitate vector optimization on SIMD-capable processors—i.e., to minimize branching and optimize instruction scheduling—in particular it is easily transferable to programmable graphics processing units. Using the Intel C++ optimizing compiler on a Pentium4 processor, the grid algorithm applied to realistic test cases with more than 10,000 triangles can be up to five times faster than a typical HBV method and, of course, orders of magnitude faster than the linear search method.54

35.3.2.7 Features of All These Methods

All of the ray-tracing or image modeling methods that calculate impulse responses have to take into account the directivity of the sound sources and the absorptive and scattering characteristics of the surfaces encountered en route from the source to the receiving point.

The design program must allow the user to designate specific surfaces/planes as being reflective or non-reflective. This will make it possible to simulate not only sound-reflecting walls, but also simplified floor planes—i.e., which in reality are complex shapes such as seating areas or orchestra stages or pits. At present these methods use statistical absorption factors that are readily available instead of angle-dependent ones (for the latter no sources are available in textbooks), as well as some diffusion factors estimated by rule of thumb and/or specially measured diffusion factors. The diffraction behavior is still in the academic stage and some program approaches are using FEM or BEM methods26,35, see Section 35.1.4.2. and Fig. 7-46. Additionally the dissipation of sound energy in air—i.e., the frequency-dependent air attenuation—must be considered too.

A library of potential natural sound sources must be available, such as the human voice and various orchestral instruments/sections to go along with the electroacoustic sources/loudspeakers that should include the sound power level and directivity of these sources/loudspeakers. As a result of all these calculations you get impulse responses or energy-time curves as shown in the following figures.

The program CATT-Acoustic36 shows the complete echogram with all input data (room, loudspeaker, listener position, frequency) and presents all resulting room acoustic measures this way, Fig. 35-41. With EASE and AURA it looks different, Fig. 35-42.

The calculated energy-time curve should be able to be stepped through reflection by reflection, with the appropriate rays and surfaces being highlighted to indicate the ray’s path and the surfaces it encounters en route from source to receiver, Fig. 35.43. The software should indicate median/lateral/horizontal positioning of energy arrivals (and relative magnitude as well) at the receiver’s location, Fig. 35-44.

Additionally, a simulation program should provide the capability to calculate early/late energy ratios. It is important to be able to set the early/late transition time and also to select the cutoff time for the late energy integral, Fig. 35-45.

The software’s ray-tracing or image modeling method of deriving an energy-time curve should provide the ability to indicate interaural cross-correlation (IACC) as well as lateral energy coefficient predictions at specified listener positions.

35.3.3 Auralization

The simulation program must have the ability to transfer the calculated impulse response curve to a postprocessing routine that will be used to auralize the room time/energy data with anechoic music or speech source material. Of course the routine must generate a binaural data file in WAV-format or other computer sound file format in common use, Fig. 35-46.

35.3.4 Sound Design

35.3.4.1 Aiming 

Aiming the individual loudspeakers is an important operation insuring the proper spatial arrangement and orientation of the sound reinforcement systems. Once the corresponding room or open-air model is at hand and the mechanical and acoustical data of the loudspeaker systems is exactly known, these systems are approximately positioned and then one may begin with the fine tuning of the same. A modern simulation program uses a kind of isobeam/isobar method to initially aim the loudspeakers, preferably utilizing the –3 dB, –6 dB or –9 dB contours.

Fig. 35-47 shows various types of projection of the –3, –6, and –9 dB curves into the room. On audience areas one can then also see superposed aiming curves for multiple loudspeakers, Fig. 35.48.
Figure 35-41. Echo and data plot in CATT acoustics.

35.3.4.2 SPL Calculations

After the loudspeakers have been correctly aimed, one may begin to calculate the sound-level conditions attainable by these. The first results are given for the direct sound pressure level (SPL). As long as we predict a good direct sound coverage over the listener area we have also to expect perfect intelligibility numbers, of course under the condition that the reverberation level is not too high.

A complex summation—phase conditions including travel-time differences should be included—has to be used as the standard method of calculating the direct SPL. This method is exact for a planar wave, but only an approximation for the superposition of waves with different propagation directions. But the complex sound pressure components of different coherent sources must first be added and afterward squared to obtain SPL numbers. In so-called DLL or GLL approaches one always calculates the complex sum of all sources in the array.

Today simulation programs are usually still only analyzing programs, capable of calculating which levels can be obtained by which loudspeakers and under which acoustical conditions. But questions are more and more asked the other way around. The program of the future also should query the user for a desired average SPL of the system, and automatically adjust the power provided to each loudspeaker—with a warning when the power required exceeds the capabilities for the loudspeaker, based on the desired SPL of the design, the sensitivity and directivity of the loudspeaker, the distance of throw, and the number of loudspeakers. This presupposes, of course, new algorithms that in most of the simulation programs are just being developed.
In Fig. 35-49 the level-time-frequency-behavior of a loudspeaker cluster at a chosen listener seat in a room is shown by a simulated waterfall diagram.

The target of all the efforts is to cover the whole audience area(s) evenly with musically pleasing and intelligible sound, while providing sound pressure levels suitable for the intended purpose.

**Figure 35-46.** Auralization.

**Figure 35-47.** 3D aiming presentations in simulation programs.
35.3.4.3 Time Arrivals, Alignment

A graph of time arrivals (direct, direct + reflected, reflected only) should allow the user to show the first energy arrival as required by the design, to adjust a signal delay loudspeaker to bring the loudspeakers into synchronicity, and to realize an acoustic localization of an amplified source—via distance and the HAAS effect, see Figs. 35-50A and B.

Matters are often complicated by special requirements such as localization, stereo imaging, etc. Simulation programs allow determining the first wave front as well as calculating initial time delay gaps or echo detections (c.f. in this respect Figs. 35-51A to C).

Predicted array lobing patterns of arrayable loudspeakers should be displayed by simulation programs, with the ability to provide signal delay and/or move the appropriate loudspeakers to attempt to bring the array into acoustic alignment. A program today will have the ability to provide signal delay to the individual loudspeakers to align them in time. The corresponding sound pressure calculations will take into account either measured phase data for the individual loudspeakers or the run-time phase if phase differences among the components can be neglected.56

Fig. 35-52A and B shows the frequency response of nonaligned and aligned loudspeaker groups, simulated by EASE/ULYSSES.

35.3.4.4 Mapping, Single-Point Investigations

Once the aiming, power setting, and alignments are completed, the program should provide a colored visual coverage map of the predicted sound system performance. This coverage map must take into account the properties of the loudspeakers as well as the impact of reflecting or shadowing planes, and provide the following displays at a minimum:
Predicted sound pressure level, viewed at octave or \( \frac{1}{3} \) octave band frequencies, and at an average of these frequencies, Figs. 35-53A to C.

Predicted intelligibility values (in the 2 kHz octave band, or the weighted average of 500 Hz to 4 kHz octave band data), listed in STI or RASTI values, Figs. 35-54A and B.

Predicted acoustic measures (for octave or \( \frac{1}{3} \) octave band frequencies), listed in C80, C50, \%Alcons, center time, strength, or other values according to ISO Standard 3382 (compare Fig. 35-55A and B).

### 35.4 Verification of the Simulation Results

After the simulation, the practical design, and the installation, it is important to check the results and to compare them with the prediction. For this purpose tools we developed during the last 20 years:

- The most famous TEF 10, 12, and 20 by Crown (later Gold Line).
- MLSSA by DRA Laboratories.
- SMAART by SIA Soft.
- WinMLS by Morset Sound Development.
- DIRAC by Brüel & Kjær.
- SpectraLAB by Sound Technology Inc.
- EASERA by AFMG Berlin.
- EASERA SysTune by AFMG Berlin.

All measurements with predefined excitation signals generally utilize two or more ports. The input port of the system under test (DUT) is fed with an excitation signal, generated by the analyzer. Fig. 35-56 shows the block-diagram for a modern software-based four-port measurement tool including the needed AD/DA converter.
At first the unprocessed output of the DUT (raw data) is recorded and stored on the PC hard disk. Based on this original data set, the corresponding processing algorithm including band pass filters or time windows can be used multiple times with different parameters to look at the parts of interest.

A simple way to calculate the transfer function $H(\omega)$ from the recorded raw data is to divide the measured frequency response $Y(\omega)$ by the frequency response of the signal $X(\omega)$ (or by a reference response that was previously measured). The impulse response $h(t)$ can then be computed using the inverse Fourier Transform.

Until now it is common to utilize a static measuring procedure where the impulse response is derived in a separate step after every acoustic measurement. In contrast, a newly developed, dynamic method allows one to measure room acoustic impulse responses (RIR) in an efficient manner and to analyze this way the acoustic properties of an investigated acoustics space very user friendly—i.e., in real time,\textsuperscript{57} see Fig. 35-57.

Determining the impulse response in real time means in this respect that gathering the acoustic source signals and calculating the impulse response data are a simultaneous and continuous process.

The dynamically derived RIR is because of a number of optimized postprocessing steps qualitatively absolutely equivalent to a statically derived RIR and may have typical lengths of 4–10 s.

The transformation between the frequency and time range is linear and of full length, analogous to the static procedure. Averaging can be likewise used to suppress the noise.
The real-time ability of the measuring system is based on very high refresh rates for the calculation of results and their display and analysis—approximately 10/s. One can understand such a measuring system also as an “oscilloscope for room impulse responses.” Possible changes of the acoustic behavior may be seen immediately and directly.

In Fig. 35-57, the excitation is done with noise, sweep, or MLS. In live situations this will be quite often annoying and cannot be done under all circumstances. So the next step is to use running music or speech signals as excitation signals and to derive impulse responses. Fig. 35-58 shows a block diagram for such a tool usable with natural signals like music or speech and in Fig. 35-59 the graphic user interface of EASERA SysTune is shown, a tool that allows such a kind of measurements.

Once the IR has been computed in either a dynamic or static manner, electroacoustic and room-acoustic measures can be derived from it, such as the RT₆₀, D/R ratio, C₅₀, or STI. These values can then be compared with the modeling results.
When performing such a comparison, it is always necessary to estimate the errors on each side, measurement and simulation, quantitatively in order to determine the significance of the deviations. The agreement between the results will depend on the degree to which measurement and model can provide reliable results.

36.1 Introduction

The fundamental purpose of a paging, announcement, voice alarm, or speech reinforcement system is to deliver intelligible speech to the listener. A surprising number of systems, however, fail to achieve this basic goal. There can be many reasons for this, ranging from inadequate signal-to-noise ratio to poor room acoustics or inappropriate choice or location of the loudspeaker. It is the job of the sound system designer to be aware of these factors and take them into account when designing a sound system and selecting devices to provide the degree of intelligibility required. In order to do this, however, an understanding of the basic factors that affect speech intelligibility and the way we hear speech is required. This chapter therefore begins by taking a look at the nature of the speech signal and how we hear it before discussing design strategies and ways of optimizing system design and performance. Current methods of assessing and measuring intelligibility are then also discussed together with comments on their practical limitations.

36.2 Parameters Affecting Speech Intelligibility

Although sound quality and speech intelligibility are inextricably linked, they are not the same thing. For example it is quite possible to have a poor sounding system that is highly intelligible (e.g., the frequency response limited and resonant re-entrant horn) or alternatively a high-quality system that is virtually unintelligible (e.g., a hi-fi loudspeaker in an aircraft hangar). Similarly a common mistake, often made when discussing intelligibility, is to confuse audibility with clarity. Just because a sound is audible does not mean to say that it is intelligible. Audibility relates to the ability of a listener to physically be able to hear a sound, whereas clarity describes the ability to detect the structure of the sound. In the case of speech, this means hearing the consonants and vowels correctly in order to identify the words and sentence structure and so give the speech sounds intelligible meaning.

36.3 The Nature of Speech

A speech signal involves the dimensions of sound pressure, time, and frequency. Fig. 36-1 shows some typical speech waveforms representing the numbers “one,” “two,” and “three.” The waveforms are highly complex, with amplitudes and frequency contents that change almost millisecond by millisecond. Consonant sounds typically have durations of around 65 ms and vowels 100 ms. The duration of syllables is typically 300–400 ms whereas complete words are about 600–900 ms in length dependent on their complexity and rate of speech. When speech is transmitted into a reverberant space, local reflections and the general reverberation distort the speech waveform by smearing it in time. The reverberant tail of one syllable or word can overhang the start of the next and so mask it, thereby reducing the potential clarity and intelligibility, Fig. 36-2. Equally if the background noise level is high or more accurately if the speech signal-to-noise ratio is too low, then again parts of words or syllables become lost and intelligibility deteriorates, Fig. 36-3. There are many other factors that can affect the potential intelligibility and perceived clarity of a speech signal, the most important are summarized below.

![Figure 36-1](image1.png)

**Figure 36-1.** Anechoic speech waveforms for the numbers “one,” “two,” and “three.”

![Figure 36-2](image2.png)

**Figure 36-2.** Speech waveforms (as Fig. 36-1) but with reverberation (RT$_{60}$ = 2.4 s). The way one word runs into the next can clearly be seen, but with concentration the individual words can still be understood.
36.4 Factors Affecting Sound System Intelligibility

36.4.1 Primary Factors Include

- Sound system bandwidth and frequency response.
- Loudness and signal-to-noise ratio.
- Room reverberation time (RT60).
- Volume and size and shape of the space.
- Distance from the listener to a loudspeaker.
- Directivity of the loudspeaker.
- The number of loudspeakers operating within the space.
- The direct to reverberant ratio** (this is directly dependent upon the previous 5 factors).
  * Talker annunciation/rate of delivery.
  * Listener acuity.

** Strictly speaking a more complex characteristic than the simple D/R ratio should be used. Better correlation with perceived intelligibility is obtained by using the ratio of the direct sound and early reflected energy to late reflected sound energy and reverberation. This may be termed C50 or C35 depending upon the split time used to delineate between the useful and deleterious sound arrivals.

36.4.2 Secondary Factors Include

- System distortion (e.g., harmonic or intermodulation).
- System equalization.
- Uniformity of coverage.
- Presence of very early reflections (<1–2 ms).
- Sound focusing or presence of late or isolated higher-level reflections (>70 ms).
- Direction of sound arriving at the listener.
- Direction of any interfering noise.
  * Gender of talker.
  * Vocabulary and context of speech information.
  * Talker microphone technique.

The bulleted parameters marked with a bullet (•) are building or system related, while those marked with an asterik (*) relate to human factors outside the direct control of the system itself.

How each of the above factors affects the potential intelligibility of a sound system is discussed below together with ways that a system designer can minimize the deleterious effects and optimize the desirable characteristics.

36.5 System Frequency Response and Bandwidth

Speech covers the frequency range from approximately 100 Hz–8 kHz, although there are also higher harmonics affecting the overall sound quality and timbre extending up to 12 kHz and above. Fig. 36-4 shows an averaged speech spectrum with the relative frequency contributions in octave bands. Maximum speech energy occurs over the approximate range 200–600 Hz—i.e., in the 250 Hz and 500 Hz octave bands, and falls off rapidly at about 6 dB per octave at higher frequencies as can be seen in Fig. 36-4.

![Figure 36-4. Average speech spectrum (octave band resolution).](image-url)
three bands therefore provide over 75% of the available spectral intelligibility content.

Whereas the range 300–3000 Hz has been shown to be adequate for telephone intelligibility, a wider range is generally required for sound system use—particularly under more difficult acoustic conditions. This effect is shown in Fig. 36-6. This contrasts the results of telephone (monophonic listening) with some recent research carried out by the author in a reverberant space (RT₆₀ = 1.5 s). The upper curve after Fletcher (1929) shows that the contribution to intelligibility hardly increases beyond 4 kHz, while the lower curve, made on a system in a real space (binaurally) shows improvements occurring up to 10 kHz. The need for an extended bandwidth can therefore immediately be seen. Limited bandwidth should not be a problem with modern sound system equipment and loudspeakers. However, there are some notable exceptions. These include:

1. Inexpensive poor-quality microphones.
2. Some re-entrant horn loudspeakers (or CD horn drivers used without equalization).

Many potentially adequate sound systems are often let down by employing a cheap or restricted bandwidth microphone at the front end of the system. In the author’s experience, even on a basic paging system employing restricted bandwidth loudspeakers—e.g., re-entrant horns—the difference between a microphone with a reasonably wide and well-controlled frequency response can always be readily identified over one with a restricted response, even if it exceeds the response of the loudspeakers themselves. Rubbish in equals rubbish out is certainly the case here. However, when operating under high-background noise conditions, a compromise may need to be reached between optimal frequency response and optimal noise rejection, as the two parameters are often divergent.

Apart from component equalization (or the lack of it) by far the most common problems associated with system frequency response stem from either loudspeaker/boundary-room effects or interactions between closely spaced (multiple) loudspeakers. Fig. 36-7 shows the effect of positioning a high-quality monitor loudspeaker with an impeccably flat response close to a boundary wall. As can be seen the response is now far from flat!

Equalization alone cannot correct for this problem. Reduction of the peaks is possible but the notches in the response cannot be equalized out as they are caused by complex phase interactions that cannot be corrected by means of frequency filtering. Interaction between loudspeakers is a common problem in cluster design, where the radiated wave fronts can suffer from missynchronization due to different acoustic path lengths occurring—e.g., due to differences between acoustic centers. Fig. 36-8 shows a typical interaction problem (after Davis and Davis).
Here the frequency response of two horn loudspeakers is shown. In the upper curve, the sound arrivals are synchronized and hence add constructively. However, in the lower curve, the horns are missynchronized by just 300 μs. A series of sharp comb filters occur. Not only is useful speech information lost in the extensive series of nulls but also the polar radiation pattern is often undesirably affected as shown in Fig. 36-9. The resultant lobes may not only result in certain frequencies not being transmitted to the listeners, but lobes may also be created that can cause undesirable reflections to occur. These may cause either additional unwanted excitation of the reverberant field or cause the generation of late reflections (echoes) that may damage intelligibility.

Fig. 36-10 shows the corresponding ETC reflection sequence for the horns in a reverberant space in and out of synchronization. Note the increased excitation of the reverberant field when out of synchronization.

The lobes caused my missynchronization, apart from potentially reducing intelligibility, may also reduce system feedback margin, either by directly radiating sound back to a live microphone or by causing a strong early reflection to occur back into the microphone.

36.6 Loudness and Signal-to-Noise Ratio

The sound level produced by a sound system must be adequate for the intended listeners to be able to hear it comfortably. If the level is too low, many people, partic-
Designing for Speech Intelligibility

ularly the elderly or those suffering even a mild hearing loss, may miss certain words or strain to hear, even under quiet conditions. Although normal face to face conversation may take place at around 60 dBA, regularly listeners demand higher sound pressure levels from sound systems, with 70–75 dBA being typical for conference systems even when under quiet listening conditions.

In noisy situations, it is essential that a good SNR is achieved. Various rules of thumb have been developed over the years. As a general minimum, 6 dBA is required and at least 10 dBA should be aimed for. Above 15 dBA there is still some improvement to be had, but the law of diminishing returns sets in for most practical systems.

There is some disagreement among the generally accepted reference data. Fig. 36-11, for example, shows the general relationship between SNR and intelligibility. As the curve shows, this is an essentially linear relationship. In practice, the improvement curve flattens out at high signal-to-noise ratios—though this is highly dependent on the test conditions. This fact is shown in Fig. 36-12, which compares the results of a number of studies, using different test conditions and signals.

The curve, for example, shows that for more difficult listening tasks, the greater the SNR has to be in order to achieve good intelligibility. Fig. 36-13 shows the effect of SNR on the %Alcons intelligibility scale. Here, the improvement can be seen to clearly flatten out above 25 dB SNR. Under high noise conditions, such a SNR could demand excessively high SPLs and caution must be exercised.

Where noise is a particular problem, a full spectral analysis should be carried out. Ideally this should be in terms of 1/3 octaves but for many applications 1/2 octave band analysis will be adequate and certainly more informative than a single dBA value. Fig. 36-14 shows such an analysis.

In the upper curve, which depicts a positive SNR, it can be seen that the speech signal is greater than the noise over each of the octave band frequencies. However, in the lower curve, it can be seen that at high frequencies the noise exceeds the desired speech signal. The overall effect on potential intelligibility can be calculated by looking at the individual octave band SNRs and then weighting and summing them in accordance to their relative contributions as shown earlier in Fig. 36-5.

This is the basis of the Articulation Index (AI), which is a good measure for determining the effects of noise on speech—either over single channel transmission lines such as telephone or radio communications or over PA
systems in low but noisy spaces. The AI method is not able to take account of room reverberation or reflections.

In many situations, the background noise may not be steady but vary over time. This is particularly the case in many industrial complexes or transportation concourses. Spectator sports also can exhibit highly variable crowd noise levels dependent on the action at any given time. Fig. 36-15 shows a typical noise profile for an underground train station. Peaks of 90 dBA plus were recorded as the trains moved in and out of the platforms. A PA system would therefore need to generate at least 96–100 dBA in order to achieve an appropriate SNR at these times.

Noise sensing and automatic level control are essential under such conditions, otherwise during the relatively quiet periods when ambient levels drop down to around only 66 dBA, significant startle may be caused by such high-level announcements. (A better solution is to store announcements and wait for the regularly occurring quieter periods rather than trying to compete with the background noise all the time.)

Spectator sports can also create wildly fluctuating noise levels. Again if possible, announcements should be made during the quieter periods, the levels of which can be best determined by a statistical analysis of the crowd behavior at the particular venue in question. Fig. 36-16 shows part of the time history for a soccer match. Note that peak values in excess of 110 dBA can occur.
It must not be forgotten that any noise occurring at the microphone itself will reduce the perceived SNR—indeed this is directly additive to the SNR at the listener’s position. At least 20 dBA should be aimed for and preferably >25 dBA. A number of techniques can be employed to achieve this, including:

- Close talking/noise canceling microphones.
- Use of highly directional microphones (e.g., gun microphones or adaptive arrays).
- Providing a noise hood or preferably by locating the microphone in a suitable quiet room or enclosure.
- Digital, noise canceling and processing can also be used in extreme conditions to improve the SNR.

36.7 Reverberation Time and Direct-to-Reverberant Ratios

Just as noise can mask speech signals so too can excessive reverberation. However, unlike the simpler case of SNR, the way in which the direct-to-reverberant (D/R) ratio affects speech intelligibility is not constant but depends on the room reverberation time, the level of the reverberant sound field and on the nature of the speech itself.

The effect is illustrated in Fig. 36-17A–C. The upper trace is the speech waveform of the word back. The word starts suddenly with the relatively loud “ba” sound. This is followed some 300 ms later by the consonant “ck” sound. Typically the “ck” sound will be 20 dB – 25 dB lower in amplitude than the “ba” sound.

With short reverberation times—e.g., 0.6 s—the “ba” sound has time to die away before the start of the “ck” sound. Assuming a 300 ms gap, the “ba” will have decayed by around 30 dB and will not mask the later “ck.” However, if the reverberation time increases to 1 s and if the reverberant level in the room is sufficiently

![Figure 36-15. Noise-time history profile of underground trains entering and leaving station.](image)

![Figure 36-16. Noise-time history analysis of soccer game crowd noise—note short-term variability and peak of 111 dB as compared to average of 82 dB.](image)

![Figure 36-17. Waveform of the word back](image)
high (i.e., a low \( Q \) device is used), then the “ba” sound will have only decayed by approximately 18 dB and will completely mask the “ck” sound by 8 dB to 13 dB. It will therefore not be possible to understand the word back or distinguish it from similar words such as bat, bad, bath, or bass since the all important consonant region will be lost. However, when used in the context of a sentence or phrase, the word may well be worked out by the listener from the context. Further increasing the reverberation time (or reverberant level) will further increase the degree of masking.

Not all reverberation, however, should necessarily be considered to be a bad thing, a degree of reverberation is essential to aid speech transmission and to aid the talker by returning some of the sound energy back to him or her. This enables subconscious self-monitoring of their speech signal to occur and so feed back information about the room and projected level. The room reverberation and early reflections will not only increase the perceived loudness of the speech, thereby acting to reduce the vocal effort and potential fatigue for the talker, but also provide a more subjectively acceptable atmosphere for the listeners. (No one would want to live in an anechoic chamber.) However, as we have seen the balance between too much or not enough reverberation is a relatively fine one.

The sound field in a large space can be highly complex. Statistically, it can be divided into two basic components, the direct field and the reverberant field. However, from the point of view of subjective impression and speech intelligibility the sound field needs to be further subdivided to produce four distinct components. These are:

1. Direct Sound—that directly from source to listener.
2. Early Reflections—arriving at the listener approximately 35–50 ms.
3. Late Reflections—arriving at the listener approximately 50–100 ms later (though discrete reflections can also be later than this).
4. Reverberation—high density of reflections arriving after approximately 100 ms.

Fig. 36-18 summarizes the sound field components discussed above.

To the above list one could also add “Early Early” reflections—those occurring within 1–5 ms. (If specular in nature, these generally cause comb filtering and sound coloration to occur. Reflections of 1–2 ms are particularly troublesome as they can cause deep notches in the frequency response to occur around 2 kHz and thereby reduce intelligibility by attenuating the primary speech intelligibility frequency region.)

Opinion as to how the direct sound and early reflections integrate is currently somewhat divided. Many believe that reflections occurring up to around 35–50 ms after the direct sound fully integrates with it, provided that they have a similar spectrum. This causes an increase in perceived loudness to occur, which under noisy conditions can increase the effective SNR and hence intelligibility. Under quieter listening conditions, however, the case is not quite so clear, with factors including spectral content and direction of reflection becoming increasing important. Equally some research suggests that the integration time may be frequency dependent but generally around 35 ms for speech signals. However, there is general agreement that later arriving reflections (>50 ms) act such as to degrade intelligibility with increasing effect as the arrival time delay increases.

Sound arriving after approximately 100 ms generally signals the start of the reverberant field though strong discrete reflections arriving after 60 ms or so will be heard as discrete echoes. It is the ratio of direct + early reflections to late reflections and reverberation that determines the potential intelligibility in a reverberant space (assuming that other effects such as background noise and frequency response considerations are neglected). As a rule, positive ratios are desirable but rarely achieved in reality, though there are exceptions.

This is demonstrated in Figs. 36-19 and 36-20. Fig. 36-19 shows the energy time curve (ETC) sound arrival analysis for a highly directional (high \( Q \)) loudspeaker in a large reverberant church (RT\(_{60} = 2.7\) s at 2 kHz). The D/R ratio at the measuring position (approximately \( 2/3 \) way back) is 8.7 dB resulting in a high degree of intelligibility. Other intelligibility measures taken from the
same TEF data (see Section 36-13 on measuring intelligibility) are:

- $\%Alcons$ 4.2%.
- Equivalent rasti 0.68.
- C50 9.9 dB.

An opportunity to exchange the high $Q$ device for an almost omnidirectional, low $Q$ loudspeaker was taken and found to have a profound effect on the perceived intelligibility and the resulting ETC. This is shown in Fig. 36-20, which presents an obviously very different curve and pattern of sound arrivals. Clearly there is far more excitation of the reflected and reverberant sound fields. The D/R ratio is now $-4$ dB (a degradation of some 12 dB) and other computed data is:

- $\%Alcons$ is now only 13%.
- C50 has been reduced to $-3.6$ dB.
- Equivalent rasti to 0.48.

All the indicators and even a visual inspection of the graphs show there to be a significant reduction in the potential intelligibility.

While visual inspection of an ETC can be very enlightening, it can also at times be misleading. Take for example the curve shown in Fig. 36-21. At first glance this resembles the ETC for the low $Q$ device shown above and might suggest low intelligibility since no clear direct sound component is visible. However, densely distributed ceiling loudspeaker systems in a controlled environment do not work in the same way as point source systems in large spaces. In the former, the object is to provide a dense, short path length sound arrival sequence, from multiple nearby sources. The early reflection density will be high and in well-controlled rooms, the later arriving reflections and reverberant field will be attenuated. This results in smooth coverage and high intelligibility. In the case shown in Fig. 36-21, the RT$_{60}$ was 1.2 s and the resulting C50 was $+2.6$ dB and the Rasti was 0.68, results both indicating high intelligibility, which indeed was the case.

It should not be forgotten that whereas it may well be possible to produce high intelligibility in a localized area, even in a highly reverberant space, extending the coverage to a greater area will always result in reduced intelligibility at this point, as the number of required sources (additional loudspeakers) to accomplish the task increases. This is primarily due to the resulting increase in acoustic power fed into the reverberant field (i.e., increase in reverberant sound level) often referred to as the loudspeaker system $n$ factor.

### 36.7.1 Intelligibility Prediction—Statistical Methods

While it is relatively trivial to accurately calculate the direct and reverberant sound field components by
means of traditional statistical acoustics, it is not possible to accurately estimate, on a statistical basis, the early and late reflection fields. (To do this requires a computer model of the space and ray-tracing/reflection analysis program.)

Prior to such techniques being available, a number of statistically based intelligibility prediction methods based on calculation of the direct and reverberant fields were developed and are still useful in order to provide a quick ball park review of a design or idea. They have greater accuracy when applied to center cluster or point source systems as opposed to distributed loudspeaker systems (particularly high-density distributed systems).

The best known equation is that of Peutz as later modified by Klein and is the articulation loss of consonants equation (%\text{Alcons}). Peutz related intelligibility to a loss of information. For a loudspeaker-based system in a reverberant room, the following factors are involved:

- Loudspeaker directivity ($Q$).
- Quantity of loudspeakers operating in the space ($n$).
- Reverberation time ($RT_{60}$).
- Distance between listener and loudspeaker ($D$).
- Volume of the space ($V$).

\[
%\text{Alcons} = \frac{200* D^2 (T_{60}^2)(n + 1)}{Q V} \quad (36-1)
\]

* use 656 for American units

The %\text{Alcons} scale is unusual in that the smaller the number, the better the intelligibility. From Eq. 36-1 it can be seen that the intelligibility in a reverberant space is in fact proportional to the volume of the space and the directivity ($Q$) of the loudspeaker, (i.e., increasing either of these parameters while maintaining the others constant will improve the intelligibility). From the equation it can also be seen that intelligibility is inversely proportional to the squares of reverberation time and distance between the listener and the loudspeaker.

The equation was subsequently modified to take account of talker articulation and the effect that an absorbing surface has on the area covered by the loudspeakers.

\[
\text{Alcons} = \frac{200* D^2 (T_{60}^2)(n + 1)}{Q V ma} + K \quad (36-2)
\]

* use 656 for American units

\[m = (1 - a)/(1 - ac)\] where $a$ is the average absorption coefficient, $ac$ is the absorption in the area covered by the loudspeaker,

$k$ is the listener/talker correction constant typically 1–3, but for poor listeners/talkers can increase to 12.5%.

Peutz found that the limit for successful communication was around 15% Alcons. From 10 to 5% intelligibility is generally rated as good and below 5% the intelligibility can be regarded as excellent. A limiting condition

\[\text{Alcons} = 9T + k \quad (36-3)\]

was also found to occur by Peutz.

Although not immediately obvious from the equations, they are effectively calculating the direct-to-reverberant ratio. By rearranging the equation, the effect of the direct-to-reverberant ratio on %\text{Alcons} can be plotted with respect to reverberation time. This is shown in Fig. 36-21. From the figure, the potential intelligibility can be directly read from the graph as a function of D/R and reverberation time. (By reference to Fig. 36-13 the effect of background noise SNR can also be incorporated.)

The Peutz equations assume that the octave band centered at 2 kHz is the most important in determining intelligibility and uses the values for the direct level, reverberation time, and $Q$ to be measured in this band. There is also an assumption that there are no audible echoes and that the room or space supports a statistical sound field being free of other acoustic anomalies such as sound focusing.

In the mid-1980s Peutz redefined the %\text{Alcons} equations and presented them in terms of direct and reverberant levels and background noise level.

\[
%\text{Alcons} = 100(10^{-2(A + BC) - ABC}) + 0.015 \quad (36-4)
\]

where,

\[A = -0.32\log\left(\frac{L_R + L_N}{10L_D + L_R + L_N}\right)\]

for $A \geq 1$, let $A = 1$

\[B = -0.32\log\left(\frac{L_N}{10L_R + L_N}\right)\]

for $B \geq 1$, let $B = 1$

\[C = -0.50\log\left(\frac{RT_{60}}{12}\right)\]
The %Alcons equations work well with single point or center cluster systems or even split clusters, however, with distributed systems (especially high-density ceiling systems for example) determining the \((n + 1)\) factor becomes extremely difficult, as it is difficult to apportion what percentage of the radiation from adjacent or semiadjacent speakers is actually contributing to the direct field and early fields and which is contributing to the reverberant.

To a certain extent this is made easier in the more complex or long form version as a straight apportionment factor can be applied, though some considerable skill in doing this is required. Because the %Alcons equations do not effectively account for the early or late reflected energy, their accuracy needs to be treated with some caution. Furthermore, the method and equations are based on statistical acoustics, which at low reverberation times (e.g., \(< 1.5\) s) in itself becomes less accurate.

### 36.7.2 Intelligibility and Reverberation Time

Although, as we have seen, there is a lot more to intelligibility than reverberation alone, knowing the reverberation time of a space is a good starting point for a system design and immediately allows the potential difficulty of the task to be quantified. Some general rules of thumb can be applied in this context as seen in Table 36-2.

When designing or setting up systems for use in reverberant and reflective environments, the main rule to follow is, “Aim the loudspeakers at the listeners and keep as much sound as possible off the walls and ceiling.” This automatically partially maximizes the direct-to-reverberant ratio, though in practice it may not be quite so simple. The introduction of active and phased line arrays has had a huge impact on the intelligibility that now can be achieved in reverberant and highly reverberant spaces. Arrays of up to 5 m (~16 ft) are readily available and can produce remarkable intelligibility at distances of over 20–30 m even in 10 s plus reverberation time environments. The use of music line arrays has also led to a significant improvement in music/vocal clarity in arenas and concert halls. Whereas the intelligibility form a point or low \(Q\) source effectively reduces as square of the distance, this is not the case for a well-designed/installed line array. An example of this is Fig. 36-23 where it can readily be seen that the intelligibility (as measured using the Speech Transmission Index—STI) remains virtually constant over a distance of 30 m in a highly reverberant cathedral (RT = 4 s).

### 36.8 Some Further Effects of Echoes and Late Reflections

As already noted, speech signals arriving within 35 ms of the direct sound generally integrate with the direct sound and aid intelligibility. In most sound system applications
and particularly in distributed loudspeaker systems, a considerable number of early reflections and sound arrivals will occur at a given listening position. These can provide a useful bridging effect (sequential masking) which can extend the useful arrival time to perhaps 50 ms. The way in which single or discrete reflections affect intelligibility has been studied by a number of researchers—perhaps the best known being Haas.

Haas found that under certain conditions, delayed sounds (reflections) arriving after an initial direct sound could in fact be louder than the direct sound without affecting the apparent localization of the source. This is often termed the Haas effect. Haas also found that later arriving sounds may or may not be perceived as echoes depending on their delay time and relative level. These findings are of significant importance to sound system design and enable, for example, delayed infill loudspeakers to be used to aid intelligibility in many applications ranging from balcony infills in auditoria and pew back systems in churches to large venue rear fill loudspeakers. If the acoustic conditions allow, then improved intelligibility and sound clarity can be achieved without loss of localization.

Fig. 36-24 presents a set of echo disturbance curves produced by Haas and shows the sensitivity to disturbance by echoes or secondary sounds at various levels and delay times.

Fig. 36-25, after Meyer and Shodder, shows a curve of echo perception for various delay times and levels (dotted curve) and indicates that delayed sounds become readily discernible at delays in excess of 35 ms (e.g., at 50 ms delay), a single reflection or secondary signal has to be more than 10 dB lower before it becomes imperceptible and has to be more than 20 dB lower at 100 ms. The solid curve in Fig. 36-25 shows when a delayed sound will be perceived as a separate sound source and ceases to be integrated with the direct sound.

Although potentially annoying, echoes may not degrade intelligibility as much as is generally thought. Fig. 36-26, based on work by Peutz, shows the reduction in %Alcons caused by discrete sound arrivals or echoes.

The curve starts at just under 2% as this was the residual loss due to the particular talker and listener group taking part in the experiment. As the figure shows, the single reflections typically only caused an additional loss of around 2–3%.

However, typically more complex systems operating in reverberant spaces can often give rise to the creation of groups of late reflections which, anecdotally at least,
would appear to be rather more detrimental. Fig. 36-27 shows the ETC measured on the stage of a 1000 seat concert hall auditorium. A small group of prominent late reflections is clearly visible.

Another interesting problem found in the same auditorium during initial setup of the system is shown in Fig. 36-28. Again a group of late reflections is clearly visible. A strong reflection occurred 42 ms after the direct sound just 1.9 dB down and the later group arrived 191 ms after the direct and 4.5 dB down.

Perhaps surprisingly, the effect of these reflections was not to create a distinct echo but rather to cause a general loss of intelligibility and blurring of the sound. In other nearby seats, the intelligibility was good and measured 0.70 STI but in the seats where the intelligibility was poor the STI was 0.53. Although significantly lower than 0.7, a value of 0.53 would still appear to be too high in relation to the subjective impression obtained. However, Houtgast and Steeneken specifically warn against the use of STI for assessing situations with obvious echoes or strong reflections. Identifying the problem however, would not have been possible without the ability to see the ETC.

36.9 Uniformity of Coverage

It is essential when designing systems to work in noisy and/or reverberant spaces to ensure that the direct sound level is as uniform as practical. For example, while a 6 dB variation (±3 dB) may be acceptable under good acoustic conditions, such a variation in a reverberant space can lead to intelligibility variations of 20–40%. A 40% degradation of clarity under such conditions is usually unacceptable. For the case of noise alone, the variation would be at least a 20% reduction in potential intelligibility—though this will be dependent upon the spectrum of the noise. The off-axis performance of a selected loudspeaker is therefore of critical importance—a smooth and well-controlled response being a highly desirable feature.
Where listeners are free to move about—e.g., on a concourse or in a shopping mall—it may be possible to have a greater variation in coverage and hence intelligibility. However, with a seated audience or spectators in an enclosed space, it is essential to minimize seat to seat variations. In critical applications, variations in coverage may need to be held within 3 dB in the 2 kHz and 4 kHz octave bands. This is a stringent and often costly requirement. To put this into perspective consider the following example: assume a given space has an RT60 of 2.5 s. Calculation shows that on-axis to the loudspeaker at a given distance gives a value of 10% Alcons—an acceptable value. However going off-axis or to a position where the direct sound reduces by just 3 dB will result in a predicted %Alcons of 20%—an unacceptable value, see Fig. 36-22. This shows that it is vital to remember off-axis positions as well as the on-axis ones when carrying intelligibility predictions and system designs. Particularly when it is considered that in many applications, the potential intelligibility will be further degraded by the presence of background noise— even when it is not the primary factor.

### 36.10 Computer Modeling and Intelligibility Prediction

Computer modeling and the current state of the art are discussed in depth in Chapters 9 and 35 and so will only be briefly mentioned here. The ability to accurately predict the direct and reverberant sound fields and compute the complex reflection sequences that occur at any given point are truly remarkable advances in sound system design. As we have seen, calculation of intelligibility from the statistical sound fields alone is not sufficiently accurate for today’s needs—particularly with respect to distributed sound systems. The computation of the reflection sequence and hence the impulse response at a point allows far more complex analyses to be carried out including predictions of the early-to-late sound field ratios and the direct calculation of STI. (It should be noted that some of the current simpler programs and many of the earlier prediction programs, although purportedly providing a prediction of STI, in fact base this on a statistical %Alcons calculation and convert the resulting value to Rasti. The accuracy of the result value is therefore highly questionable.)

Some program, however, are capable of highly accurate prediction, particularly as the precision of the loudspeaker data increases to 1/2-octave bandwidths and 10 degrees or better angular resolution. Also as the computing power continually increases, greater reflection sequence lengths and orders can be more practically accommodated and hence more accurate reflection field data can be calculated. The main restriction currently is not the mathematical accuracy of the model itself, but the time and effort required to build it in the first place. For many schemes this is simply not economically viable so some form of simple prediction routine, to at least insure that the proposed system will achieve roughly the right order of magnitude of intelligibility, is still required.

### 36.11 Equalization

It is surprising how many sound systems are still installed either with no or totally inadequate equalization facilities. Yet the major variations in frequency response (both perceived and measured) that systems exhibit when normally installed can have significant effect on the resultant intelligibility and clarity. Equally many systems after they have been equalized often sound worse than they did before.

This is primarily due to a lack of understanding on behalf of the person carrying out the task. There would appear to have been very little research carried out on the effects of equalization on intelligibility. The author has noted improvements of up to 15–20% on some systems, but otherwise the improvements that can be gained are not well publicized.

There are probably about eight main causes of the frequency response anomalies generally observed prior to equalizing a sound system. Assuming that the loudspeaker(s) has a reasonably flat and well-controlled response to begin with these are:

1. Local boundary interactions, Fig. 36-7.
2. Mutual coupling or interference between loudspeakers.
3. Missynchronization of units in a cluster.
4. Incorrectly acoustically loaded loudspeaker, (e.g., a ceiling loudspeaker in too small a back box and/or a coupled cavity).
5. Irregular (poorly balanced) sound power characteristic interacting with reverberation and reflection characteristics of the space.
6. Inadequate coverage, resulting in dominant reverberant sound off-axis.
7. Excitation of dominant room modes (Eigen tones). (These may not appear as large irregularities in the frequency response but subjectively can be very audible and intrusive.)
8. Comparison for high-frequency losses caused by long cable runs or excess atmospheric absorption.

To these may be added abnormal or deficient room acoustics particularly if exhibiting strong reflections or focusing.

Equalization is a thorny subject, with many different views being expressed as to how it should be carried out and what it can and cannot achieve. Suffice it to say that equalization can make a significant improvement to both the intelligibility and clarity of a sound system.

In some cases the improvements are dramatic—particularly when considering not so much the intelligibility per se but associated factors such as ease of listening and fatigue. The essential point is that there is no one universal curve or equalization technique that suits all systems all of the time.

Two examples of this are given below. Fig. 36-29 shows the curves before and after equalization of a distributed loudspeaker system in a highly reverberant church. The anechoic response of the loudspeakers in question is reasonably flat and well extended at high frequencies. Because the measurement (listening) position is beyond the critical distance, the reverberant field dominates and it is the total acoustic power radiated into the space that determines the overall response.

The power response of the loudspeaker in question is not flat but falls off with increasing frequency. (This is the normal trend for cone-based devices but some exhibit sharper roll-offs than others.) This, coupled with the longer reverberation time at lower frequencies due to the heavy stone construction of the building, results in an overemphasis at low and lower midfrequencies. The peak at around 400 Hz is due to a combination of power response, mutual coupling of loudspeakers, and boundary interaction effects. The resultant response causes considerable loss of potential intelligibility as high-frequency consonants are lost. Equalizing the system as shown by the solid curve improved the clarity and intelligibility significantly resulting in an improvement of some 15%.

Fig. 36-30 shows a widely quoted equalization curve for speech systems. This has been found to work well for distributed systems in reverberant spaces, but it is only a guideline and should not be regarded too rigorously. Loudspeakers that have a better balanced power response that more closely follows the on-axis frequency response will exhibit less high-frequency roll-off and will generally allow a more extended high-frequency equalization curve.

![Figure 36-30. Typical response guideline curve for speech reinforcement systems.](image)

An example of this is shown in Fig. 36-31. This is the response of a distributed loudspeaker system employing two-way enclosures in a reflective but well-controlled acoustic environment. In this case, rolling off the high-frequency response would be wholly inappropriate and would degrade the clarity of the system.

Adding bass to a sound system may make it sound impressive but will do nothing for the clarity and intelligibility. Indeed, in general, such an approach will actually reduce the intelligibility and clarity particularly in reverberant spaces. Where music as well as speech need to be played through a system, different paths with different equalization settings should be employed so that the different requirements of each signal can be optimized.

### 36.12 Talker Articulation and Rate of Delivery

Whereas the sound system designer has some control or at least influence over many of the physical parameters that affect the potential intelligibility of a sound system, an area where no such control exists is that of the person using the microphone. Some talkers naturally articulate
better than others and so the resultant broadcast announcements are also inherently clearer.

However, it must not be forgotten that even good talkers cause some loss of potential intelligibility. Peutz, for example, found that good talkers produced 2–3% additional Alcons loss over and above that caused by the system and local environment. Poor talkers can produce additional losses of up to 12.5%. It is therefore important to design in some element of safety margin into a sound system in order to compensate for such potential losses.

The rate at which a person speaks over a sound system is also an important factor—particularly in reverberant spaces. Considerable improvement in intelligibility can be achieved by making announcements at a slightly slower rate than normal in acoustically difficult environments such as large churches, empty arenas, gymnasiums, or other untreated venues.

Training announcers or users on how to use the system and how to speak into a microphone can make a significant improvement. The need for proper training can not be overstated but is frequently an area that is often ignored. Prerecorded messages loaded into high-quality, wide bandwidth digital stores can overcome certain aspects of the problem.

For highly reverberant spaces, the speech rate needs to be slowed down from the normal rate of speaking—e.g., from around five syllables per second down to about three syllables per second. This can be very difficult to do under normal operating conditions but carefully rehearsed, slower recordings can be very effective. Equally, the author has found that feeding back a slightly delayed or reverberated signal of the person speaking (e.g., via headphones or an earpiece) can be a very effective way of slowing down the rate of speech—though this has to be carefully controlled and set up, as too much delay can become off-putting and counterproductive.

Research has shown that intelligibility is improved when the lips of the talker can be seen. At low levels of intelligibility (e.g., 0.3 to 0.4 AI [Articulation Index]) visual contact can produce improvements of up to 50%. Even with reasonably good intelligibility (e.g., 0.7 to 0.8 AI) improvements of up to 10% have been observed. This suggests that paging and emergency voice alarm systems may have a more difficult task than speech reinforcement systems where additional visual cues are generally also present.

### 36.13 Summary of Intelligibility Optimization Techniques

The following tips should hopefully prove useful in optimizing sound system intelligibility or act as a catalyst for other ideas and design strategies. Although some would appear very basic, it is remarkable how many systems could be improved with just a minor adjustment or simple redesign.

- Aim the loudspeakers at the listeners and keep as much sound off the walls and ceiling—particularly in reverberant spaces or where long path echoes can be created.
- Provide a direct line of sight between the loudspeaker and listener.
- Minimize the distance between the loudspeaker(s) and listener.
- Insure adequate system bandwidth, extending from a minimum of 250 Hz to 6 kHz and preferably >8–10 kHz.
- Avoid frequency response anomalies and correct unavoidable peaks with appropriate equalization.
- Try to avoid mounting loudspeakers in corners.
- Avoid long path delays (>45 ms). Use electronic signal delays to overcome such problems where loudspeaker spacing >20 ft/6 m (30 ft/9 m max).
- Use directional loudspeakers in reverberant spaces to optimize potential D/R ratios. (Use models exhibiting smoothly controlled and reasonably flat or a gently sloping power response if possible.)
- Minimize direct field coverage variations. Remember that variations of as little as 3 dB can be detrimental in highly reverberant spaces.
- Insure speech SNR is at least 6 dBA and preferably >10 dBA.
- Use automatic noise level sensing and gain adjustment to optimize SNR where background noise is variable.
• Provide a quiet area or refuge for the announcement microphone or use a good quality and effective noise canceling microphone with good frequency response.
• Insure that the microphone user is properly trained and understands the need not to go off mic and to speak clearly and slowly in reverberant environments.
• Repeat important messages.
• In very difficult environments, use simple vocabulary and message formats. Consider use of high-quality specially annunciated prerecorded messages.
• Consider making improvements to the acoustic environment. Do not design the sound system in isolation. Remember, the acoustical environment will impose limitations on the performance of any sound system.

36.14 Intelligibility Criteria and Measurement

A number of intelligibility criteria and rating and assessment methods have already been noted in earlier sections. Here they are treated in a rather more comprehensive overview. However as each technique is quite complex, readers are referred to the bibliography at the end of this chapter to obtain more detailed information.

It is obviously important to be able to specify the desired degree of intelligibility required either for a particular purpose or so that it can be objectively specified for a given project or system. The need then also automatically follows that there has to be a corresponding method of measuring and assessing that a given criterion has been met. Intelligibility measurement and assessment techniques can be divided into two broad categories. These are:

1. Subject based measures—employing a panel of listeners and using a variety of speech-based test materials.
2. Objective acoustic measures of a parameter or parameters that correlate with some aspect of perception.

Subject-based measures include writing down word scores, sentence recognition, modified rhyme tests, and logotom recognition. Objective acoustic measures include broadband and weighted SNR, Articulation Index, Speech Interference Level (SIL and PSIL), direct-to-reverberant measures (including TEF %Alcons and C35/C50), and STI. There are also a number of subsets of these latter techniques.

It should not be forgotten that it is not just sound reinforcement or public address systems where the resultant intelligibility may require assessment. Other related audio applications include telephone and intercom systems (telephone/headphone or loudspeaker based) as well as teleconferencing systems and other communication channels—e.g., radio. Hearing assistance systems for the hard of hearing can also be assessed and rated using a number of the techniques described below as can the effectiveness of noise masking systems where conversely a reduction in intelligibility is deliberately sought. Measurements may also need to be made in order to assess the natural intelligibility of a space perhaps so that the potential benefits or need for a speech reinforcement system can be evaluated and objectively rated (e.g., churches, classrooms and lecture rooms/auditoria, etc.).

Not all of the techniques are applicable to every application. The area of application is therefore noted at the end of each section. The practical limitations of each of the methods described are also briefly discussed.

36.14.1 Subject-Based Measures and Techniques

The fundamental measurement of intelligibility is of course speech itself. A number of techniques have been developed to rate speech intelligibility. The initial work was carried out in the 1920s and 1930s and was associated with telephone and radio communication systems. From this work the effects of noise, SNR, and bandwidth were established and subjective test methods formulated. (Much of this work was carried out at Bell Labs under the direction of Harvey Fletcher.) The sensitivity of the various test methods was also established and it was found that tests involving sentences and simple words were the least sensitive to corruption but often did not provide sufficiently detailed information to enable firm conclusions to be drawn regarding the effects and parameters under study to be definitely made.

The need to insure that all speech sounds were equally included led to the development of phonemically balanced (PB) word lists. Lists with 32, then 250, and finally 1000 words were developed. Tests using syllables (logatoms) were also developed. These latter tests provide the most sensitive measure of speech information loss but are complex and very time consuming and costly in application.

The modified rhyme test (MRT) was developed as a simpler alternative to PB word lists and is suitable for use in the field with only a short training period. (The more sensitive methods can require several hours of training of the subjects before the actual tests can begin.) The various methods and their interrelationships are shown in Fig. 36-12 where the Articulation Index is used as the common reference.
36.14.2 Objective Measures and Techniques

36.14.2.1 Articulation Index

The Articulation Index (AI) was one of the first criteria and assessment methods developed to use acoustic measurements and relate these to potential intelligibility. AI is concerned with rating the effects of noise on intelligibility and was primarily developed for assessing telephone communication channels. Later corrections were added in attempt to take account of room reverberation but these methods are not considered sufficiently accurate for sound system use. AI is a very accurate and useful method of assessing and rating the effects of noise on speech. ANSI Standard S3.5 1969 (subsequently revised in 1988 and 1997) specifies the methods of calculation based on measurements of the spectrum of the interfering noise and desired speech signal. (Either in terms of 1/3-octave or 1/5-octave bands.)

The Index ranges from 0 to 1 with 0 representing no intelligibility and 1 representing 100% intelligibility. The Index is still very good for assessing the effects of noise on speech in range of applications where room reverberation effects are negligible—e.g., communication channels or aircraft cabins, etc.

Another important application relates to the assessment of speech privacy in offices and commercial environments. Here a very low AI score is required in order to insure that neighboring speech is not intelligible. This is extremely useful when setting up and adjusting sound masking systems and a speech privacy scale has been developed for this purpose. Unfortunately, few commercial analyzers incorporate the measurement, which would be an extremely simple matter to do if a 1/5-octave real-time spectrum display and data are available. Currently, most users of AI in this application either have to compute the result manually or by a simple spreadsheet procedure.

36.14.2.2 Articulation Loss of Consonants

This method was developed by Peutz during the 1970s and further refined during the 1980s. The original equation is simple to use and is in fact based on a calculation of the D/R ratio, although this is not immediately obvious from the equation. The long form of the equation takes into account both noise and reverberation—but unfortunately does not give exactly similar values to the simpler form—which is regarded by many to be overly optimistic. The original work was based on human talkers and not sound systems. (The original prediction equation was modified by Klein in 1971 to its now familiar form in order to do this.)

During 1986, a series of speech intelligibility tests were run that enabled a correlation to be found between MRT word scores carried out under reverberant conditions and a D/R measurement carried out on the TEF analyzer. For the first time this allowed the widely used predictive and design rating technique to be measured in the field. However the correlation does have a number of limitations which need to be considered when applying the method. The measurement bandwidth used at the time was equivalent to approximately 1/3 octave centered at 2 kHz. Although three very different venues were employed, each with three significantly different loudspeakers and directivities, the correlation and hence method is only valid for a single source sound system.

The measurement requires considerable skill on behalf of the operator in setting up the ETC measurement parameters and divisor cursors, so a range of apparently correct answers can be obtained. Nonetheless the measurement does provide a very useful method of assessment and analysis. In 1989 Mapp and Doany proposed a method for extending the technique to distributed and multiple source sound systems by extending the duration of the measurement window out to around 40 ms.

A major limitation of the method is that it only uses the 2 kHz band. For natural speech where there is essentially uniform directivity between different talkers, single band measurements can be acceptably accurate. However, the directivity of patterns of many if not the majority of loudspeakers used in sound systems is far from constant and can vary significantly with frequency—even over relatively narrow frequency ranges. Equally, by only measuring over just one narrow frequency band, no knowledge is obtained regarding the overall response of the system. The accuracy of the measurement correlation can therefore become extremely questionable and any apparent acceptable values extracted must be viewed with caution.

36.14.2.3 Direct-to-Reverberant and Early-to-Late Ratios

Direct-to-reverberant measurements or more accurately direct and early reflected sound energy-to-late reflected and reverberant energy ratios have been used as predictors of potential intelligibility in architectural and auditorium acoustics for many years. A number of split times have been employed as delineators for the direct or direct and early reflected sounds and the late energy. The most common measure is C50, which takes as its ratio the total energy occurring within the first 50 ms to the total sound energy of the impulse response. Other
measures include C35, whereby the split time is taken as 35 ms and also sometimes C7 where this early split time effectively produces an almost pure D/R ratio.

A well-defined scale has not been developed, but it is generally recommended that for good intelligibility (in an auditorium or similar relatively large acoustic space) a positive value of C50 is essential and that a value of around +4 dB C50 should be aimed for. (This is equivalent to about 5% Alcons.) Measurements are usually made at 1 kHz or may be averaged over a range of frequencies. The method does not take account of background noise and is of limited application with respect to sound systems due to the lack of a defined scale and frequency limitations—although there is no reason why the values obtained at different frequencies could not be combined in some form of weighted basis. (See Lochner and Burger 1964.) Bradley has extended the C50 and C35 concept and introduced U50 and U80 etc. where U stands for useful energy. He also included signal-to-noise ratio effects. While the concept is a useful addition to the palette of speech intelligibility measures, it has not caught on to any extent—but it can be a very useful diagnostic tool and further extends our knowledge and understanding of speech intelligibility.

36.14.2.4 Speech Transmission Index STI, RASTI, and STI-P-A

The STI technique was also developed in Holland at about the same time as Peutz was developing %Alcons. While the %Alcons method became popular in the United States, STI became popular and far more widely used in Europe and has been adopted by a number of International and European Standards and codes of practice relating to sound system speech intelligibility performance as well as International Standards relating to aircraft audio performance. It is interesting to note that while %Alcons was developed primarily as a predictive technique, STI was developed as a measurement method and is not straightforward to predict! (See later.)

The technique considers the source/room (audio path)/listener as a transmission channel and measures the reduction in modulation depth of a special test signal as it traverses the channel, Figs. 36-32 and 36-33. A unique and very important feature of STI is that it automatically takes account of both reverberation and noise effects when assessing potential intelligibility.

Schroeder later showed that it is also possible to measure the modulation reduction and hence STI via a system’s impulse response. Modern signal processing techniques now allow a variety of test signals to be used to obtain the impulse response and hence compute the

---

Figure 36-32. Principle of STI and modulation reduction of speech by room reverberation.

STI—including speech or music. A number of instruments and software programs are currently available that enable STI to be directly measured. However, care needs to be taken when using some programs to insure that any background or interfering noise is properly accounted for.

The full STI technique is a very elegant analysis method and is based on the amplitude modulations occurring in natural speech, Figs. 36-33 and 36-34. Measurements are made using octave band carrier frequencies of 125 Hz to 8 kHz, thereby covering the majority of the normal speech frequency range. Fourteen individual low-frequency (speechlike) modulations are measured in each band over the range 0.63 to 12.5 Hz.

A total of 98 data points are therefore measured for each STI value (7 octave band carriers each × 14 modulation frequencies). Because the STI method operates over almost the entire speech band it is well suited to assessing sound system performance. The complete STI data matrix is shown in Table 36-2. “X” represents a data value to be provided.

When STI was first developed, the processing power to carry out the above calculations was beyond economic processor technology and so a simpler derivative measure was conceived—RaSTI. RaSTI stands for Rapid Speech Transmission Index (later changed to Room Acoustic Speech Transmission Index when its shortfalls for measuring sound system performance were realized (see Mapp 2002 and 2004). RaSTI uses just nine modulation frequencies spread over two octave band carriers thereby producing an order of magnitude reduction in the processing power required.

The octave band carriers are 500 Hz and 2 kHz, which, although well selected to cover both vowel and consonant ranges, does mean that the system under test
has to be reasonably linear and exhibit a well-extended frequency response. Unfortunately many paging and voice alarm systems do not fulfill these criteria and so can give rise to readings of questionable accuracy. (However, this still takes account of a wider frequency range than the traditional D/R and %Alcons methods.)

Fig. 36-35 shows a system response simulated by the author and evaluated via RaSTI. Although the majority of the speech spectrum is completely missing, the result was an almost perfect score of 0.99 STI!

Figure 36-34. STI subjective scale and comparison with %Alcons.
The first commercially available instrument that could measure STI was the RaSTI meter introduced by Brüel and Kjær in 1985. Modulated pink noise in the 500 Hz and 2 kHz octaves is generated and transmitted either acoustically or electronically into the system under test. A useful feature of the method is that the resultant signal is very speechlike in nature having a crest factor of around 12 dB, which compares well with normal speech (at around 15–20 dB). The relative levels of the 500 Hz and 2 kHz signals are also automatically transmitted in their correct ratios as compared to natural speech. This makes setting up the test signal levels comparatively straightforward and enables measurements to be carried out by trained but nonexpert personnel. The introduction and adoption of the RaSTI test method has literally revolutionized the performance of many PA systems ranging from aircraft cabins and flight recording systems to trains, malls, and cathedrals as, for the first time, the intelligibility of such systems could be set and readily verified. As the limitations of RaSTI as a measure of sound system performance became more widely known and understood (e.g., Mapp 2002 and 2004) it became clear that a replacement method would be required. In 2001, STIPA (STI for PA systems) was introduced and became part of IEC 268-16 in 2003. Unlike RaSTI STIPA measures over virtually the complete speech bandwidth range from 125 Hz to 8 kHz. However, a sparse matrix is used to cut down the complexity of the stimulus and associated measurement processing time. Table 36-3 shows the modulation matrix for STIPA.

The current version of IEC 268-16 (Edition 3, 2003) employs the above modulations. It can be seen that for some reason the 125 Hz and 250 Hz carriers employ the same modulation frequencies—although there is a spare set available (there are no modulations at 1.6 Hz and 8 Hz). However, it is quite likely that a future version of the standard (2010) will correct this apparent anomaly and use the missing modulations (indeed some meters already do this).

Since its introduction, the STIPA technique has rapidly taken off with at least four manufacturers offering handheld portable measurement devices (though some are more accurate than others—see Mapp 2005). In a similar manner to RaSTI, the STIPA signal is speech shaped and so automatically presents the correct signal for assessing a sound system. (STIPA is a protected name and refers to a measurement made with a modulated signal. Although STIPA can be derived from an impulse response, any such measurement must be clearly indicated as being an equivalent STIPA). At the time of writing, the STIPA signal has been relatively loosely defined, but it is understood that the fourth edition of IEC 268-16 will clarify the issue. This should also help insure that the various STIPA meters are fully compatible, so that any 2 meters using the same IEC268-16 Ed 4 test signal should give the same result.

The typical time required to carry out a single STIPA measurement is around 12–15 s. However, as the test signal is based on a pseudorandom signal, there can be some natural variation between readings. For this reason it is recommended that at least three readings be taken to insure that a reliable measurement result is produced. STIPA correlates very closely with STI and overcomes

![Figure 36-35. Simulated system frequency response curve favoring 500 and 2000 Hz, giving an excellent RASTI value but very poor sound quality.](image-url)
most of the problems associated with RaSTI. However, just as with STI, it is a far from perfect measure and there are a number of limitations that need to be understood.

STIPA is vulnerable to some forms of digital signal processing and in particular CD player errors. STIPA test signals are generally distributed on CDs, and some CD players can introduce significant errors. It is therefore essential to conduct a loop back measurement to insure that a valid signal is being generated. More recently, however, signals have been distributed as wav files on solid state memory cards and can also be directly downloaded, which helps overcome the problem (see Mapp 2005 for further details). Most hardware implementations include some form of error detection—particularly the detection of the occurrence of impulsive noise during a test. Not all STIPA meters have incorporated the level dependency relationship that exists between speech level and intelligibility—although it is clearly defined within the IEC 268-16 standard. The same is also true of the masking function that the standard requires.

One of the major shortcomings of STI and STIPA is their inability to correctly assess the effect that equalization can have on a sound system. For example, STI measurements made on the system described earlier and whose frequency response is depicted in Fig. 36-27 were exactly the same pre and post equalization—although the word score intelligibility improved significantly. Adapting STI to correctly account for such occurrences is not a simple or straightforward matter and it will be some time yet before we have a measure that can accurately do this.

The STI/RaSTI scale ranges from 0 to 1. Zero represents total unintelligibility while 1 represents perfect sound transmission. Good correlation exists between the STI scale and subject-based word list tests. As with all current objective electroacoustic measurement techniques, STI does not actually measure the intelligibility of speech, but just certain parameters that correlate strongly with intelligibility. It also assumes that the transmission channel is completely linear. For this reason, an STI measurement can be fooled by certain system nonlinearities or time-variant processing. STI is also liable to corruption by the presence of late discrete arrivals (echoes). These, however, can be readily spotted by examination of the modulation reduction matrix.

The basic equation for the STI modulation reduction factor \( m(f) \) is

\[
m(f) = \frac{1}{1 + \left( \frac{2FT}{13.8} \right)^{10}} \times \frac{1}{1 + 10^{\frac{\text{AIS/N}}{10}}} \quad (36-5)
\]

Unfortunately, this equation cannot be directly solved, making STI prediction a complex procedure requiring detailed computer modeling and analysis of the sound field. An approximate relationship exists between STI (RASTI) and \( \%\text{Alcons} \). Fig. 36-34 shows the two scales while Table 36-4 gives a numerical set of equivalent values.

The subjective scale adopted for STI (and RaSTI/STIPA) has led to considerable confusion when rating PA and sound systems. (For example a rating of 0.5 STI would normally be rated as good if heard in a highly reverberant or difficult acoustic environment rather than only fair. Also, in practice, there is usually a marked difference in perception between 0.45 and 0.50 STI (and more particularly 0.55 STI)—although they are all rated as fair. In an attempt to overcome the problem and also to add a degree of tolerance to the measure, the author has proposed that a new rating scale be employed for PA/sound systems (Mapp 2007). The proposed scale is shown in Fig. 36-36 and is based on a series of designated bands rather than absolute categories. While the bands will remain fixed, their application can vary so that, for example, an emergency voice
announcement system may be required to meet category “G” or above whereas a high-quality system for a theater for a concert hall might be required to meet category “D,” or an assistive hearing system might be required to meet category “B” or above, etc. (Table 36-5). It is anticipated that the new scale will be adopted by IEC 268-16 and form part of the fourth edition of the standard.

Figure 36-36. New STI scale proposal.

Whereas STI does incorporate a degree of diagnostic ability—e.g., it can readily be determined if the speech intelligibility is primarily being reduced by noise or reverberation and the presence of late reflections—a visual display of the ETC or impulse response is invaluable when actually determining appropriate remedial measures and identifying the underlying cause or offending reflective surfaces. A combination of techniques is therefore employed by the author when tackling such problems including the use of directional and polar ETC measurements.

36.14.2.5 SII Speech Intelligibility Index

This relatively new index (ANSI S3.5 1997) is closely related to the Articulation Index (AI) but also makes use of some STI concepts. SII calculates the effective signal-to-noise ratio for a number of frequency bands related to the speech communication bandwidth. Several procedures with different frequency domain resolutions are available. These include conventional $\frac{1}{3}$-octave and $\frac{1}{1}$-octave as well as a twenty one band critical bandwidth (ERB) analysis. An analysis based on seventeen equally contributing bands is also incorporated. The method would appear to be more suitable for direct communication channels rather than for sound reinforcement and speech announcement systems, but in situations where reverberation has little or no effect, the method would be applicable. It should also be useful for evaluating and quantifying the effectiveness of speech masking systems.

36.14.3 The Future for Speech Intelligibility Measurements

As can be seen from the foregoing discussions, we are still a long way from truly measuring speech intelligibility itself. Currently all we can do is to measure a number of physical parameters than correlate under certain conditions to intelligibility. An order of magnitude improvement is required for these to become less anomalous and fallible. The power of the modern PC should allow more perceptually based measurements to be made, as is already happening with telephone networks. However, it must not be forgotten that what is needed in the field is a simple to operate system that does not require highly trained staff to operate, as one thing is for certain: the need to measure and prove that intelligibility criteria have been met is going to rapidly expand over the next few years—indeed the introduction of STIPA is already hastening the process. The range of applications where such testing will need to be performed is also going to rapidly expand and will encompass almost all forms of public transport as well as all forms of voice-based life safety systems. The more traditional testing of churches, auditoria, classrooms, stadiums, and transportation terminals is also set
to rapidly expand. As DSP technology continues to grow and as our understanding of psychoacoustics and speech continues to develop, the ability to manipulate speech signals to provide greater intelligibility will increase. Measuring such processes will be a further and interesting challenge.

Particular areas that are likely to see progress over the next few years are the development and use of binaural intelligibility measurements—probably using STI as their basis. The author has also tried using STI and STIPA to assess speech privacy and the effectiveness of speech masking systems. While potentially a promising technique, there are still many obstacles to overcome before it can become a viable technique—not least of which requires considerable research to be carried out between speech intelligibility and STI at the lower end of the STI scale (Mapp 2007). The measurement and intelligibility assessment of assistive hearing systems is also currently under investigation (Mapp 2008) and is showing considerable promise. It is anticipated that a series of new criteria and measurement techniques will be developed specifically for this specialized but increasingly important field. The use of real speech and other conventional PA signals is also under research and should pave the way for less invasive measurement techniques.

Acknowledgments

The author gratefully acknowledges the assistance of JBL Professional for allowing a number of graphs and figures originally created for their Technical Note “Speech Intelligibility” (TN, vol. 1, no. 26) to be reproduced in this chapter. The author would also like to thank Don and Carolyn Davis for holding the first Syn-Aud-Con Speech Intelligibility Workshop in 1986, which has acted as an inspiration to further work on this subject ever since.

37.1 Background

The emergence of modern sound reinforcement systems for music in the 1960s brought with it the need for performers to be able to better hear themselves onstage. Prior to the days of arena concerts and stacks of Marshall™ amplifiers, it wasn’t that difficult for performers to hear vocals through the main PA loudspeakers. Most concerts were held in smaller venues, with a few notable exceptions. When the Beatles played Shea Stadium in 1964, the only PA was for voice; guitars were only as loud as the guitar amplifiers. Of course, the crowd noise was so loud even the audience couldn’t hear what was going on, let alone the band! As rock and roll shows continued to get bigger and louder, it became increasingly difficult for performers to hear what they were doing. The obvious solution was to turn some of the loudspeakers around so they faced the band. A further refinement came in the form of wedge-shaped speakers that could be placed on the floor, facing up at the band, finally giving singers the ability to hear themselves at a decent volume, Fig. 37-1. With the size of stages increasing, it became difficult to hear everything, not just the vocals. Drums could be on risers 15 feet in the air, and guitar amps were occasionally stowed away under the stage. These changes required the use of a monitor console—a separate mixer used for the sole purpose of creating multiple monitor mixes for the performers—to accommodate all the additional inputs as well as create separate mixes for each performer. Today, even the smallest music clubs offer at least two or three separate monitor mixes, and it is not uncommon for local bands to carry their own monitor rig capable of handling four or more mixes. Many national touring acts routinely employ upwards of sixteen stereo mixes, Fig. 37-2.

The problems created by traditional monitor systems are numerous; the next section examines them in detail. Suffice it to say, a better way to monitor needed to be found. Drummers have used headphones for years to monitor click tracks (metronomes) and loops. Theoretically, if all performers could wear headphones, the need for monitor wedges would be eliminated. Essentially, headphones were the first personal monitors—a closed system that doesn’t affect or depend on the monitoring requirements of the other performers. Unfortunately, they tend to be cumbersome and not very attractive. The adoption of transducer designs from hearing aid technology allows performers to use earphones, essentially headphones reduced to a size that fit comfortably in the ear. Professional musicians, including Peter Gabriel and The Grateful Dead, were among the first to employ this new technology. The other major contribution to the development of personal monitors is the growth of wireless microphone systems. Hardwired monitor systems are fine for drummers and keyboardists that stay relatively stationary, but other musicians require greater mobility. Wireless personal monitor systems, essentially wireless microphone systems in reverse, allow the performer complete freedom of movement. A stationary transmitter broadcasts the monitor mix. The performer wears a small receiver to pick up the mix. The first personal monitor systems were prohibitively expensive; only major touring acts could afford them. As with any new technology, as usage becomes more widespread, prices begin to drop. Current personal monitor systems have reached a point where they are within many performers’ budgets.

---

Figure 37-2. Large frame monitor console. Courtesy Shure Incorporated.
37.2 Personal Monitor System Advantages

The traditional, floor wedge monitor system is fraught with problems. Performers, especially singers, find it difficult to hear things clearly. Feedback is a constant and annoying issue. And the monitor engineer forever battles to keep up with the needs of the individual performers. Anyone who has performed live has probably dealt with a poor monitor system, but even a great system has many limitations due to the laws of physics, and those laws bend for no one. The concept of in-ear monitoring rose from the desire to create an onstage listening experience that could overcome the limitations imposed by a traditional floor monitor system.

Many parallels exist between personal monitors and a traditional floor wedge setup. The purpose of any monitor system is to allow performers to hear themselves. The sounds to be monitored need to be converted to electronic signals for input to the monitor system. This is usually accomplished via microphones, although in the case of electronic instruments such as keyboards and electronic drums, the signals can be input directly to a mixing console. The various signals are then combined at a mixer, and output to either power amplifiers and loudspeakers or to the inputs of personal monitor systems. Any amount of signal processing, such as equalizers or dynamics processing (compressors, limiters, etc.) can be added inbetween. A hardwired personal monitor system is similar (in signal flow terms) to a traditional wedge system, since the belt pack is basically a power amplifier, and the earphones are tiny loudspeakers. A wireless personal monitor system, however, adds a few more components, specifically a transmitter and receiver, Fig. 37-3. From the output of the mixer, the audio signal goes to a transmitter, which converts it to a radio frequency (RF) signal. A belt-pack receiver, worn by the performer, picks up the RF signal and converts it back to an audio signal. At this stage the audio is then amplified and output to the earphones.

The term personal monitors is derived from several factors, but basically revolves around the concept of taking a monitor mix and tailoring it to each performer’s specific needs, without affecting the performance or listening conditions of the others. The concept is broader than that of in-ear monitoring, which states where the monitors are positioned, but gives no further information on the experience.

The four most prominent benefits when using them are:

• Improved sound quality.
• Portability.

37.3 Sound Quality

There are several factors that, when taken as a whole, result in improved sound quality with personal monitor systems. These factors include adequate volume for the performers, gain-before-feedback, hearing conservation, reduced vocal strain, and less interference with the audience mix.

37.3.1 Adequate Volume

The most common request given to monitor engineers is “Can you turn me up?” (Sometimes not phrased quite so
politely.) Unfortunately, it is not always quite that simple. Many factors can limit how loud a signal can be brought up when using traditional floor monitors: size of the power amplifiers, power handling of the speakers, and most importantly, potential acoustic gain (see Gain-Before-Feedback below). Another factor that makes hearing oneself difficult is the noise level onstage. Many times, vocalists rely solely on stage monitors, unlike guitarists, bassists, and keyboardists whose instruments are generally amplified to begin with. Drummers, of course, are acoustically loud without amplification. Volume wars are not uncommon as musicians struggle to hear themselves over the ever-increasing din. The clarity of the vocals is often obscured as other instruments are added to the monitor mix, which becomes increasingly necessary if fewer mixes are available. Keyboards, acoustic guitars, and other instruments that rely on the monitors often compete with the vocals for sonic space. A personal monitor system, which isolates the user from crushing stage volumes and poor room acoustics, allows the musician to achieve a studiolike quality in the onstage listening experience. Professional, isolating earphones, when used properly, provide more than 20 dB of reduction in background noise level. The monitor mix can then be tailored to individual taste without fighting against otherwise uncontrollable factors.

### 37.3.2 Gain-Before-Feedback

More amplification and more loudspeakers can be used to achieve higher monitoring levels with traditional stage wedges, but eventually the laws of physics come into play. The concept of gain-before-feedback relates to how loud a microphone can be turned up before feedback occurs. Closely related is PAG, or potential acoustic gain. The PAG equation is a mathematical formula that can be used to predict how much gain is available in a sound system before reaching the feedback threshold, simply by plugging in known factors such as source-to-microphone distance and microphone-to-loudspeaker distance, Fig. 37-4. Simply stated, the farther away a sound source is from the microphone, or the closer the microphone is to the loudspeaker, or the farther away the loudspeaker is from the listener, then the less available gain-before-feedback. Now picture a typical stage. The microphone is generally close to the performer’s mouth (or instrument); that’s good. The microphone is close (relatively) to the monitor loudspeaker; that’s bad. The monitor loudspeaker is far (relatively) from the performer’s ears; that’s also bad. Feedback occurs whenever the sound entering a microphone is reproduced by a loudspeaker and “heard” by the same microphone again. To achieve a decent monitoring level requires quite a bit of available gain. But given the above situation, two major factors drastically reduce the available gain-before-feedback. Compounding the problem is the issue of NOM, or number of open microphones. Every time you double the number of open microphones, the available gain-before-feedback drops by 3 dB. With four open microphones onstage instead of one, the available gain has dropped by 6 dB.

![Figure 37-4. PAG values.](image)

**Potential Acoustic Gain**

\[
PAG = 20 \left( \log D_1 - \log D_2 + \log D_0 - \log D_0 \right) - 10 \log \text{NOM} - 6
\]

Solutions? The PAG equation assumes omnidirectional microphones, so using cardioid or even supercardioid pattern microphones will help; just don’t point them at the speakers. Also, the equation assumes that the sound system has a perfectly flat frequency response. The most commonly employed tool for reducing feedback due to response problems is the graphic equalizer. Since some frequencies will feed back before others, an equalizer allows a skilled user to reduce the monitor system’s output of those troublesome frequencies. This technique results in approximately 3–9 dB of additional gain, assuming the microphone position doesn’t change. It is common practice for some monitor engineers to attempt to equalize the monitor system to the point where there is no feedback, even with a microphone pointed right into the speaker cone. Unfortunately, the fidelity of the monitor is often completely destroyed in an effort to eliminate feedback using equalizers. Even after equalization has flattened the response of the monitor system, PAG again becomes the limiting factor. At this point, the microphone can’t be moved much closer to the sound source, and moving the loudspeaker closer to the performer’s ears also makes it closer to the microphone, negating any useful effect on PAG.

Personal monitoring completely removes PAG and gain-before-feedback issues. The “loudspeakers” are
now sealed inside the ear canal, isolated from the microphone. With the feedback loop broken, it is possible to achieve as much volume as necessary—which leads to the next topic.

### 37.3.3 Hearing Conservation

If there’s an overriding theme in switching performers to personal monitors, it’s so that they can hear themselves better. But it doesn’t do any good if eventually they can’t hear at all. As mentioned earlier, volume wars on stage are a universal problem. Prolonged exposure to extremely high sound pressure levels can quickly cause hearing to deteriorate. Some performers have taken to wearing ear plugs to protect their hearing, but even the best ear plugs cause some alteration of frequency response. Personal monitors offer a level of hearing protection equal to that of ear plugs, but with the additional benefit of tiny loudspeakers in the plugs. The monitoring level is now in the hands of the performer. If it seems to be too loud, there is no excuse for not turning the monitors down to a comfortable level. The use of an onboard limiter is strongly recommended to prevent high-level transients from causing permanent damage. In larger, complex monitor rigs, outboard compressors and limiters are often employed to offer a greater degree of control and protection.

**NOTE:** Using a personal monitor system does not guarantee that the user will not or cannot suffer hearing damage. These systems are capable of producing levels in excess of 130 dB SPL. Prolonged exposure to these kinds of levels can cause hearing damage. It is up to the individual user to be responsible for protecting his or her own hearing. Please see the section Safe Listening with Personal Monitors for more information.

**Reduced Vocal Strain.** Closely related to the volume issue, the ability to hear more clearly reduces vocal strain for singers. In order to compensate for a monitor system that does not provide adequate vocal reinforcement, many singers will force themselves to sing with more power than is normal or healthy. Anyone who makes a living with their voice knows that once you lose it, you lose your livelihood. Every precaution should be taken to protect your instrument, and personal monitors are a key ingredient in helping vocalists continue to sing for years to come. (See Adequate Volume, previously discussed.)

**Interference with the Audience Mix.** The benefits of personal monitors extend beyond those available to the performer. An unfortunate side-effect of wedge monitors is spill from the stage into the audience area. Although directional at high frequencies, speaker cabinets radiate low-frequency information in a more or less omnidirectional manner. This situation aggravates the already complex task facing the FOH (front-of-house) engineer, who must fight against loud stage volumes when creating the audience mix. The excessive low frequencies coming off the backs of the monitors make the house mix sound muddy and can severely restrict the intelligibility of the vocals, especially in smaller venues. But eliminate the wedges, and the sound clears up considerably.

### 37.3.4 Portability

Portability is an important consideration for performing groups that travel, and for installations where the sound system or the band performance area is struck after every event. Consider the average monitor system that includes three or four monitor wedges at roughly 40 pounds each, and one or more power amplifiers at 50 pounds—this would be a relatively small monitor rig. A complete personal monitor system, on the other hand, fits in a briefcase. Purely an aesthetic consideration, removing wedges and bulky speaker cables from the stage improves the overall appearance. This is of particular importance to corporate/wedding bands and church groups, where a professional, unobtrusive presentation is as important as sound quality. Personal monitors result in a clean, professional-looking stage environment.

### 37.3.5 Mobility

Monitor wedges produce a *sweet spot* on stage, a place where everything sounds pretty good, Fig. 37.5. If you move a foot to the left or right, suddenly things do not sound as good anymore. The relatively directional nature of loudspeakers, especially at high frequencies, is responsible for this effect. Using personal monitors, though, is like using headphones—the sound goes where you go. The consistent nature of personal monitors also translates from venue to venue. When using wedges, room acoustics play a large part in the overall quality of the sound. Since professional earphones form a seal against ambient noise, acoustics are removed from the equation. In theory, given the same band with the same members, the monitor settings could remain virtually unchanged, and the mix will sound the same every night.
37.3.6 Personal Control

Perhaps the most practical benefit to personal monitors is the ability for performers to have direct control over what they are hearing. While still relying on the sound engineer to make fine adjustments, personal monitor systems give the performer some ability to make broad adjustments, such as overall volume, pan, or the ability to choose different mixes. If everything in the mix needs to be louder, instead of giving a series of complex hand gestures to the monitor engineer, the performer can raise the overall volume directly from the belt pack.

Many professional systems utilize a dual-mono scheme, where the belt pack combines the left and right audio channels of a stereo system and sends the combined signal to both sides of the earphones, Fig. 37-6. The inputs to the system should now be treated as “Mix 1” and “Mix 2” instead of left and right. The balance control on the receiver acts as a mix control, allowing the performer to choose between two mixes, or listen to a combination of both mixes with control over the level of each. Panning to the left gradually increases the level of Mix 1 in both ears, while reducing the level of Mix 2, and vice versa. This feature is referred to by different names, such as MixMode™ (Shure) or FOCUS (Sennheiser), but the function is basically the same. Less expensive, mono-only systems can offer a similar type of control by providing multiple inputs at the transmitter, with a separate volume control for each. Consequently, the transmitter should be located near the performer for quick mix adjustments.

Putting a small, outboard mixer, such as the Shure P4M, near the performer increases the amount of control, Fig. 37-7. By giving control of the monitor mix to the performer, the sound engineer can spend more time concentrating on making the band sound good for the audience instead of worrying about making the band happy.

The cost of transitioning to personal monitors has recently dropped dramatically. A basic system costs as much, if not less than, a typical monitor wedge, power amplifier, and graphic equalizer combination. Expanding a system is also more cost effective. When providing additional wedges for reproducing the same mix, a limited number can be added before the load on the amplifier is too great, and another amp is required. With a wireless personal monitor system, however, the number of receivers monitoring that same mix is unlimited. Additional receivers do not load the transmitter, so feel free to add as many receivers as necessary without adding more transmitters. For bands that haul their own PA, transportation costs may be reduced as well. Less gear means a smaller truck, and possibly one less roadie.
37.4 Choosing a System

Given the personal nature of in-ear monitoring, choosing the right system is an important step. Several choices are available. Present as well as future needs should be taken into account before making an investment.

Personal monitor systems come in two basic varieties—wireless or hardwired. A hardwired system requires the performer to be tethered to a cable, which is not necessarily a negative. Drummers and keyboard players who stay relatively stationary, or even backup singers, can take advantage of the lower cost and greater simplicity of a hardwired personal monitor system. Simply connect the monitor sends to the inputs of the hardwired system and dial up a mix. Hardwired systems also work worldwide without the hassle of finding clear frequencies or dealing with local wireless laws and codes. Lastly, if several performers require the same mix, hardwired systems with sufficiently high input impedance can be daisy-chained together without significant signal loss. Alternately, a distribution amplifier could be used to route a signal to multiple hardwired systems. A distribution amplifier takes a single input and splits it to multiple outputs, often with individual level control.

Wireless equipment, by nature, requires special considerations and attention to detail. But the advantages many times outweigh the increased cost and complexity. One of the main benefits of personal monitors is a consistent mix no matter where the performer stands; going wireless allows full exploitation of this advantage. Additionally, when several performers require the same mix, hardwired systems with sufficiently high input impedance can be daisy-chained together without significant signal loss. Alternately, a distribution amplifier could be used to route a signal to multiple hardwired systems. A distribution amplifier takes a single input and splits it to multiple outputs, often with individual level control.

Secondly, consider the travel requirements, if any, of the users. Most wireless equipment, whether it is a microphone system or personal monitors, transmits on unused television channels. Since these unoccupied channels will be different in every city, it is imperative that appropriate frequencies are chosen. For a group that performs only in one metropolitan area, or for a permanent installation, once a good frequency is chosen, there should be no need to change it. However, for touring acts, the ability to change operating frequencies is essential.

The following important specifications for selecting wireless microphones also apply when selecting a personal monitor system:

- Frequency range.
- Tuning range (bandwidth).
- Number of selectable frequencies.
- Maximum number of compatible frequencies.

37.5 Configuring a Personal Monitor System

Choosing the proper system requires some advance planning to determine the monitoring requirements of the situation. At a minimum, the three questions below require answers:

- How many mixes does the situation require.
- Will the monitor mix be stereo or mono.
- How many monitor mixes can be supplied by the mixing console.

This information directly relates to the equipment needed to satisfy the in-ear monitoring requirements of the performers. The following example details the thought process involved in deciding how to configure a system.

37.5.1 How Many Mixes Are Required?

The answer to this question depends on how many performers there are, and their ability to agree on what they want to hear in the monitors. For example, typical rock band instrumentation consists of drums, bass, guitar, keys, lead vocal, and two backup vocals provided by the guitar player and keyboardist. In a perfect world, everyone would want to listen to the same mix, so the answer to this question would be one mix. However, most real-world scenarios require more than one monitor mix. An inexpensive configuration uses two mixes, one consisting of vocals, the other of instruments. Using a system that features dual-mono operation, the performers individually choose how much of each mix they wish to hear, Fig. 37-8. This scenario is a cost-effective way to get into personal monitors, yet still requires a fairly good degree of cooperation among band members.

Another scenario gives the drummer a separate mix, Fig 37-9. This option works well for two reasons:
1. Drummers, in general, will want to hear considerably more drums in the monitors than other band members.
2. For bands who perform on small stages the drums are so loud that they are easily heard acoustically (with no additional sound reinforcement). Therefore, drums may not even be necessary in the other mixes. Now there are three mixes—the vocal mix, the instruments (minus drums), and the drummer’s mix.
Up to this point, it is assumed that the vocalists are able to agree on a mix of the vocal microphones. While forcing singers to share the same mix encourages a good vocal blend, this theory commonly falls apart in practice. Often, separating out the lead vocalist to an individual mix will address this issue, and this can be handled in one of two ways. First, place some of the backup vocal mics in the instruments mix, and adjust the vocal mix to satisfy the lead singer, even if that means adding some instruments to the vocal mix. This scenario results in:

- An individual mix for the lead singer.
- A mix for the guitarist and keyboardist that includes their vocals.
- A drum mix (at this point the bass player can drop in wherever he or she wants, often on the drummer’s mix).

The second option is to create a fourth mix for the lead singer, without affecting the other three. This configuration allows the guitarist and keyboardist to retain control between their vocals and instruments, while giving the lead singer a completely customized mix. Does the bass player need a separate mix? That is number five. Adding a horn section? That could easily be a sixth mix. More mixes can be added until one of two limitations is reached; either the mixer runs out of outputs, or the maximum number of compatible frequencies for the wireless monitor system has been reached.

37.5.2 Stereo or Mono?

Most personal monitor systems allow for monitoring in either stereo or mono. At first glance, stereo may seem the obvious choice, since we hear in stereo, and almost every piece of consumer audio equipment offers at least
stereo, if not multichannel surround, capabilities. While it may not be applicable to all situations, especially with a limited number of mixes available, a monitor mix created in stereo can more accurately re-create a realistic listening environment. We spend our entire lives listening in stereo; logically, a stereo monitor mix increases the perception of a natural sound-stage. Monitoring in stereo can also allow for lower overall listening levels. Imagine a group with two guitar players sharing the same mix. Both instruments are occupying the same frequency spectrum, and in order for each guitarist to hear, they are constantly requesting their own level be turned up. When monitoring in mono, the brain differentiates sounds based only on amplitude and timbre. Therefore, when two sounds have roughly the same timbre, the only clue the brain has for perception is amplitude, or level. Stereo monitoring adds another dimension, localization. If the guitars are panned, even slightly, from center, each sound occupies its own “space.” The brain uses these localization cues as part of its perception of the sound. Research has shown that if the signals are spread across the stereo spectrum, the overall level of each signal can be lower, due to the brain’s ability to identify sounds based on their location.

Stereo, by its very nature, requires two channels of audio. What this means for personal monitor users is two sends from the mixer to create a stereo monitor mix—twice as many as it takes to do a mono mix, Fig. 37-10. Stereo monitoring can rapidly devour auxiliary sends; if the mixer has four sends, only two stereo mixes are possible, versus four mono. Some stereo transmitters can be operated in a dual-mono mode, which provides two mono mixes instead of one stereo. This capability can be a great way to save money. For situations that only require one mix, such as solo performer, mono-only systems are another cost-effective option. Strongly consider a system that includes a microphone input that will allow the performer to connect a microphone or instrument directly to the monitor system, Fig. 37-3.

37.5.3 How Many Mixes Are Available from the Mixing Console?

Monitor mixes are typically created using auxiliary sends from the front-of-house (audience) console, or a dedicated monitor console if it’s available. A typical small-format console will have at least four auxiliary sends. Whether or not all these are all available for monitors is another matter. Aux sends are also used for effects (reverb, delay, etc.). At any rate, available auxiliary sends are the final determinant for the number of possible monitor mixes. If the answer to question 1 (number of required mixes) is greater than the answer to question number 3 (number of mixes available), there are two options: reconfigure the required monitor mixes to facilitate sharing mixes with the existing mixer, or get a new mixer.

37.5.4 How Many Components Are Needed?

After answering the above questions, plug the numbers into the following equations to determine exactly how many of each component are needed and choose a system that can handle these requirements.

**Stereo Mixes:**
Number of transmitters = number of desired mixes.
Number of aux sends = 2 (number of transmitters), (ex. 4 mixes requires 4 transmitters and 8 aux sends).

**Dual-Mono Mixes:**
Number of transmitters = (number of desired mixes)/2
Number of required aux sends = 2(number of transmitters) (ex. 4 mixes requires 2 transmitters and 4 aux sends).

**Mono Mixes:**
Number of transmitters = number of desired mixes.
Number of aux sends = number of transmitters (ex. 4 mixes requires 4 transmitters and 4 aux sends).

**Number of receivers = number of performers**

37.6 Earphones

37.6.1 Earphone Options

The key to successful personal monitoring lies in the quality of the earphone. All the premium components in the monitoring signal path will be rendered ineffective by a low-quality earphone. A good earphone must combine full-range audio fidelity with good isolation, comfort, and inconspicuous appearance. The types of earphones available include inexpensive Walkman®-type ear-buds, custom molded earphones, and universal earphones. Each type has its advantages and disadvantages. While relatively affordable, ear-buds have the poorest isolation, are not really designed to withstand the rigors of a working musician’s environment, and are likely to fall out of the ear. On the other end of the spectrum, custom molded earphones offer exceptional sound quality and isolation, a considerably higher price tag,
and are difficult to try before buying since they are made specifically for one person’s ears. The procedure for getting custom molds involves a visit to an audiologist. The audiologist makes an impression of the ear canals by placing a dam inside the ear to protect the eardrum, and fills them with a silicone-based material that conforms exactly to the dimensions of the ear canal. The impressions are then used to create the custom molded earphones. Another visit to the audiologist is required for a final fitting. Manufacturers of custom molded earphones include Ultimate Ears, Sensaphonics, and Future Sonics, Fig. 37-11.

A third type of earphone is the universal fit, Fig 37-12. Universal earphones combine the superior isolation and fidelity of custom molded designs with the out-of-the-box readiness of ear-buds. The universal nature of this design is attributed to the interchangeable sleeves that are used to adapt a standard size earphone to any size and shape of ear canal. This design allows the user to audition the various sleeves to see which works best, as well as being able to demo the earphones before a purchase is made. The different earphone sleeve options include foam, rubber flex sleeves, rubber flange tips, and custom molded. The foam sleeves resemble regular foam earplugs, but with a small hole in the center of the foam lined with a tube of plastic. They offer excellent isolation and good low-frequency performance. On the downside, they eventually get dirty and worn, and need to be replaced. Proper insertion of the foams also takes longer—relative to the other options—since the earphone needs to be held in place while the foam expands. For quick insertion and removal of the earphones, flexible rubber sleeves may be a good choice. Made of soft, flexible plastic, flex sleeves resemble a mushroom cap and are usually available in different sizes. While the seal is usually not as tight as with the foams, rubber sleeves are washable and reusable. The triple-flange sleeves have three rings (or flanges) around a central rubber tube. They are sometimes referred to as Christmas trees based on their shape. The pros and cons are similar to that of the flex sleeves, but they have a different comfort factor that some users may find more to their liking. The fourth, and most expensive, option is custom sleeves. The custom sleeves combine the relative ease of insertion and permanency of flex sleeves with the superior (depending on the preference of the user) isolation of the foams. The process for obtaining custom sleeves for universal earphones is very similar to that of getting custom molded earphones; a visit to an audiologist is required to get impressions made. Custom sleeves also give the user many of the same benefits as custom molded earphones, but usually at a lower cost, and with the added benefit of being able to interchange earphones.

Figure 37-11. Custom molded earphones. Courtesy Sensaphonics.
with the sleeves if they get lost, stolen, or are in need of repair. A final option, for users of the ear-bud type of earphone, is a rubber boot that fits over the earphone. This option typically has the poorest isolation.

**Figure 37-12.** Shure SCL5 universal earphone. Courtesy Shure Incorporated.

If there is ever a problem with a universal earphone, another set can be substituted with no negative repercussions. A custom molded earphone does not allow for this kind of versatility; if one needs repair, the only alternative is to have a backup to use in the interim.

**IMPORTANT NOTE:** There are several brands of custom molded earplugs with internal filters that have relatively flat frequency response and different levels of attenuation. Although it may be physically possible to make universal earphones fit into the plugs with the filter removed, this is not advised. The location of the earphone shaft in the ear canal is crucial to obtaining proper frequency response, and most earplugs will prevent them from getting in the proper position. Once again, custom molded earplugs are NOT an acceptable alternative to custom sleeves.

### 37.6.2 Earphone Transducers

The internal workings of earphones vary as well. There are two basic types of transducer used in earphone design—dynamic and balanced armature.

The dynamic types work on the same principle as dynamic microphones or most common loudspeakers. A thin diaphragm is attached to a coil of wire suspended in a magnetic field. Diaphragm materials include Mylar (in the case of dynamic microphones) or paper (for loudspeakers). As current is applied to the coil, which is suspended in a permanent magnetic field, it vibrates in sympathy with the variations in voltage. The coil then forces the diaphragm to vibrate, which disturbs the surrounding air molecules, causing the variations in air pressure we interpret as sound. The presence of the magnet-voice coil assembly dictates a physically larger earphone. Dynamic transducers are commonly used in the ear-bud types, but recent technological advances have allowed them to be implemented in universal designs. They are also found in some custom molded earphones.

Originally implemented in the hearing aid industry, the balanced armature transducer combines smaller size with higher sensitivity. A horseshoe-shaped metal arm has a coil wrapped around one end and the other suspended between the north and south poles of a magnet. When alternating current is applied to the coil, the opposite arm (the one suspended in the magnetic field) is drawn towards either pole of the magnet, Fig. 37-13. The vibrations are then transferred to the diaphragm, also known as the *reed*, usually a thin layer of foil. Balanced armature transducers are similar to the elements used in controlled magnetic microphones. In addition to the increased sensitivity, they typically offer better high-frequency response. Achieving a good seal between the earphone and the ear canal is crucial to obtaining proper frequency response.

**Figure 37-13.** Dynamic and balanced armature transducer. Courtesy Shure Incorporated.

A further subdivision occurs with the use of multiple transducers. Dual transducer (*dual driver*) earphones are the most common. Another example of a loudspeaker
with dual-transducer design is one with a horn (or tweeter) for high-frequency reproduction and a woofer for low-frequency sounds. The frequency spectrum is divided in two by a crossover network. Each driver only has to reproduce the frequency range for which it has been optimized. Dual driver earphones work on a similar principle—each earphone contains a tweeter and a woofer optimized for high- and low-frequency performance, respectively. Additionally, a passive crossover is built into the cable to divide the audio signal into multiple-frequency bands. The end result is usually much better low end, as well as extended high-frequency response. The additional efficiency at low frequencies may be of particular interest to bassists and drummers. A few companies have introduced triple-driver earphones, and hybrid earphones that combine both dynamic and balanced armature transducers in a single earphone.

37.6.3 The Occluded Ear

One final note for users who are new to earphones. When the ear canal is acoustically sealed (occluded), the auditory experience is different from normal listening. For those performers who have spent many years using traditional floor monitors, an adjustment period may be necessary. A common side effect for vocalists is undersinging. The sudden shock of hearing oneself without straining causes some vocalists to sing softer than they normally would, making it difficult for the FOH engineer to get the vocals loud enough in the house mix. Remember, the FOH engineer is still fighting the laws of PAG, so singers still need to project.

Another side effect of the occluded ear is a buildup of low frequencies in the ear canal. Sealing off the ear canal such as with an earplug, causes the bones of the inner ear to resonate due to sound pressure levels building up in the back of the mouth. This resonance usually occurs below 500 Hz and results in a hollow sound that may affect vocalists and horn players. Recent studies have shown, however, that ear molds that penetrate deeper into the ear canal (beyond the second bend) actually reduce the occlusion effect. The deeper seal reduces vibration of the bony areas of the ear canal.

37.6.4 Ambient Earphones

Some users of isolating earphones complain of feeling closed off or too isolated from the audience or performance environment. While isolating earphones provide the best solution in terms of hearing protection, many performers would appreciate the ability to recover some natural ambience. There are several ways in which this can be accomplished, the most common being ambient microphones. Ambient microphones are typically placed at fixed locations, nowhere near the listener’s ear, and the levels are controlled by the sound engineer instead of the performer. Additionally, the directional cues provided by ambient microphones (assuming a left/right stereo pair) are dependent on the performer facing the audience. If the performer turns around, the ambient cues will be reversed.

More natural results can be obtained by using a newer technology known as ambient earphones. An ambient earphone allows the performer, by either acoustic or electronic means, to add acoustic ambience to the in-ear mix. Passive ambient earphones have a port, essentially a hole in the ear mold, which allows ambient sound to enter the ear canal. While simple to implement, this method offers little in the way of control and could potentially expose the user to dangerous sound pressure levels. Active ambient earphones use minuscule condenser microphones mounted directly to the earphones. The microphones connect to a secondary device that provides the user with a control to blend the desired amount of ambience into the personal monitor mix. Since these microphones are located right at the ear, directional cues remain constant and natural. Ambient earphones not only provide a more realistic listening experience, but also ease between-song communication amongst performers.

37.7 Applications for Personal Monitors

Configuring personal monitor systems and making them work is a relatively simple process, but the ways in which they can be configured are almost limitless. This section takes a look at several typical system set-up scenarios. Personal monitor systems are equally useful for performance and rehearsal, and their benefits extend from small nightclub settings to large arena tours to houses of worship.

37.7.1 Rehearsals

For groups that already own a mixer, implementing a system for rehearsals is a simple process. There are a number of ways to get signal into the system, depending on how many mixes are necessary. To create a simple stereo mix, simply connect the main outputs of the mixer directly to the monitor system inputs. (Note that this works just as well for mono systems). Auxiliary
sends can also be used if separate mixes are desired. For bands that carry their own PA system (or at least their own mixer), this method allows them to create a monitor mix during rehearsal, and duplicate it during a performance. No adjustment needs to be made for the acoustic properties of the performance environment.

37.7.1.1 Performance, Club/Corporate/Wedding Bands—No Monitor Mixer

The majority of performing groups do not have the benefit of a dedicated monitor mixer. In this situation, monitor mixes are created using the auxiliary sends of the main mixing console. The number of available mixes is limited primarily by the capabilities of the mixer. At a basic level, most personal monitor systems can provide at least one stereo or two mono mixes. Therefore, any mixer employed should be capable of providing at least two dedicated, prefader auxiliary sends. Prefader sends are unaffected by changes made to the main fader mix. Postfader sends change level based on the positions of the channel faders. They are usually used for effects. Although postfader sends can be used for monitors, it can be somewhat distracting for the performers to hear level changes caused by fader moves.

For users that only have two auxiliary sends available, the best choice is a system that allows a dual-mono operating mode, since this allows for the most flexibility. Hookup is straightforward—just connect Aux Send 1 of the console to the left input and Aux Send 2 to the right input. (Use Aux 3 and 4 if those are the prefader sends—all consoles are different!) Then, depending on who is listening to what, create the mixes by turning up the auxiliary sends on the desired channels. A few common two-mix setups are listed below.

Each performer can choose which mix they want to listen to by adjusting the balance control on the receiver. Be sure the receivers are set for dual-mono operation, or each mix will only be heard on the left or right side, but not in both ears. Also remember that any number of receivers can monitor the same transmitter.

Some performers may prefer to listen to the house mix, so they can monitor exactly what the audience is hearing. Keep in mind that this may not always produce the desired results. Rarely will what sounds good in the ear canal sound equally as good through a PA system in a less-than-perfect acoustic environment. Many times, a vocal that seems to blend just right for an in-ear mix will get completely lost through the PA, especially in a small room when live instruments are used. This technique may be appropriate for electronic bands, where the majority of instruments is input directly to the mixer. The only sound in the room is that created by the sound system.

The more auxiliary sends a console has, the greater number of monitor mixes that is possible. See Tables 37-1 to 37-3 for more examples.

37.7.1.2 Club Level Bands—With Monitor Console

At this point, a typical small format FOH console has reached its limit for monitoring purposes. Bands that have graduated to the next level of performance (larger, more prestigious clubs and theaters or small tours) may find themselves in a position to take advantage of a dedicated monitor console. Most monitor boards are capable of providing at least eight mono (or four stereo) mixes. It now becomes practical for each band member to have his or her own dedicated mix. System hookup is again very simple—the various mix outputs from the monitor console are connected directly to the personal monitor system. Stereo monitoring is a much more viable option due to the large number of mixes available, as well as the presence of a skilled monitor engineer to adjust the mixes to the point of perfection.

Some performers even carry their own monitor console. Due to the consistent nature of personal monitors, a band with the same instrumentation and performers for every show can leave the monitor mix dialed-in on its console. Since venue acoustics can be completely disregarded, a few minor adjustments are all that is typically necessary during sound check.

A personal monitor mixer can also be used to augment the monitor console, if the performer desires some personal control over what is heard. In the past, drummers or keyboard players would use a small mixer and Y-cables to submix their instruments for in-ear monitors. A mixer with built-in mic splitting capability, such as the Shure P4M Personal Monitor Mixer, Fig. 37-7, can be used in the same capacity, but without the need for Y-cables.

37.7.1.3 Professional Touring System

When budget is no longer a consideration, personal monitoring can be exploited to its fullest capabilities. Many systems used by professional artists on large-scale tours often employ greater than sixteen stereo mixes.

A completely separate, totally personalized mix is provided for every performer onstage. Large frame monitor consoles are a requirement. For example, to provide sixteen stereo mixes requires a monitor console with thirty two outputs.

Effects processing is generally employed to a much larger extent than with a smaller system.

When operating a large number of wireless personal monitor systems, R-related issues become much more important. Frequency coordination must be done carefully to avoid interaction between systems as well as outside interference. Depending on the extent of the touring, a frequency agile system is desirable, if not required. Proper antenna combining, to reduce the number of transmitter antennas in close proximity, is a necessity. Directional antennas may also be used to increase range and reduce the chances of drop-outs due to multipath interference.

37.7.2 Mixing for Personal Monitors

Mixing for personal monitors may require a different approach than one used for a traditional monitor system. Often, the requirements for the performers are very involved, and can require a greater degree of attentiveness from the monitor engineer. In particular, many small nightclub sound systems typically provide monitors for the sole purpose of vocal reinforcement. An in-ear monitor system, due to its isolating nature, usually demands other sound sources be added to the monitor mix, especially if the instrumentalists choose to reduce their overall stage volume. Some performers may prefer a more active mix, such as hearing solos boosted, or certain vocal parts emphasized. This luxury usually requires a dedicated monitor console and sound engineer. The FOH engineer has enough responsibility mixing for the audience, and generally only alters the monitor mix on request from the performers. In most situations, except for the upper echelon of touring professionals, this approach is perfectly acceptable and still far superior to using wedges.

For performers who are mixing for themselves, there are other considerations. One of the advantages of having a professional sound engineer or monitor engineer is years of experience in mixing sound. This skill cannot be learned overnight. For bands that are new to personal monitors, there is a strong temptation to try to create a CD-quality mix for in-ears. While this is certainly possible with a trained sound engineer and the right equipment, it is unlikely that someone unfamiliar with the basic concepts behind mixing will be able to successfully imitate a professional mix.

A common mistake made by in-ear monitor novices is to put everything possible into the mix. Here’s an alternative to the everything-in-the-mix method:

1. Put the earphones on and turn the system on. DO NOT put any instruments in the mix yet.
2. Try to play a song. While performing, determine what instruments need more reinforcement.
3. Begin bringing instruments into the mix, one at a time. Usually, vocals come first since those are often the only unamplified instruments onstage.
4. Only turn things up as loud as necessary, and resist
the temptation to add instruments to the mix that can
be heard acoustically.

A note on monitor mixing: performers now have an
unprecedented level of personal control over what they
are hearing. The temptation to make oneself the loudest
thing in the mix is great, but this may not be the best for
the situation. Proper blending with the other members
of the ensemble will be next to impossible if the mix is
skewed too far from reality. Consider big bands that
normally play acoustically, or a vocal choir. These types
of ensembles create their blend by listening to each
other, not just themselves. If the lead trumpet player
uses a personal monitor system, and cranks the trumpet
up three times louder than everything else, there is no
accurate reflection for the musician on whether he or
she is playing too loud or too soft. Remember, great
bands mix themselves—they don’t rely entirely on the
sound tech to get it right.

37.7.3 Stereo Wireless Transmission

Many microphones and most circuitry used in the repro-
duction of audio signals have a bandwidth of 20 kHz
(20 Hz–20 kHz) or more. Digital devices operating at a
sampling rate of 44.1 kHz have frequency responses
extending to 22 kHz; 48 kHz sample rates are flat out to
24 kHz. Many boutique analog devices boast flat
response beyond 30 kHz and sometimes 40 kHz.
Undoubtedly, these are great advances in the sound
reproduction field, unless audio with that kind of band-
width is sent through the air in the form of a stereo
encoded wireless transmission.

Every so often, a performer will complain of an ear
mix that just doesn’t sound quite right, no matter what
adjustments are made to levels or EQ. Sometimes it’s a
simple image shift; other times it is distortion with no
apparent cause. The output of the mixing console
sounds fine, as does the headphone output of the trans-
mitter. Changing frequencies, cables, earpieces, and
bodypacks makes no difference. Ultimately, respecting
the frequency response limitations of stereo wireless
transmission is the key to successfully creating stable,
good-sounding ear mixes. There are several ways this
can be accomplished, but as a general rule, avoid any
frequency boosts above 15 kHz. Stereo multiplexed
wireless transmission has a limited frequency response
of 50 Hz–15 kHz. This frequency response limitation
has been in place since the FCC approved stereo multi-
plexed transmissions (MPX) back in 1961. Audio engi-
neers mixing stereo wireless transmissions for on-stage
talent wearing in-ear monitors should be aware of the
operating principles of MPX stereo to achieve the
desired results at the receiver.

In many cases, switching to mono transmission
clears up any wireless anomaly (except for interference)
in these types of monitoring systems. However, many
users want to monitor in stereo, so being aware of the
limitations of MPX encoding will allow for greater
talent satisfaction.

Stereo wireless transmitters use a steep cut filter, or
brick-wall filter, prior to modulation, centered at 19 kHz
to create a safe haven for the required pilot tone. MPX
encoders in stereo wireless transmitters use a 19 kHz
pilot tone to inform receivers that the transmission is
encoded in stereo. If the receiver does not sense a
19 kHz pilot tone, it will only demodulate a mono
signal. Moreover, if the 19 kHz pilot tone is not stable,
stereo imaging degrades at the receiver. Most impor-
tantly, if in-ear monitor receivers do not sense stable
19 kHz pilot tones, they will mute (this is called tone-
key squelch, a circuit designed to keep the receiver
muted when the corresponding transmitter is turned
off). Problems are created due to the extensive EQ capa-
bilities of modern mixing consoles, which offer high-
frequency shelving equalization from as low as 10 kHz
to as high 12, 15, and even 16 kHz. Digital mixing
consoles offer parametric filtering that can center on
practically any frequency and boost by as much as
18 dB. With a multichannel mixing board, it is easy
enough to create a counteractive frequency response at
the frequency of interest—19 kHz. In stereo wireless,
there are two pieces of information actually being trans-
mitt ed, the mono or sum signal (left + right) and the
difference (left – right) channel, each occupying a
15 kHz-wide swath of spectrum. The 19 kHz pilot tone
is centered in between these two signals, Fig. 37-14.

![Figure 37-14. Stereo MPX encoding.](image-url)
The stereo image is restored in the receiver by adding the sum and difference signals to create the left channel, and subtracting them to derive the right channel.

\[(L + R) + (L - R) = 2L\]

\[(L + R) - (L - R) = 2R\]

This system ensures mono compatibility, since the received signal will simply collapse to mono when the pilot tone is lost. Only the \(L + R\) sum signal remains.

However, since the 19 kHz pilot tone resides in the audio band, it can easily be compromised by the program material. The result of these high-frequency components getting into the modulator can cause, at best, degradation of stereo separation and distortion, and in worst-case situations, muting of the receiver. Add the high-frequency shelf used in the pre-emphasis curves prior to the companding circuits in stereo transmitters (a form of noise reduction), and it is easy to see how a small high-frequency boost on a channel strip can have a huge effect on what is heard after the RF link. If the audio signal modulates the pilot tone, stereo reception and the resultant sound quality will be poor. If upper harmonics of musical instruments aggravate the \((L - R)\) sidebands (especially in a transient manner—tambourines, triangles, high hats, click tracks, etc.), stereo separation can degrade, frequency response can be compromised, and even dynamic interactions between one channel and another can be detected.

Several simple practices go a long way toward improving stereo transmission:

- Refrain from extreme stereo panning. Instead of panning hard left and right, try the 10 o’clock and 2 o’clock positions.
- Use equalization sparingly prior to stereo transmission for smoother MPX encoding.
- Use \(1/10\) of an octave notch filters at 16 kHz on console output busses to increase the slope of the MPX filter. This is the best way to avoid disturbing the pilot tone.

### 37.7.4 Personal Monitors for Houses of Worship and Sound Contractors

The advantages of using personal monitors extend beyond those of just the performers. The above examples illustrate the benefits to the performer, and from a strictly music industry-oriented point of view. This section will discuss how personal monitors can be a useful tool for the sound contractor, specifically as they apply to modern houses of worship.

Musical performances are rapidly becoming a more prominent part of the worship service. Praise teams and contemporary music groups, while bringing new levels of excitement to traditional church services, also bring with them the problems of an average rock band. Most prominent among these problems are volume wars. Drums naturally tend to be the loudest thing on stage. The guitarist, in order to hear himself better, turns his amplifier up louder. The singers then need more monitor level to compete with the rest of the band. And then the cycle begins again. In any live sound situation, church or otherwise, loud stage volumes can distract from the overall sound in the audience. Try an easy experiment at the next sound check. When the band is satisfied with the monitor mix, turn off the audience PA and just listen to the sound coming off the stage. It’s probably loud enough that the main sound system doesn’t need to be turned on! To compound matters, the “backwash” off the floor monitors consists primarily of low-frequency information that muddies-up the audience mix. While this situation creates headaches for most sound engineers, it is even worse in the church environment. The majority of Sunday morning service attendees are not looking for an extremely loud rock and roll concert, but in some cases the congregation mix gets this loud just so it can be heard over the stage monitors. If the main system is off, and it’s still too loud, what can be done? Turn down the floor monitors and the band complains—not to mention how terrible it will sound.

With the band using personal monitors, these problems evaporate. Traditional floor monitors can be completely eliminated. For part two of our experiment, turn off the stage monitors while the band is playing. Notice how much clearer the audience mix becomes? This is how it would sound if the band were using personal monitors. Also, personal monitors are not just for vocalists. Drummers with in-ear monitors tend to play quieter. When the loudest instrument on stage gets quieter, everything else can follow suit. Some churches take this a step further by using electronic drums, which create little, if any, acoustic noise. Bass, keyboard, and electric guitar can also be taken directly into the mixer if the players are using personal monitors, eliminating the need for onstage amplifiers. The end result is a cleaner, more controlled congregation mix, and musicians can have very loud monitors without affecting the congregation.

Secondly, consider the feedback issue. Feedback occurs when the sound created at the microphone comes out of a loudspeaker, and reenters the microphone. The closer the loudspeaker is to the microphone, the greater
the chance for feedback. Eliminating the floor monitor also eliminates the worst possible feedback loop. With the “loudspeakers” sealed inside the ear canal, there is no chance for the signal to reenter the microphone. No equalizer or feedback reducer will ever be as effective as personal monitors at eliminating feedback on the stage.

Many other uses are possible for personal monitors. Choir directors could use them for cues, or to hear the pastor more clearly. Pastors who desire monitor reinforcement of their speech microphones, a sure-fire recipe for feedback, will find this a much better solution. Organists located at the rear of the sanctuary could use them to better hear the choir located up front, or also to receive cues. The advantages extend well beyond the benefits to the performer, and increase the overall quality of the service and the worship experience.

### 37.8 Expanding the Personal Monitor System

#### 37.8.1 Personal Monitor Mixers

Personal monitoring gives the performer an unprecedented level of control. But for the performer who desires more than simple volume and pan operation, an additional mixer may be implemented. Personal monitor mixers are especially useful for bands who have a limited number of available monitor mixes, or who do not have a monitor engineer, or anyone at all to run sound. In a perfect world, all performers would be happy listening to the exact same mix; in reality, everyone may want to hear something different. A small mixer located near the performers allows them to customize their mix to hear exactly what they desire. Theoretically, any mixer can double as a personal monitor mixer, but most lack one key feature; the input signals need to find their way to the main (FOH) mixer somehow. Large sound systems with separate monitor consoles use transformer-isolated splitters to send the signals to two places, but these are prohibitively expensive for most working bands and small clubs. Y-cables can be used to split microphone signals, but they can get messy and are somewhat unreliable. A few manufacturers produce mixers with integrated microphone splitters. These range from basic four channel mixers with only volume and pan controls for creating a single mix to larger monitor consoles that can provide four or more stereo mixes along with fader control and parametric equalization.

#### 37.8.2 Distributed Mixing

Distributed mixing is the direct result of advances in the area of digital audio networking. By converting analog audio signals to digital, audio can be routed to many locations without degradation or appreciable signal loss. Unlike with analog personal mixers, cabling is far simpler. Typically, analog outputs from a mixing console connect to an analog-to-digital converter. Multiple channels of digital audio can then be routed from the A/D converter to personal mixing stations located by each performer, using a single common Ethernet (Cat-5) cable, thus eliminating a rat’s nest of microphone cables or the large, unwieldy cable snakes required for analog audio distribution. Cat-5 cable is inexpensive and readily available. The mixing station provides an analog headphone output that can drive a set of isolating earphones directly, or better yet, connect to either a hardwired or wireless personal monitor system. If nothing else, the personal monitor system offers the advantage of a limiter for some degree of hearing protection, as well as a volume control at the performer’s hip. The mixers supplied with most distributed systems do not always have a limiter. Most systems provide eight or sixteen channels of audio, allowing each performer to create his or her own custom mix, independent of other performers and without the intervention of a sound engineer. Note that giving this level of control to the performers will probably require some training in the basics of mixing to be successful (see Creating a Basic Monitor Mix above).

#### 37.8.3 Supplementary Equipment

In-ear monitoring is a different auditory experience from traditional stage monitoring. Since your ears are isolated from any ambient sound, the perception of the performance environment changes. There are several other types of audio products that can be added to a personal monitor system to enhance the experience, or try to simulate a more “live” feel.

##### 37.8.3.1 Drum Throne Shakers

Something performers may miss when making the transition to personal monitors are the physical vibrations created by amplified low-frequency sounds. Drummers and bass players are particularly sensitive to this effect. Although using a dual driver earphone usually results in more perceived bass, an earphone cannot replicate the physical sensation of air moving (sound) anywhere but in the ear canal. Drum shakers exist not to provide
audible sound reinforcement, but to re-create the vibrations normally produced by subwoofers or other low-frequency transducers. Commonly found in car audio and cinema applications, these devices mechanically vibrate in sympathy with the musical program material, simulating the air disturbances caused by a loud subwoofer, Fig. 37-15. They can be attached to drum thrones or mounted under stage risers.

37.8.3.2 Ambient Microphones

Ambient microphones are occasionally employed to restore some of the “live” feel that may be lost when using personal monitors. They can be used in several ways. For performers wishing to replicate the sound of the band on stage, a couple of strategically placed condenser microphones can be fed into the monitor mix. Ambient microphones on stage can also be used for performers to communicate with one another, without being heard by the audience. An extreme example (for those whose budget is not a concern) is providing each performer with a wireless lavalier microphone, and feeding the combined signals from these microphones into all the monitor mixes, but not the main PA. Shotgun microphones aimed away from the stage also provide good audience pick-up, but once again, a good condenser could suffice if shotguns are not available.

37.8.3.3 Effects Processing

Reverberant environments can be artificially created with effects processors. Even an inexpensive reverb can add depth to the mix, which can increase the comfort level for the performer. Many singers feel they sound better with effects on their voices, and in-ear monitors allow you to add effects without disturbing the house mix or other performers.

Outboard compressors and limiters can also be used to process the audio. Although many personal monitor systems have a built-in limiter, external limiters will provide additional protection from loud transients. Compression can be used to control the levels of signals with wide dynamic range, such as vocals and acoustic guitar, to keep them from disappearing in the mix. More advanced monitor engineers can take advantage of multiband compression and limiting, which allows dynamics processing to act only on specific frequency bands, rather than the entire audio signal.

In-ear monitor processors combine several of these functions into one piece of hardware. A typical in-ear processor features multiband compression and limiting, parametric equalization, and reverb. Secondary features, such as stereo spatialization algorithms that allow for manipulation of the stereo image, vary from unit to unit.

37.8.4 Latency and Personal Monitoring

An increasing number of devices used to enhance the personal monitor system are digital instead of analog. While the advantages of digital are numerous, including more flexibility and lower noise, any digital audio device adds a measurable degree of latency to the signal path, which should be of interest to personal monitor users. Latency, in digital equipment, is the amount of time it takes for a signal to arrive at the output after entering the input of a digital device. In analog equipment, where audio signals travel at the speed of light, latency is not a factor. In digital equipment, however, the incoming analog audio signal needs to be converted to a digital signal. The signal is then processed, and converted back to analog. For a single device, the entire process is typically not more than a few milliseconds.

Any number of devices in the signal path might be digital, including mixers and signal processors. Additionally, the signal routing system itself may be digital. Personal mixing systems that distribute audio signals to personal mixing stations for each performer using Cat-5 cable (the same cable used for Ethernet computer networking) actually carry digital audio. The audio is digitized by a central unit and converted back to analog at the personal mixer. Digital audio snakes that work in a similar manner are also gaining popularity.

Since the latency caused by digital audio devices is so short, the signal will not be perceived as audible delay (or echo). Generally, latency needs to be more than 35 ms to cause a noticeable echo. The brain will integrate two signals that arrive less than 35 ms apart. This is known as the Haas Effect, named after Helmut Haas who first described the effect. Latency is cumulative, however, and several digital devices in the same signal path could produce enough total latency to cause the user to perceive echo.
As discussed, isolating earphones are the preferred type for personal monitors, because they provide maximum isolation from loud stage volume. Isolating earphones, however, result in an effect known as the occluded ear. Sound travels by at least two paths to the listener’s ear. The first is a direct path to the ear canal via bone conduction. An isolating earphone reinforces this path, creating a build-up of low frequency information that sounds similar to talking while wearing earplugs. Secondly, the “miked” signal travels through the mixer, personal monitor transmitter and receiver, and whatever other processing may be in the signal path. If this path is entirely analog, the signal travels at the speed of light, arriving at virtually the same time as the direct (bone-conducted) sound. Even a small amount of latency introduced by digital devices, though, causes comb filtering.

Before continuing, an explanation of comb filtering is in order. Sound waves can travel via multiple paths to a common receiver (in this case the ear is the receiver). Some of the waves will take a longer path than others to reach the same point. When they are combined at the receiver, these waves may be out of phase. The resultant frequency response of the combined waves, when placed on a graph, resembles a comb, hence the term comb filtering, Fig. 37-16.

Figure 37-16. Comb filtering.

Hollow is a word often used to describe the sound of comb filtering.

It is generally believed that the shorter the latency, the better. Ultimately, changing the amount of latency shifts the frequency where comb filtering occurs. Even latency as short as 1 ms produces comb filtering at some frequencies. What changes is the frequency where the comb filtering occurs. Lower latency creates comb filtering at higher frequencies. For most live applications, up to 2 ms of delay is acceptable. When using personal monitors, though, total latency should be no more than 0.5 ms to achieve sound quality equivalent to an analog, or zero latency, signal path. While in reality it may be difficult to achieve latency this short, be aware that any digital device will cause some latency.

The individual user will have to determine what amount of latency is tolerable. As an alternative, some users report that inverting the polarity of certain input channels, or even the entire mix, improves the sound quality. Keep in mind that comb filtering still occurs, but at frequencies that may be less offensive to the listener.

The degree of latency is generally not more than a few milliseconds, which, as mentioned, will not cause the processed signal to be perceived as an audible delay. The concern for users of in-ear monitors, though, lies primarily with horn players, and occasionally vocalists. When a horn player sounds a note, the vibrations are carried directly to the ear canal via bone conduction. If the microphone signal is subject to digital processing, too much latency can cause comb filtering. The user generally perceives this as a hollow, unnatural sound. Care should be taken to avoid introducing unnecessary processing if comb filtering occurs. Adjusting the delay time in the processor (assuming digital delay is one of the available effects) could also compensate for latency. Alternately, route the effects through an auxiliary bus, rather than right before the monitor system inputs, which will minimize the latency effect by keeping the dry signal routed directly to the monitor system.

### 37.8.5 Safe Listening with Personal Monitors

No discussion of monitoring systems would be complete without some discussion of human hearing. The brain’s ability to interpret the vibrations of air molecules as sound is not entirely understood, but we do know quite a bit about how the ear converts sound waves into neural impulses that are understood by the brain.

The ear is divided into three sections; the outer, middle, and inner ear, Fig. 37-17. The outer ear serves two functions—to collect sound and act as initial frequency response shaping. The outer ear also contains the only visible portion of the hearing system, the pinna. The pinna is crucial to localizing sound. The ear canal is the other component of the outer ear, and provides additional frequency response alteration. The resonance of the ear canal occurs at approximately 3 kHz, which, coincidentally, is right where most consonant sounds exist. This resonance increases our ability to recognize speech and communicate more effectively. The middle ear consists of the eardrum and the middle ear bones (ossicles). This section acts as an impedance-matching amplifier for our hearing system, coupling the relatively low impedance of air to the high impedance of the inner ear fluids. The eardrum works in a similar manner to the diaphragm of a microphone, it moves in sympathy to
incoming sound waves, and transfers those vibrations to the ossicles. The last of these bones, the stapes, strikes an oval-shaped window that leads to the cochlea, the start of the inner ear. The cochlea contains 15,000 to 25,000 tiny hairs, known as cilia, which bend as vibrations disturb the fluids of the inner ear. This bending of the cilia sends neural impulses to the brain via the auditory nerve, which the brain interprets as sound.

Hearing loss occurs as the cilia die. Cilia begin to die from the moment we are born, and they do not regenerate. The cilia that are most sensitive to high frequencies are also the most susceptible to premature damage. Three significant threats to cilia are infection, drugs, and noise. Hearing damage can occur at levels as low as 90 db SPL. According to OSHA (Occupational Safety and Health Administration), exposure to levels of 90 dB SPL for a period of 8 hours could result in some damage. Of course, higher levels reduce the amount of time before damage occurs.

Hearing conservation is important to everyone in the audio industry. As mentioned before, an in-ear monitor system can assist in helping to prevent hearing damage—but it is not foolproof protection. The responsibility for safe hearing is now in the hands of the performer. At this time, there is no direct correlation between where the volume control is set and the sound pressure level present at the eardrum. Here are a few suggestions, though, that may help users of personal monitors protect their hearing.

37.8.5.1 Use an Isolating Earphone

Without question, the best method of protection from high sound pressure levels is to use a high-quality earplug. The same reasoning applies to an in-ear monitor. When using personal monitors, listening at lower levels requires excellent isolation from ambient sound, similar to what is provided by an earplug. Hearing perception is based largely on signal to noise. To be useful, desired sounds must be at least 6 dB louder than any background noise. Average band practice levels typically run 110 dB SPL, where hearing damage can occur in as little as 30 minutes. Using a personal monitor system with a nonisolating earphone would require a sound level of 116 dB SPL to provide any useful reinforcement, which reduces the exposure time to 15 minutes. Inexpensive ear buds, like those typically included with portable MP3 players, offer little, if any, isolation. Avoid these types of earphones for personal monitor applications.

Not all types of isolating earphones truly isolate, either. Earphones based on dynamic drivers typically require a ported enclosure to provide adequate low frequency response. This port, a small hole or multiple holes in the enclosure, drastically reduces the effectiveness of the isolation. Note that not all dynamic earphones require ports. Some designs use a sealed, resonating chamber to accomplish the proper frequency response, thus negating the need for ports but preserving the true isolating qualities of the earphone. Earphones that employ a balanced armature transducer, similar to those used in hearing aids, are physically smaller and do not require ports or resonating chambers. In fact, balanced armature-type earphones rely on a good seal with the ear canal to obtain proper frequency response. They can be made somewhat smaller, but are typically more expensive, than their dynamic counterparts.

37.8.5.2 Use Both Earphones!

A distressing, yet increasingly common, trend is only using one earphone and leaving the other ear open. Performers have several excuses for leaving one ear open, the most common is a dislike for feeling removed from the audience, but the dangers far outweigh this minor complaint. First, consider the above example of a 110 dB SPL band practice. One ear is subjected to the full 110 dB, while the other ear needs 116 dB to be audible. Using only one earphone is equivalent to using a nonisolating earphone, except one ear will suffer damage twice as fast as the other. Second, a phenomenon known as binaural summation, that results from using both earphones, tricks the ear-brain mechanism into perceiving a higher SPL than each ear is actually subjected to. For example, 100 dB SPL at the left ear...
and 100 dB SPL in the right ear results in the perception of 106 dB SPL. Using only one earphone would require 106 dB SPL at that ear. The practical difference is potential hearing damage in one hour instead of two. Using both earphones will usually result in overall lower listening levels.

Table 37-4 shows OSHA recommendations for exposure time versus sound pressure level.

Ambient microphones are commonly employed to help overcome the closed-off feeling. An ambient microphone can be a lavalier clipped to the performer and routed directly to the in-ear mix, or a stereo microphone pointed at the audience. The common thread is that they allow the user to control the level of the ambience.

37.8.5.3 Keep the Limiter On

Unexpected sounds, such as those caused by someone unplugging a phantom-powered microphone or a blast of RF noise, can cause a personal monitor system to produce instantaneous peaks in excess of 130 dB SPL, the equivalent of a gun shot at the eardrum. A brickwalltype limiter can effectively prevent these bursts from reaching damaging levels. *Only use a personal monitor system that has a limiter at the receiver, and do not defeat it for any reason.* A well-designed limiter should not adversely affect the audio quality, as it only works on these unexpected peaks. If the limiter seems to be activating too often, then the receiver volume is probably set too high (read as: unsafe!). Outboard compressors and limiters placed before the inputs of the monitor system are certainly appropriate, but are not a substitute for an onboard limiter, as they cannot protect against RF noise and other artifacts that may occur post-transmitter.

37.8.5.4 Pay Attention to What Your Ears Are Telling You

Temporary threshold shift (TTS) is characterized by a stuffiness, or compressed feeling, like someone stuck cotton in the ears. Ringing (or tinnitus) is another symptom of TTS. Please note, though, that hearing damage may have occurred even if ringing never occurs. In fact, the majority of people who have hearing damage never reported any ringing. After experiencing TTS, hearing may recover. Permanent damage has possibly occurred, though. The effects of TTS are cumulative, so a performer who regularly experiences the above effects is monitoring too loud and hearing damage will occur with repeated exposure to those levels.

37.8.5.5 Have Your Hearing Checked Regularly

The only certain way to know if an individual’s listening habits are safe is to get regular hearing exams. The first hearing test establishes a baseline that all future hearing exams are compared against to determine if any loss has occurred. Most audiologists recommend that musicians have their hearing checked at least once a year. If hearing loss is caught early, corrections can be made to prevent further damage.

A frequently asked question about in-ear monitors is: “How do I know how loud it is?” At this time, the only way to develop a useful correlation between the volume knob setting and actual SPL at the eardrum is by measuring sound levels at the eardrum with specially made miniature microphones. A qualified audiologist (not all have the right equipment) can perform the measurements and offer recommendations for appropriate level settings.

Personal monitors can go a long way toward saving your hearing, but only when used properly. Monitoring at lower levels is the key to effective hearing conservation, and this can only be accomplished through adequate isolation. Used correctly, professional isolating earphones, combined with the consultation of an audiologist, offer the best possible solution for musicians interested in protecting their most valuable asset. It cannot be stated strongly enough: a personal monitor system, in and of itself, does not guarantee protection from hearing damage. However, personal monitors not only offer improved sound quality and convenience, but they also provide performers with an unprecedented level of control. Reducing stage volume also improves the listening experience for the audience, by minimizing
feedback and interference with the house mix. As with most new technologies, an adjustment period is usually required, but few performers will ever return to floor monitors after using personal monitors.

For more information on hearing health for musicians, contact one of the following organizations.

38.1 The Design of Sound Systems

Sound systems are made of three primary components:

- Input transducers.
- Signal processing.
- Output transducers

38.1.1 Analog Systems

Transducers are devices that convert energy from one form into another.

The primary type of input transducer used in sound systems is the microphone. It converts the form of acoustic energy we call sound into electrical energy carrying the same information. Other common audio input transducers include the magnetic tape head, the optical sensor, the radio receiver, and the phonograph pickup cartridge. Tape recorders, floppy and hard drives use magnetic heads to transform analog or digital magnetic patterns on the magnetic media into electrical signals. Optical free-space links, optical fiber receivers, and CD and DVD players all use optical sensors to turn optical energy into electrical energy. Radio receivers turn carefully selected portions of radio frequency energy into electrical energy. Phonograph cartridges turn the mechanical motion of the grooves in a record into electrical energy.

Similarly, the most common type of output transducer used in sound systems is the loudspeaker. It converts electrical energy back into the form of acoustic energy we call sound. Other common output transducers include headphones, magnetic tape heads, lasers, radio transmitters, and record cutting heads. Headphones are specialized electrical to acoustic transducers, which are intended to produce sound for one person only. Tape recorders, floppy and hard drives use magnetic heads to transform electrical signals into magnetic patterns on the magnetic media. Optical free-space links, optical fiber transmitters, CDR, CDRW, DVD±RW, and BD recorders all use lasers to turn electrical energy into optical energy. Radio transmitters turn electrical signals into radio frequency energy. Phonograph cutting heads turn electrical energy into the mechanical motion of the grooves in a record.

In general, we can’t just connect a microphone to a loudspeaker and have a usable sound system. While there are exceptions such as “sound powered” telephones, in almost all cases there needs to be something that falls under the general heading of signal processing to connect the two.

In its most simplified form this processing might only consist of amplification. In general, microphones have low electrical power output levels, while loudspeakers require more electrical input power in order to produce the desired acoustic output level. Thus the processing required is amplification.

The next most common form of audio signal processing is the level control. This is used to adjust the amount of amplification to match the requirements of the system at this moment.

Multiple inputs to the signal processing are often each equipped with their own level control, and the outputs of the level controls combined. This forms the most basic audio mixer.

Much of the rest of what is done in signal processing can be classified as processing that is intended to compensate for the limitations of the input and output transducers, the environment of the input and output transducers, and/or the humans using and experiencing the sound system. Such processing includes, among other things, equalization, dynamics processing, and signal delay.

Equalization includes shelving, parametric, graphic, and the subcategories of filtering, and crossovers among others. Common filters include high pass, low pass, and all pass. Crossovers are made of filters used to separate the audio into frequency bands.

Dynamics processing is different in that the parameters of the processing vary in ways that are dependent on the current and past signal. Dynamics processors include compressors, limiters, gates, expanders, automatic gain controls (AGC), duckers, and ambient level controlled devices.

Signal delays produce an output some amount of time (usually fixed) after the signal enters the device.

The biggest early breakthrough in sound systems was the development of analog electrical signal processing. No longer was the designer limited to some sort of mechanical or acoustic system. This was taken a large step forward with the development of vacuum tube-based electronic circuitry.

Later, transistor circuitry allowed smaller product sizes and more complex processing to be done. The development of analog integrated circuits accelerated this trend.

Analog signal processing had its limitations, however. Certain types of processing such as signal delays and reverb's were very difficult to produce. Every time the signal was recorded or transmitted, quality was lost. Cascades of circuitry required to meet the ever more complex requirements of sound systems had
reduced dynamic range when compared to the individual building blocks making them up.

38.1.2 The Introduction of Digital Devices in Analog Systems

These factors combined together spurred the application of digital signal processing (DSP) to audio.

DSP is the application of numerical processes to perform signal processing functions on signals that have been converted into sequences of numbers. The conversion of an analog signal into a sequence of numbers is done by an analog to digital converter or A/D. Similarly, the conversion of a sequence of numbers back into an analog signal is done by a digital to analog converter, or D/A.

Delays in the analog world almost always involved acoustic, mechanical, or magnetic systems. In other words, you had to use transducers to go from the electrical realm to some alternative form of energy and back, since it was very difficult to delay the signal enough to matter for audio systems while staying strictly in electrical form.

Early digital signal delays had very poor performance compared to today’s digital products, but they were popular since the available analog delays were often of even worse audio quality, had very short maximum delay times, and often were not adjustable in delay time.

Digital signal delays offered much longer delay times, easy adjustability of the delay time, and often multiple outputs, Fig. 38-1.

Figure 38-1. Introduced in 1974, the Eventide Clockworks Model 1745M modular digital audio delay was the first to use random access memory (RAM) instead of shift registers for storage of sound. Options included pitch changing and flanging.

Analog reverbs always required some sort of mechanical, magnetic, or acoustic system.

The first analog reverbs were simply isolated rooms built with very reflective surfaces, and equipped with a loudspeaker for inserting the sound, and one or more microphones for picking up the reverberated sound.

Obviously, there are major drawbacks to this approach. The size and cost limited the application of this technique, as did the difficulty in adjusting the characteristics of the reverberation.

Another analog technique involved vibrating a large thin steel plate with sound, and picking up the vibrations at multiple locations on the surface of the plate. This had the advantage of smaller size, and adjustable reverberation by moving acoustic damping materials closer to or farther away from the plate.

Smaller yet analog reverbs were made using a gold foil instead of the steel plate, or by using springs that were driven at one end and had vibration pickups at their other end. The gold foil technique resulted in quite acceptable sound, but the spring-based systems were often of low cost and barely usable sound quality.

The first digital reverbs were very expensive, and of a size comparable to that of the gold foil or better spring systems, but had the advantage of much greater control over the reverberation characteristics than could be achieved with the analog systems. As the cost of digital circuitry has come down over the years, so has the price and size of DSP-based reverbs.

Analog recording and transmission of sound have always involved significant reduction in the sound quality as compared to the original sound. Each time the sound was rerecorded or retransmitted, the quality was further reduced.

Digital recording and transmission of sound offered a dramatic difference. While the conversion of analog signals into digital always involves some loss, as long as the signal was kept in digital form and not turned back into an analog signal, making additional copies or transmitting the signal did not impose any additional losses. Therefore, the generational losses associated with the analog systems we had been using were eliminated.

38.2 Digitally Controlled Sound Systems

38.2.1 Digitally Controlled Analog Devices

The physical controls of an audio device have always constituted a significant portion of the cost of the product. This was fine for devices such as mixing consoles where the operator needed instant access to all the controls. There have always been controls, however, that while necessary to the initial setup of the sound system, were best hidden from easy adjustment by the user. These controls were often placed behind security covers to reduce the chance of their adjustment by unauthorized users.
Crossovers, system equalizers, and delays are some of the more common examples of this class of device.

Until the introduction of the inexpensive graphically oriented personal computer, there was no practical way to avoid this cost, or to provide other than physical limitation of access to controls. Once graphical computers became commonplace and inexpensive, we saw the introduction of a new class of digitally controlled analog devices. These devices had greatly reduced numbers of physical controls, and in some cases had no physical controls. Instead the devices were adjusted by connecting them to a personal computer and running a control program on the computer. Once the “controls” were set using the program, the computer could be disconnected and the device would retain the settings indefinitely.

Since there were no or a limited subset of actual physical controls, there was no need for physical access restriction devices. Without both a computer and the appropriate control program, there was no way for the user to adjust the controls.

Preset, which could be recalled either from the front panel or remotely, now became possible. Different system configurations, which required multiple changes to controls, now became as simple as pressing a single button.

Computer control also allowed many more controls to be provided on a physically small product than would otherwise be practical. For example, a 1/3-octave equalizer might have 27 bands, plus a number of presets, and yet could be packaged in a small box.

Remote control of the device allows the control point to be distant from the audio device itself. This opened the possibility of reducing the amount of audio cabling in a system and replacing it with inexpensive data cabling to the operator's control point. The data cabling is much more resistant to outside interference than audio cabling.

In the initial versions of such control systems, a different control program and physical connection from the computer to the audio device was required for each device that was to be so controlled. This was fine in smaller systems, but in larger installations where there might be many such digitally controllable devices, it quickly became cumbersome.

To address this limitation, Crown developed what they called the IQ system. It used a single control program together with a control network that connected many digitally controllable devices. Thus it provided a single virtual control surface on the computer screen, which allowed the adjustment and monitoring of multiple individual audio devices.

### 38.2.2 Digitally Controlled Digital Audio Devices

Early digital audio devices had physical controls that mimicked the controls of analog devices. As with digitally controlled analog devices, the advantages of remote control programs quickly became apparent, particularly for those devices with many controls.

Digital audio devices already were internally digitally controlled, so providing for remote control was an easy and relatively inexpensive step. Some such devices provided physical controls that communicated with the signal processor. Others provided only control programs that would run on a personal computer and connect via a data connection back to the device controlled.

As with the digitally controlled analog devices, most such control schemes required an individual data line from the control computer to each device controlled. Several manufacturers including TOA and BSS developed techniques to allow many of their devices to be controlled by a single data line. These schemes were limited to products of a single manufacturer. Work went on for many years under the auspices of the Audio Engineering Society to try to develop a universally applicable common control scheme, but the requirements were so diverse that a universal standard has yet to be achieved.

This was one of the factors leading to the rise of universal control systems from companies such as Crestron and AMX that have the ability to control and automate remote controllable equipment using any control protocol. For the first time such control systems allow the user to have a single control surface that operates all these systems with their diverse control protocols. These control systems control audio, video, lighting, security, and mechanical systems, allowing a degree of total system integration never before achieved.

Despite the success of these universal control systems, often the user just needs to control all his or her audio system components from a single interface. This has been a driving force behind the continued efforts to develop a common control protocol, or some other easy way to bring all these controls together for the user. Besides the work that the AES has done toward developing such a common protocol, control and monitoring protocols developed for other industries have been adapted for use with audio systems. Among these protocols are Simple Network Management Protocol, or SNMP, and Echelon LonWorks.

The desire for unified systems with reduced control interfaces has also been one reason for the popularity of integrated devices that combine the functions of many formerly discrete devices in a single unified product.
38.2.3 Integration of Digital Products into Analog Systems

38.2.3.1 Dynamic Range

The dynamic range of analog systems is characterized by a noise floor, nominal operating level, and maximum output level before a rated distortion is exceeded. The noise floor is usually constant and does not change with the audio signal. Distortion generally increases with increasing level. The increase in distortion as the maximum output level is approached may be gradual or sudden. Most professional analog audio equipment today has a maximum output level in the range from +18 to +28 dB relative to 0.775 V (dBu), and a nominal operating level in the 0 to +4 dBu range. While optimum operation requires matching of the maximum output levels so that all devices in the signal chain reach maximum output level at the same time, in practice many engineers do not bother to match maximum output levels, relying instead on the easier matching of nominal levels. The best signal levels to run through typical analog equipment are moderate levels, far away from the noise floor, but not too close to the maximum output level.

Digital equipment, on the other hand, has a different set of characteristics. Distortion decreases with increasing level, and reaches the minimum distortion point just before the maximum output level. At that maximum output level distortion rises very abruptly. The noise floor of digital equipment is often not constant. In some cases the noise is very signal dependent, and sounds to the ear much more like distortion than noise. These characteristics come together to suggest that the optimal signal levels would be those close to but just a little below the maximum level.

38.2.3.2 Level Matching

As we combine analog and digital equipment in the same system, the different characteristics of the two technologies suggest that for maximum performance and widest dynamic range we must align the maximum output levels.

Each device has its own dynamic range, but those ranges will have different characteristics. In all cases we want the audio signal to stay as far as possible from the noise floor.

In any system some device will have the smallest dynamic range, and thus set the ultimate limitation on the performance of the system.

The system as a whole may not perform as well as the worst performing component, unless care has been taken to assure that all devices reach their own maximum output level at the same time.

38.2.3.3 Level Matching Procedure

To match the maximum output levels, apply a midfrequency tone to the input of the first device in the system. Increase the applied level and/or the gain of the device until the maximum output level is reached as determined by the increase in distortion. This point may be determined by using a distortion meter, watching the waveform using an oscilloscope for the onset of clipping, or listening with a piezo tweeter connected to the output of the device.

This latter technique was developed by Pat Brown of Syn-Aud-Con. If a frequency in the range of 400 Hz is selected, the piezo tweeter can’t reproduce it, and will remain silent. When the device under test exceeds its maximum output level, the resulting distortion will produce harmonics of the 400 Hz tone that fall in the range the piezo tweeter can reproduce, and it will sound off in a very noticeable way. The level is then reduced until the tweeter just falls silent, and maximum level has been determined. Rane has produced a commercial tester based on this concept called the Level Buddy.

Once the first device is at its maximum output level, the gain of the second device is adjusted to achieve its maximum output level. In some cases the input of the second device will be overloaded by the maximum output level of the first device and no adjustment of the gain of the second device will eliminate the distortion. In such a case, an attenuator must be used between the devices to drop off the level so the second device’s input is not overloaded. One place where such an attenuator is often needed is at the input of a power amplifier. Many times professional power amplifiers have input overload points far lower than the maximum output levels of any of the common devices used to drive them.

Once the second device is at maximum output level, the process is repeated in turn for each subsequent device in the system.

Once all device interfaces have been optimized, the system is capable of maximum possible performance.

38.2.3.4 Minimization of Conversions

Up until now, digital components have been treated just like the analog components they have replaced in the sys-
tem. This is not the optimal way, however, to integrate digital processing into a system.

All devices, analog or digital, impose quality limitations on the performance of the system. In a properly designed digital device, the major performance limitations are due to the conversions from analog into digital and back. Properly done DSP will not introduce significant distortions or other artifacts into the signal. Early analog to digital converters had significantly worse distortions than early digital to analog converters. With modern converters the pendulum has swung back the other way with analog to digital converters often having less distortion than digital to analog converters. In any case, the majority of the distortions and other quality degradations in a properly designed digital based audio signal processor are due to the converters.

This suggests that we should consider carefully how many A/D and D/A converters are used in our systems, with an eye to minimize the number of converters in any given signal path.

This requires a change in how we treat digital audio devices in our systems. No longer can we consider them to be interchangeable with traditional analog components. Instead we must use system design practices that will allow a reduction in the number of converters our audio must go through.

One powerful technique is to group all the digital devices together in only one part of the signal flow of our systems, and use digital interconnects between the devices instead of analog. While not all of our digital processors are available with digital interconnections, many of them are.

The most popular two channel consumer digital interconnect standard is known as SPDIF, while the most popular two channel professional interconnect standard is AES3. The European Broadcasting Union (EBU) adopted the AES3 standard with only one significant change. The EBU required transformer coupling, which was optional under AES3. As a result, this interconnect standard is often called AES/EBU. Many products are made with these interconnects, and converters are available to go from SPDIF to AES3 and from AES3 to SPDIF.

There are many interfaces that carry more than two channels. One that is popular in the home studio market is the ADAT interface, which carries eight channels. Most of the interfaces that originated in the home studio market are limited in the distance they can be run.

To address the need for greater distances and larger numbers of channels in professional applications, CobraNet was developed. It also differs from the other digital interfaces in that it allows point to multipoint connections instead of only point to point. This is due to it running on Ethernet, which is an industry standard computer networking protocol. Today there are several different digital interface systems sold that use some or all of the Ethernet Standard to transmit digital audio.

By grouping as many of our digital devices in one portion of the system as possible, and making all the interconnections between them in the digital domain, we have minimized the number of conversions our signal has gone through, and maximized the potential performance.

### 38.2.3.5 Synchronization

Digital audio consists of a series of consecutive numeric samples of the audio, each of which must be received in sequence. If the samples are not received in proper sequence, or if samples are lost or repeated, then the audio will be distorted.

In order for digital audio devices to interconnect digitally, both ends of each connection must run at the same sampling rate. If the source is running at even a very slightly faster rate than the receiver, sooner or later the source will output a sample that the receiver is not ready to receive yet. This will result in the sample being lost. Similarly, if the source is running at even a very slightly slower rate than the receiver, eventually the receiver will be looking for a sample before the source is ready to send it. This will result in a new false sample being inserted into the data stream.

In a simple chain of interconnected digital audio devices, it is possible for each device to look at the sampling rate of the incoming digital audio, and lock itself to that incoming rate. One problem with this system is that the sampling rate as recovered from the incoming digital audio is less than a perfect steady rate. It will have slight variations in its rate known as jitter. While there are techniques available to reduce this jitter, they add cost, and are never perfect. Each consecutive device in the chain will tend to increase this jitter. As a result, it is not recommended to cascade very many digital audio devices in this manner.

If a single digital audio device such as a mixer will be receiving digital audio from more than one source, then this simple scheme for synchronizing to the incoming digital audio signal breaks down, since there is more than one source. There are two ways to solve this problem.

One way is to use a sample rate converter (SRC) on each input to convert the incoming sample rate to the internal sample rate of the processor. Such a SRC will add cost to the input, and will in some subtle ways
degrade the quality of the audio. Of course, there are different degrees of perfection available in SRCs at correspondingly different levels of complexity and cost. Some SRCs will only handle incoming digital audio that is at a precise and simple numeric ratio to the internal sample rate. Others will accept any incoming sample rate over a very wide range and convert it to the internal sampling rate.

This second sort of SRC is very useful when you must accept digital audio from multiple sources that have no common reference, and convert them all to a common internal sampling rate.

As implied above, the other way to handle inputs from multiple digital audio sources is to lock all the devices in the digital audio system to a common reference sample rate. In large systems this is the preferred solution, and the Audio Engineering Society has developed the AES11 Standard, which explains in detail how to properly implement such a system. Such a system can have excellent jitter performance since each device directly receives its sampling rate reference from a common source. Interconnections between the digital audio devices can be rearranged freely since we do not have to be concerned about synchronization and jitter changes as the signal flow is changed.

The only flaw in this scheme, is that some digital audio devices may not have a provision for accepting an external sampling rate reference. As a result, in many complex systems while there may be a master sample rate clock that most equipment is locked to, there often is still a need for sample rate that can’t lock to the master clock, or that operate at a different sample rate.

38.2.3.6 Multifunction Devices

Once we grouped most or all of our digital devices in a single subsection of our system, the next natural question is why not combine these multiple separate devices into a single product. Obviously, such a combined device greatly reduces or eliminates the need for the system designer to be concerned with synchronization issues, since the equipment designer has taken care of all the internal issues. Only if the system contains more than one digital audio device with digital interconnections does the issue of synchronization arise.

Some of the first examples of such combination products were digital mixers and loudspeaker processors.

Digital mixers were developed that combined not only the traditional mixing and equalization functions, but also often added reverb and dynamics processors inside the same device. Depending on the intended application, such digital mixers might also integrate automation systems, and remote control surfaces. Remote control surfaces allow the separation of the signal processing from the human operated controls. This might allow all the signal processing to remain on stage, for example, while only the control surface is placed at the operator’s position, Fig. 38-2.

Figure 38-2. The CueConsole from Level Control Systems is a modular audio control surface. The size of the control surface has no direct relationship to the number of audio inputs and outputs controlled. The actual audio processing is performed in Matrix3 processors (lower right corner) located remotely from the control surface. These systems are very popular for Broadway- and Las Vegas-style shows since very large and powerful automated consoles can take up very little of the valuable space in the theater.
Loudspeaker processors are another common example of integrated digital subsystems. Such devices might include input-level adjustment, compression, signal delay, equalization, and crossover functions. Each crossover output might include further signal delay, equalization, level adjustment, and limiting. Often manufacturers provide standard settings for their loudspeakers using these processors, thus optimizing the performance of the loudspeaker to a degree not otherwise possible, while allowing one universal processor to be used for many different products in their line.

The limitation of such products is that their internal configuration is fixed, and therefore the possible applications are limited to those the manufacturer anticipated.

One solution is the one pioneered by Dave Harrison in his analog console designs. In an age when most recording consoles were custom built, and provided just the features and signal flow capabilities requested by the studio owner, David designed a console with so many features, and such flexible signal routing, that it could meet the needs of a very wide range of users. Any one user may not need any but a small subset of the available features. A few users might have requested additional features if they were having a custom console manufactured. Through innovative engineering, David was able to design this console in such a way that it could be mass produced for significantly less cost than the more limited custom consoles it replaced.

Applying this same concept to integrated digital devices led to devices designed with signal processing and routing capabilities well beyond the average user’s requirements. This, of course, made such a device capable of application to more situations than a more limited device would have been.

38.2.3.7 Configurable Devices

The next significant advance in integrated digital signal processing was the user configurable device. In such a device, the basic configuration of the signal flow and routing remains constant, or the user can select from one of several different possible configurations. Next, the user can select the specific signal processing that takes place in each of the processing blocks in the selected configuration, within certain constraints.

This sort of device is fine for situations where the basic functions needed are limited, but some degree of customization to suit the job is required. The TOA Dacsys II was an early example of this sort of system, and was available in two in by two out and two in by four out versions, Fig. 38-3.

For example, a complex processor for a loudspeaker might have multiple inputs optimized for different types of audio inputs. There might be a speech input that is bandlimited to just the speech frequency range, equalized for speech intelligibility, and has moderate compression. There might be a background music input that has a wider frequency range, music-oriented equalization, and heavy compression. There might be a full range music input which has music equalization, and no compression.

The input processing chain for each will have a level control and a high pass filter for subsonic reduction or speech bandwidth reduction. The speech input chain might next have a low pass filter to reduce the high-frequency range. All three inputs will then have multiband parametric equalizers to tailor their frequency response. The speech and background music inputs would then have compressors for dynamic range control. The three input processing chains would end in a mixer that would combine them into a single mixed signal to drive the output processing chains.

Such a system might have three outputs, one for the low frequencies, one for the midfrequencies, and one for the high frequencies. The low-frequency processing chain will have a high-pass filter set to eliminate frequencies below the reproduction range of the woofer. Next, it would have a low-pass filter to set the crossover frequency.
frequency to the midrange speaker. This may often be
followed by a multiband parametric equalizer used to
smooth the response of the woofer. Lastly will come a
limiter to keep the power amplifier from clipping and/or
provide some degree of protection for the woofer. The
midfrequency processing chain will have a high-pass
filter to set the crossover frequency from the woofer,
and a low-pass filter to set the crossover frequency to
the high-frequency speaker. It might also have a multi-
broad parametric equalizer and a limiter. The
high-frequency processing chain will have a high-pass
filter to set the crossover frequency from the midrange,
and might have a low-pass filter to set the high-
frequency limit. It may have a shelving equalizer to
compensate for the high-frequency response of the
driver. It will also have a multiband parametric equal-
izer and a limiter.

Some of these fixed configuration audio processors
can allow quite complex systems to be built. For
example the BSS ProSys ps-8810 provides eight inputs
and ten outputs. Each input has filtering, delay, gating,
AGC, compression, automatic mixing, more filtering,
polarity, and muting available. This is followed by and
eight in by ten out matrix mixer. Each output has delay,
filtering, ambient level control, and limiter available.
The combination of all these facilities allows quite
complex systems to be built, Fig. 38-4.

38.3 Virtual Sound Processors
At times, however, even the most complex fixed configu-
ration processor will not meet the needs of a project. In
1993, the Peavey MediaMatrix system introduced the
concept of the virtual sound processor. It allowed the
designers to choose from a wide variety of virtual audio
processing devices, and wire them in any configuration
they desired. Integrated digital sound systems could now
be designed with the same flexibility of configuration
formerly enjoyed in the analog world, and with much
greater ease of wiring. Changes to the configuration
could be rapidly made on screen and loaded into the pro-
cessor at the click of a button. Complex systems, which
would not have been possible using analog technology
due to circuitry drift or cost, now became routine. Sys-
tems with as many as 256 inputs and 256 outputs, and
70,000 or more internal controls became practical, Fig.
38-5. More recently, BSS came out with the Soundweb
digital audio processor with similar capabilities but a dif-

![Figure 38-4. BSS control software for the ProSys ps-8810 showing the signal flow diagram. There is a limited ability to

different physical architecture, Fig. 38-6A. MediaMatrix was based on a PC that supports digital audio processing cards inserted in it. What is now called Soundweb Original consists of a family of digital audio processor boxes that interconnect using category 5 UTP cables, hence the web part of the name. Both products provide similar functions in different ways.

Biamp, BSS Audio, Electro-Voice, Innovative Electronic Designs, Level Control Systems, Peavey, QSC Audio Products, Symetrix, Yamaha, and others have come up with a variety of products that also give the user the ability to wire virtual devices together. These range from large systems similar to MediaMatrix or Soundweb, to a small module from QSC that provides processing for a single power amplifier, Fig. 38-6A–E.

Many of these signal processors provide multiple options for audio input and output. For example, MediaMatrix provides options for analog I/O, AES3 I/O, and a CobraNet interface.

In order for a virtual sound processor to replace all the analog processing used in a sound system, a wide variety of virtual devices must be available. MediaMatrix now provides nearly 700 standard audio processing and control logic virtual devices on its menu. It is also possible to build your own complex devices from simpler devices appearing on the menu or existing inside menu devices. Almost any audio processing device desired may be either found on the menu or built from components available.

Systems are designed in a manner very similar to drawing a schematic on a CAD system. Virtual devices are taken from the menu and placed on a work surface. They have audio input nodes on the left, and audio output nodes on the right side of the device. Some systems have control input nodes on the top, and control output nodes on the bottom of the devices. Wires are drawn interconnecting the I/O nodes and the virtual devices, Fig. 38-7.

Any number of virtual devices may be used until the available DSP processing power is exhausted. All of the systems provide some means for displaying the amount of DSP used. Devices may be added to the schematic until 100% utilization is reached. Expandable systems such as MediaMatrix and Soundweb allow the addition of more cards or boxes to add additional processing power as needed. MediaMatrix also allows the selection of sampling rate. Slower sampling rates trade off reduced bandwidth for increased processing capability.

Since the schematic may be edited at any time, one major advantage of these systems is that changes may easily be made in the field to accommodate changed requirements or field conditions. Since it is rare that a system is 100% utilized, often the needed additional virtual devices, or wiring changes, may just be added. If the change exceeds the available DSP resources, often some other change may be made in a less critical area to reduce the required DSP resources. By contrast, in an analog system physical rewiring or the purchase of additional components would be required. Both of these add significant cost. Thus often the use of virtual sound processors results in significant savings in the total project cost, over and above the cost savings of the initial equipment purchase, and a more optimized finished system.

Generally, double-clicking on a virtual device will open it, allowing the internal controls to be seen, Fig. 38-8. Inside each device is a control panel with the controls and indicators needed by that device. Sometimes seldom used controls will be placed in sub-windows.

Selected controls from the devices may be copied and placed in control panels. This is done using the standard Windows copy and paste commands. The schematic may then be hidden, and the user only allowed access to the controls that the designer wishes, placed on the control panels. Multiple controls may be
ganged, and the settings of many controls may be recalled using presets or subpresets. Presets recall the settings of all the controls in the system, while subpresets recall the settings of just a selected subset of the controls. Controls may also be edited to change their style, size, color, and orientation. This capability allows the designer to develop a very user-friendly interface. Often bitmaps may be inserted to serve as backgrounds.

Besides the virtual interface, some systems require physical interfaces. To support this requirement, most virtual sound processors provide remote control capability in addition to their virtual control surfaces. Some have a few front panel controls available, Fig. 38-9A. Many virtual sound processors provide control inputs to which external switches or level controls may be connected. Control outputs allow lamps and relays to be driven. Serial control interfaces using RS 232, RS 485, or MIDI are often available. Some processors also provide Ethernet interfaces. Others have dedicated programmable remote control panels. When remote control needs are extensive, but the user interface must be simple, touch screen operated control systems such as by AMX or Crestron are often used. These usually control the virtual audio processor by means of serial RS232, RS485, or Ethernet control lines, Figs. 38-9A–E.

Designing and using a virtual sound processor is similar to designing an analog system, except that you have the ability to more precisely optimize the system. The cost of each individual virtual device is very low, and you have the ability to wire precisely the configuration you need. Thus designs may be more efficient, and may also more exactly meet the system requirements.
Let's take our previous example of a loudspeaker processor with three inputs, each optimized for a different type of program, and three-way outputs, and design a virtual sound processor for this task using QSC. Other virtual sound processors could also be used for the same purpose although some details would be different.

The first step is to place the virtual devices for the audio inputs and outputs. Since we wish analog inputs and outputs, we will select analog I/O cards for inputs and outputs 1 through 4 from the Device menu, Fig. 38-10.

Input 1 will be our speech input. We will use a high pass filter, a 1 band parametric equalizer, a high-frequency shelving equalizer, a compressor, and a three input mixer. Input 1 will wire to the input of the high pass filter. The output of the high pass filter feeds the parametric equalizer, which feeds both the main input of the compressor, and the shelving equalizer. The output of the compressor wires to the first input of the mixer. The high pass filter will be adjusted to be a 125 Hz Butterworth 24 dB/oct filter. This band limits the input to the speech range, and prevents the entry of low-frequency noise. The parametric equalizer will be set for a bandwidth of two octaves, and 3 dB boost at 3 kHz. This provides a gentle emphasis of the speech intelligibility range. The compressor is left at its default settings of Soft Knee, 0 dB threshold, and a ratio of 2:1. The high-frequency shelving equalizer will be set to a frequency of 8 kHz, and 8 dB of boost. In combination with the compressor, this serves as a de-esser. By boosting the sibilance range at the input to the side chain of the compressor, those frequencies will be compressed more easily, and excessive high-frequency sibilance will be controlled, Fig. 38-11.

Input 2 will be for the background music. We will use a high pass filter, two bands of parametric equalization, and a compressor. The high pass filter will be set to 80 Hz with a Q of 2. This produces an underdamped response with a bass boost just above the low-frequency roll-off. One band of the parametric equalizer is set to 1.5 kHz with a bandwidth of two octaves, and a cut of 5 dB, while the other is set to 8 kHz with a bandwidth of one octave, and a boost of 5 dB. The combination of the high pass filter and the parametric equalizer produces the desired background music response. The compressor is set to Soft Knee, –10 dB threshold, and a ratio of 4:1. This provides a more aggressive compression. The output of the compressor is wired to the second mixer input.

Input 3 is for full range music. It has a high pass filter, and a low-frequency shelving equalizer. The high pass filter is set to 30 Hz at 12 dB/oct, and the low-frequency EQ is set to +10 dB at 100 Hz. The output of the EQ is wired to the third mixer input.

The output of the mixer will drive a 6 band parametric equalizer for overall system EQ. Next comes a three-way 24 dB/oct crossover. The low-frequency output of the crossover is wired to a high pass filter with the Q adjusted so it optimally tunes and protects the woofer. Next comes a three band parametric EQ, five millisecond delay, and limiter. The side chain input of the limiter is wired directly from the output of the EQ bypassing the delay. This combination of a delay and limiter wired so that the main input of the limiter sees a

Figure 38-10. QSC software showing virtual devices for audio input and output.
delayed signal, while there is no delay on the side chain input, is known as a look-ahead limiter. By setting the delay to about three times the attack time of the limiter, the limiter has time to react to an audio signal before that signal reaches the limiter. Since the limiter has an attack time of 1 ms, we will set the delay to 3 ms. A look-ahead limiter is able to accurately limit audio transients without the distortions inherent in ultrafast limiters.

The mid- and high-frequency outputs of the crossover are processed similarly. The midfrequency output just has the parametric EQ, delay, and limiter, while the high-frequency output has a shelving equalizer to compensate for the CD horn, parametric EQ, delay, and limiter, Fig. 38-11.

As you can see, while this circuit is relatively simple, using a virtual audio processor allowed us to optimize it in ways not possible using either commonly available analog components or a fixed configuration digital processor. This schematic utilizes about 3% of the resources in the small version of the QSC virtual processor. By way of comparison a similar schematic took 19% of the available DSP resources on a single MediaMatrix board. This shows the great improvement in DSP processing speed in the latest generation of virtual processors.

The larger and more complex the system, the greater the advantages of the virtual audio processor over previous technologies. Legislative chambers, stadiums, ballrooms, theme parks, and churches are among the facilities utilizing virtual audio processors.

One technique commonly used in legislative sound systems is called mix-minus. Often such systems will have a microphone and loudspeaker for each legislator. In order to prevent feedback, each loudspeaker receives a mix that does not contain its associated microphone signal. Signals from other nearby microphones are at a reduced level in the mix. The U.S. Senate sound system utilizes this technique. Since there are 100 senators each of whom has his or her own microphone and loudspeaker, plus leadership microphones and loudspeakers, there were over 100 microphones with over 100 associated loudspeakers, which would have required over 100 mixers each with over 100 inputs if it had been implemented with a straightforward matrix mixer. To reduce this complexity, the mix-minus technique was developed. It works on the concept that only a small number of microphone inputs need to be muted or reduced in level on any given output. A single large mixer is used to produce a mix of all the inputs called the sum. Each output mixer receives the sum and just those inputs that must be muted or reduced in level. The polarities of the direct inputs of the mixer are reversed, so that as their level is increased, they cancel out part or all of their audio from the sum at the output of the mixer. If a direct input is set to unity gain, it will perfectly subtract from the sum signal, thus eliminating that input from the mixer output. While this technique has been used in analog system designs, circuit stability restricted its practical use in larger systems. Digital systems add another potential complexity. As signals are processed and transferred between DSP processing chips, delays may be introduced. If the sum and direct input signals do not arrive at the mixer at exactly the same time, the direct signal will not properly cancel. Small amounts of signal delay on selected inputs may be required to assure that all the signals reach the input of any given mixer at the same time. Some virtual signal processors automatically provide such compensation, or provide it as an option. It is always possible to manually insert very small delays as required.

Today, virtually all larger sound reinforcement systems utilize some form of virtual sound processor. The advantages of more optimized system design, the ability to make easy changes, and reduced cost, have
made this sort of processor the overwhelming favorite of consultants and contractors worldwide.

Systems installed today still use analog microphones and microphone preamps, and in some cases analog mixing consoles, the outputs of which are fed to the virtual sound processor. Likewise, the outputs of the virtual sound processors are usually connected in the analog domain to conventional power amplifiers, which are then wired to loudspeakers. Thus considerable portions of the total sound system remain outside the scope of the virtual sound processor. There is a better way, however, that was first used by the U.S. Senate sound system installed in 1994, and continued in the new system installed in 2006.

Each senator has his or her own small microphone equipped with a tiny Kevlar reinforced cord. Suitable microphones with direct digital outputs were not available. The cord is managed by a Servoreeler Systems servo controlled reeler located in the senator’s desk, under the control of the virtual system. No slip rings are used, and the far end of the cord is directly connected to the preamp, also located in the desk. The analog gain of the preamp is also under the control of the virtual system. The output of the preamp drives an A/D converter, which is connected to a DSP processor, and also located in the desk. The initial audio and control processing is done in the desk. Audio, control signals, and power are carried on a single cable between the desk and the central processor portion of the virtual sound system. The central processor performs all the mix-minus processing, and many of the auxiliary functions. Outputs from the central processor go back over the same cable to the desk, where further processing is done, still under the control of the virtual system, and the power amplifiers and speakers are driven.

What is special about this system is that not only is the central processing done in a virtual sound processor, but the processing associated with the microphones and loudspeakers is also part of the virtual system. The entire system consisting of redundant central processors, over 100 desk units, custom operator’s console, and several displays, is all part of a single integrated virtual sound system. All of the DSP processing, including both central processors, and the over 100 remote processors in the desks, is loaded with their operating code and controlled, from a single common virtual sound system program. Even the microphone reebers, which are a servo controlled electromechanical subsystem, and the analog microphone preamps, are under the control of the virtual sound system. There are no unnecessary A/D and D/A conversions, and the longest analog interconnection is the microphone cable.

Sound is converted from analog into digital at the end of the microphone cable, and remains in the digital domain until it is in the loudspeaker enclosure. The U.S. Senate sound systems, both the original of 1994 and the updated 2006 system, can be considered to be prototypes for the virtual sound systems of the future.

### 38.4 Virtual Sound Systems

#### 38.4.1 Microphones

The virtual sound system of the future will be programmed and controlled through a single unified user interface program. It will have no analog interconnections.

Microphones will have a direct digital output, and receive power and control signals through the microphone cable. The Audio Engineering Society Standards Committee has issued the AES-42-2006 Standard defining a digital interface for microphones. The digital audio transmission scheme used is based on the AES3 Standard, but adds digital phantom power, microphone control, and synchronization features. The microphones can phase-lock their internal sampling clocks to that of the equipment to which they are connected. The first microphones meeting this standard contain conventional analog microphone elements with conversion into the digital domain done inside of the microphone body. In the future, we may see microphones that produce digital signals directly out of the microphone element. In either case, these new smart digital microphones can be controlled by the virtual system to which they are connected. Some of these microphones will even allow their directional patterns to be changed, and in some cases to be steered toward the sound sources under the control of the virtual sound system. By dynamically adjusting the pickup pattern and direction of each of the microphones, the sound system may adaptively optimize its performance.

Microphone arrays will enhance the control of the directional patterns and aiming of microphones. Microphone arrays consist of from three to hundreds of microphone elements whose outputs are processed to produce one or more virtual microphones with controllable directional patterns and orientation. They will have the ability to produce narrow pickup patterns if so desired, which can be aimed dynamically at the desired sound source. If the sound source moves, the pickup pattern can also move to follow the sound source. Because of this capability, array microphones will be capable of picking up intelligible sound from a greater distance than traditional microphones. This will allow
sound systems to be designed without visible microphones, even in difficult acoustic environments.

Since the outputs of the individual microphone elements in an array are processed into the single virtual microphone output by DSP processing, adding more DSP will allow additional virtual microphones to be produced from the same array. Each virtual microphone can be aimed in a different direction, with its own directional pattern. We already see the beginnings of this in some of the microphone systems that provide 5.1 surround outputs for recording from a single compact microphone array. In a speech reinforcement system, each virtual microphone could track an individual talker. Talkers would be identified by their unique individual voiceprint. When there are multiple microphone arrays in the room, each talker's individual virtual microphone can automatically be formed using the optimum nearby array. As each talker moves around the room, his personal virtual microphone will always be formed using a nearby array, and will move from array to array as he moves around the room.

Since each virtual microphone will stay with its assigned talker, the output of each microphone may be individually optimized for the person to which it is assigned. When logging of the activities in the room is required, if desired each person could be recorded on her own individual track. Where speech to text conversion is utilized, having a separate virtual microphone for each talker is a significant advantage. Speech to text conversion is much easier when the system can learn the voice of a single individual. By providing outputs to the speech to text system that only contains the voice of a single individual, accuracy is greatly improved.

Microphone arrays will also have the ability to selectively reject sounds coming from certain sources. During system setup, the virtual microphone processors will be taught the location of the system loudspeakers, and of any significant noise sources in the room. This will allow them to keep a null in the directional pattern always aimed in those directions. As a result, the chances of feedback and the pickup of noise will be significantly reduced.

It will also be possible to define regions in 3D space from which speech will not be amplified. In legislative systems, for example, it is extremely important to make sure side conversations are never amplified. By defining an area slightly back from the desks as a privacy zone, the legislators will be able to lean back and have a private conversation with their aides even if they forget to turn their microphones off.

Current voice tracking microphone arrays are limited in their bandwidth, add significant signal latency, and are costly. These factors have made them unattractive for sound reinforcement applications. However, improvements in processing algorithms, coupled with the dramatic reductions in the cost of DSP processing power we have seen each year, will soon bring this technology to a host of new applications including sound reinforcement.

### 38.4.2 Loudspeakers

Many loudspeakers today are powered with integrated power amplifiers and crossovers. Some loudspeakers have expanded on this concept by directly accepting digital audio and control signals. They contain DSP processing, which, integrated with the loudspeaker system design, allow much improved loudspeaker performance and protection. Modern DSP-based line array loudspeakers have steerable directional patterns, and in some cases can produce multiple acoustic output beams from the same loudspeaker. They may even send back an audio sample of their acoustic output for confidence monitoring.

As with microphone arrays, DS-based loudspeaker arrays allow sound to be steered to where it is needed, and kept from where it is not wanted. Dynamically controlled loudspeaker arrays will allow the loudspeaker coverage to change as room and system conditions change. Loudspeaker arrays may be produced as lines or flat panels, which mount flush with the walls, ceilings, and other architectural room elements. No longer is it necessary for loudspeakers to be aimed in the direction we wish the sound to go. For example, it is quite feasible to mount a flat panel loudspeaker array in a convenient location on the sidewall of the room, and direct the sound downwards and back into the audience area. Loudspeaker coverage patterns and directions may be changed under the control of the virtual system for different uses of the facility. This is a tremendous advantage over the older technolog, which required either multiple sets of speakers, or physically changing the loudspeaker aiming for different applications.

A single loudspeaker array may be used to simultaneously produce multiple sound coverage patterns, each of which may be driven by its own independent sound source if so desired. One application of this technique would allow greatly enlarging the area in a room where accurate multichannel reproduction could be heard. Those located towards the edges of the room could now receive properly balanced sound from all loudspeakers in the room, even though they were much closer to some of the loudspeakers than to others, thus preserving
the spatial reproduction. In another application, the same loudspeaker could aim direct sound at the audience, while simultaneously aiming ambient effects toward other portions of the room.

Control feedback from the virtual sound system will allow automatic modification of the loudspeaker coverage pattern as environmental conditions change. Such changes might include audience size and location, ambient noise, temperature, and wind speed and direction. Integration of DSP processing will also allow other useful functions to be moved into the loudspeaker cabinet. These will include source signal selection and mixing, delay, equalization, compression, limiting and driver protection, and ambient level compensation. The programming and control of the DSP processing will be over the same connection that brings the digital audio to the loudspeaker. This will allow the integration of all loudspeaker functions as part of the common virtual sound system.

38.4.3 Processing System

Those portions of the audio processing that are not contained either in the microphones or the loudspeakers will be contained in the central processing system. This may be either a single processor, or a networked array of processors. In either case there will be a single user interface for programming and controlling the entire system.

Control and monitoring of the virtual sound system may occur from many locations concurrently. The system will be controllable from PCs running either dedicated control software, or even standard Web browsers. For situations where control via a mouse is not acceptable, touch screen controllers will be available. Where physical controls are desired, a variety of standard, modular, control panel elements will be available. These will allow implementation of physical controls as simple as a wall mounted volume control, or as complex as a large mixing console.

Virtual sound processors have evolved substantially since the first products of this type were introduced in the early 90s. As the processing power available in these products has grown so have the capabilities.

Sound systems exist in a real-world environment, which also contains many other elements with which the sound system operation must be integrated. The most advanced of today's virtual sound processors contain powerful control logic subsystems to ease this integration. High-speed control connections allow exchange of data with external room and building control systems.

QSC Audio recently introduced a new audio processing product suite that has advanced the reliability, sophistication, and capabilities of virtual audio processing products. The QSC offering incorporates many functions that previously were available only in distinctly separate products. These include advanced virtual devices such as FIR filters, feedback suppressions, and ambient level sensing. It also greatly reduces the amount of time needed to compile, as well as incorporates a very low, and fixed, latency between all inputs and outputs. The QSC product allows the designer to easily create a fully redundant system, answering much of the concern that was initially generated by the use of digital systems for all of a facility's audio signal processing and control.

One very significant advantage of the most advanced virtual sound processing systems is the ease with which it is possible to make the various processing subsections interact with each other. For example, an automatic microphone mixer can be thought of as multiple-level meters and gain blocks, where the signal level at the various inputs is used to adjust the instantaneous gain of the various gain block. Such automatic microphone mixers exist in analog, digital, and virtual form. However, that sort of interaction can be expanded greatly to the system level in a virtual sound processor. For example, each microphone input processing chain might contain an AGC. The maximum possible gain an individual AGC can insert while still keeping the entire sound system stable will depend in part on the amount of gain or loss the AGCs for every other microphone are applying. In a virtual system it is possible to let each AGC know what the other AGCs are doing, and based on that information modify its behavior.

There are devices on the market that dynamically insert notch filters to keep a sound system from going into feedback. They do this by monitoring the onset of feedback and very quickly applying the corrective filters. This means the system must slightly start to ring before correction can be applied. A virtual sound system, by contrast, can monitor all the factors that impact system stability and insert corrective notch filters selectively in only the signal path required, and do so before the system starts ringing.

A virtual sound system can be programmed to know which are the most critical microphones and loudspeaker zones, and if trade-offs must be made to get optimum performance, can optimize the most important inputs and outputs. For example, if there is a person who must be heard, and that person is speaking in a very soft tone of voice and as a result the gain can't be gotten high enough, the virtual sound system can bring
the gain up higher in the most critical loudspeaker zones while not increasing the gain everywhere, thus keeping the overall system stable.

A virtual sound processor may have many thousands of controls that need to be adjusted during a system’s initial setup. Today’s advanced virtual processors contain control tools that allow the system commissioning engineer a much simplified interface for adjusting those controls. This greatly reduces the time required and the chances for error in setup.

In short a well-designed virtual sound system can apply all the little tweaks to the system’s controls that a very skilled operator would have applied if he or she could respond to conditions in a split second and adjust hundreds of controls at once.

38.4.4 Active Acoustics

The virtual sound system may also be used to modify the acoustic environment.

The reverberation time and reflection patterns of the space may be dynamically varied at any time to meet the needs of the program material. This requires that the physical acoustics of the space be at the low end of the desired reverberation range. The virtual sound system will add the initial reflections from the proper spatial directions, and the enveloping reverberant tail, to produce the desired acoustic environment. The ability to change the acoustics on an almost instantaneous basis allows each portion of a program to be performed in its optimum acoustics. For example, spoken portions of the program may only utilize a few supportive reflections. At the other extreme, choral or organ music may have a very long reverberation time. This technology may also be used to simulate the acoustic environment of the room in outdoor performance venues.

Environmental noise, particularly that of a low-frequency and/or repetitive nature, may be actively canceled by the virtual sound system. As the cost of DSP processing comes down, and the power handling of transducers goes up, this technology will become more attractive in comparison to traditional noise control and isolation methods. Vibration and low-frequency sounds are the most difficult and costly to isolate using traditional passive methods. High displacement isolation mounts together with large amounts of mass are often required for good low-frequency performance. At higher frequencies often far less expensive techniques and materials are effective. By comparison, active noise and vibration control techniques are most effective at the lowest frequencies, but find it increasingly difficult to obtain satisfactory performance over large areas at higher frequencies. Therefore, including active noise control techniques in a virtual sound system to control low-frequency noises may prove beneficial in reducing the total project cost.

38.4.5 Diagnostics

The virtual sound system will monitor its own operation, and the environment in which it operates. The entire signal path will be monitored for failures. Depending on the level of system design, the operator may just be notified, or redundant equipment may be automatically utilized to assure uninterrupted operation. Most systems will utilize multiple microphones and loudspeakers. In itself, this provides a significant degree of redundancy. If the coverage pattern of the microphones or loudspeakers is controllable, then the virtual system can compensate for any given failure of a microphone or loudspeaker. Redundancy may also be designed into the interconnections and processing subsystems of the virtual sound system. With careful design, systems with few or no single points of failure can be built.

Environmental conditions that will impact the long term health of the system, such as temperature and airflow, will be monitored and trends logged. The performance of the microphones and loudspeakers in the system will be monitored and recorded to spot degradation of performance before it becomes audible. The acoustic environment will also be monitored to spot changes that might impact on the subjective performance of the sound system. System health reports will be automatically generated and sent to the system operator, installer, and designer when any of the parameters monitored are outside of expected tolerances. This capability will result in much more consistent performance over the life of the system, and will extend that life for years.

38.4.6 The Sound System of the Future

When all these techniques are combined, the virtual sound system of the future will have better performance, be more invisible to the user, be easier to operate, and have a longer life than any current system.

39.1 Background

In most cases it is preferred to interface digital audio devices in the digital domain, instead of using analog interconnections. This is because every time audio is transformed from analog to digital, or digital to analog, there are inevitable quality losses. While analog interfacing is simple and well understood, there are few cases in which it would be desirable to interface two digital audio devices in the analog domain. If the digital audio devices are not provided with digital audio interfaces, for example, analog interfacing will be required. Such an analog interface, however, will result in subtle changes in the digital audio from one side of the interface to the other. The exact sequence of numbers that make up the digital audio will not be reproduced at the far side of an analog interface.

The numbering system commonly used in digital audio is called binary. Each of the digits (called bits) in the binary numbering system can be either a 1 or a 0. If two binary numbers are identical, then all their bits will match.

Digital audio interfaces have the potential to allow bit accurate transfer of the digital audio from one digital audio device to another, thus insuring no changes in the sequence of numbers that makes up the digital audio, and therefore potentially perfect accuracy. In order for this potential to be realized both digital audio devices must be synchronized.

Digital audio consists of a series of consecutive numeric samples of the audio, each of which must be received in sequence. If the samples are not received in proper sequence, or if samples are lost or repeated, then the audio will be distorted.

In order for digital audio devices to interconnect digitally, both ends of each connection must run at the same sampling rate. If the source is running at even a (very slightly faster) rate than the receiver, sooner or later the source will output a sample that the receiver is not ready to receive yet. This will result in the sample being lost. Similarly, if the source is running at even a (very slightly slower rate) than the receiver, eventually the receiver will be looking for a sample before the source is ready to send it. This will result in a new false sample being inserted into the data stream.

39.1.1 Synchronous Connections

The most straightforward way to carry digital audio is over a synchronous connection. In such a scheme, the data is transmitted at the exact same rate it is created, in other words, at the sample rate. When additional data is sent along with the audio in a synchronous system, it is added to the audio data and the whole package of information is transmitted at the audio sampling rate. Such systems send information in fixed-size groups of data, and introduce very little signal delay of latency. In a synchronous system the audio data words are sent and received at the audio sampling rate and both ends of the system must be locked to the same master sampling rate clock, Fig. 39-1. AES3 and IEC 90958 are examples of synchronous digital audio interconnection schemes.

![Figure 39-1. Synchronous connection between input and output.](image)

39.1.2 Asynchronous Connections

An asynchronous system is in many ways the exact opposite of a synchronous system. Information is not sent at any particular time. The size of a given packet of information may vary. The time that it takes to get a given piece of information across an asynchronous connection may well be indeterminate. There is no common master clock that both ends of the connection refer to.

Examples of asynchronous transmission abound. When you mail a letter, it may contain just a short note on a single page, or it might contain the manuscript for a book. You put your letter in the mailbox (the outbound buffer) in the expectation that it will be picked up sometime later that day. The letter will pass through many different stages of transmission and storage along the way to its destination. You might know that the average delivery time is 3 days, however, in some cases the delivery might happen in 2 days, and in others it might be 6 days. You can be (almost) certain the letter will reach its destination eventually, but the exact delivery time can’t be known.

Other examples of asynchronous transmission include the Internet, and most common computer interfaces and networks including RS-232 serial, and Ethernet networking.

RealAudio and Windows Media Audio (WMA) are two common schemes for providing a synchronous
audio connection over the asynchronous Internet. While there can be a large receive buffer of as much as 5 to 10 seconds, you will still experience dropouts in the audio due to network conditions on the Internet inserting delay on some audio packets that exceed the receive buffer delay. Generally the audio gets through OK, but every once in a while it drops out.

39.1.3 Isochronous Connections

Isochronous connections share properties of both the synchronous and asynchronous systems, and bridge the gap between the two. Information is not sent at a constant rate locked to a master clock. It provides a maximum delivery time for information that is only rarely if ever exceeded. By using buffers at each end, it can carry information such as audio where the delivery of audio words in proper sequence, and with a known and constant delay, is essential. In a properly designed isochronous system latency can be very low providing near real time operation, and reliability can be very high, Fig. 39-2.

39.1.4 AES5

AES5 standardizes on a primary sampling frequency for professional audio use of 48 kHz ±10 parts per million (ppm). It also allows 44.1 kHz to be used when compatibility with consumer equipment is required. For broadcast and transmission-related applications where a 15 kHz bandwidth is acceptable it allows a sampling frequency of 32 kHz to be used. For applications where a wider than 20 kHz bandwidth is desired, or a relaxed slope of the anti-aliasing filter is preferred, a sampling rate of 96 kHz ±10 ppm may be used.

Higher and in some cases much higher sampling rates are in use internally in digital audio equipment. When such a higher rate appears on an external digital audio interface, the AES recommends the rate be a multiple of a factor of two of one of the approved sampling rates above.

AES5 discourages the use of other sampling rates, although others are in use.

The above information is based on AES5-2003. It is always advisable to obtain the latest revision of the standard.

39.1.5 Digital Audio Interconnections

In a simple chain of interconnected digital audio devices, it is possible for each device to look at the sampling rate of the incoming digital audio, and lock itself to that incoming rate. One problem with this system is that the sampling rate as recovered from the incoming digital audio is less than a perfect steady rate. It will have slight variations in its rate known as jitter. While there are techniques available to reduce this jitter, they add cost, and are never perfect. Each consecutive device in the chain will tend to increase this jitter. If the jitter gets too high, the receiving device may not correctly interpret the digital audio signals, and bit accuracy will be lost. Worse, the performance of analog to digital and digital to analog convertors is very dependent on a precise and steady clock. Even very small amounts of jitter can significantly degrade the performance of convertors. As a result, it is not recommended to cascade very many digital audio devices in this manner.

If a single digital audio device such as a mixer will be receiving digital audio from more than one source, then this simple scheme for synchronizing to the incoming digital audio signal breaks down, since it is only possible to synchronize to a single source at a time. There are two ways to solve this problem.
One way is to use a sample rate converter (SRC) on each input to convert the incoming sample rate to the internal sample rate of the digital audio device. Such a SRC will add cost to the input, and will in some subtle ways degrade the quality of the audio. The accuracy will be better than with an analog interfacing, but the digital audio will not be transferred with bit accuracy. Of course, there are different degrees of perfection available in SRCs at correspondingly different levels of complexity and cost. Some SRCs will only handle incoming digital audio that is at a precise and simple numeric ratio to the internal sample rate. Others will accept any incoming sample rate over a very wide range and convert it to the internal sampling rate.

This second sort of SRC is very useful when you must accept digital audio from multiple sources that have no common reference, and convert them all to a common internal sampling rate.

As implied above, the other way to handle inputs from multiple digital audio sources is to lock all the devices in the digital audio system to a single common reference clock rate. In large systems this is the preferred solution, and the Audio Engineering Society has developed the AES11 Standard that explains in detail how to properly implement such a system. Such a system can have excellent jitter performance since each device directly receives its sampling rate reference from a common source. Interconnections between the digital audio devices can be rearranged freely since we do not have to be concerned about synchronization and jitter changes as the signal flow is changed.

39.1.6 AES11

AES11 defines a digital audio reference signal (DARS) that is merely an accurate AES3 signal used as the common reference clock for a facility. The DARS may contain audio signals, but is not required to do so.

There are three basic modes of operation defined in AES11: use of a DARS, use of the embedded clock in the AES3 signal, and use of a common master video reference clock from which a DARS is derived. Use of a DARS is considered normal studio practice. As mentioned above cascading AES3 signals through devices without a DARS can lead to increased jitter.

The only flaw in this scheme is that some digital audio devices may not have provisions for accepting an external sampling rate reference. As a result, in many complex systems, while there may be a master sample rate clock that most equipment is locked to, there often is still a need for sample rate convertors to accept the output of those devices that can’t lock to the master clock. AES11 acknowledges this limitation.

AES11 specifies two grades of DARS, grade 1 and grade 2. A DARS that has as its primary purpose studio synchronization should be identified in byte 4 bits 0–1 of the AES3 channel status. More details are given on this below.

A grade 1 DARS is the highest quality and is intended for use in synchronizing either a multiroom studio complex or a single room. It requires a long term stability of ±1 ppm. Devices producing a grade 1 DARS are only expected to themselves lock to signals of grade 1 quality. Devices that are only expected to lock to grade 1 signals are required to lock to signals over a range of ±2 ppm.

A grade 2 DARS is intended for use in synchronizing only within a single room where the added expense of a grade 1 solution can’t be justified. It requires a long term stability of ±10 ppm as specified in AES5. Devices expected to lock to grade 2 signals are required to lock to signals over a range of ±50 ppm.

The above information is based on AES11-2003. It is always advisable to obtain the latest revision of the standard.

39.2 AES3

The Audio Engineering Society titled their AES3 Standard “Serial transmission format for two-channel linearly represented digital audio data.” Let’s break that title apart as our first step in examining the AES3 Standard.

This standard sends the data in serial form. In other words it sends the information to be transmitted as a sequence of bits down a single transmission path, as opposed to sending each bit down a separate transmission path. Each bit of data making up a single sample of the audio is sent in sequence starting with the least significant bit on up to the most significant bit. The least significant bit is the bit that defines the smallest change in the audio level, while the most significant bit is the one that defines the largest change in the audio level.

AES3 normally is used to transmit two channels of audio data down a single transmission path. The data for channel one of a given audio sample period is sent first, followed by the data for channel two of the same sample. This sequence is then repeated for the next sample period.

Most professional digital audio today is linearly represented digital audio data. This is also sometimes called pulse code modulation, or PCM. In such a scheme for numerically representing audio, each time
sample of audio is represented by a number indicating its place in a range of equal-sized amplitude steps. If eight bits were being used to represent the audio level, there would be $2^8$ or 256 equal-sized amplitude steps between the smallest level that could be represented and the largest. The smallest amplitude change that could be represented is exactly the same at the low-level portion of the range as at the highest-level portion. This is important to understand since not all digital audio uses such a linear representation. For example, often telephone calls are encoded using nonlinear techniques to maximize the speech quality transmitted using a limited number of bits. In professional audio we generally use larger numbers of bits, usually in the range of 16 to 24, that allow excellent performance with linear representation. Linear representation makes it easier to build high-quality converters and signal processing algorithms.

The bits that make up an audio sample word are represented in two’s complement form, and range from the least significant bit (LSB) that represents the smallest possible amplitude change, to the most significant bit (MSB) that represents the polarity of the signal.

AES3 adds a considerable amount of structure around the basic sequence of bits described above in order to allow clock recovery from the received signal, provide a robust signal that is easily transmitted through paths of limited bandwidth, and provide for additional signaling and data transmission down the same path.

Each of the two audio channels that can be carried by an AES3 signal is formatted into a sequence of two subframes, numbered 1 and 2, each of which follows the following format.

The following information is based on AES3-2003. It is always advisable to obtain the latest revision of the standard.

### 39.2.1 Subframe Format

First, additional bits are added before and after the digital audio to make a subframe of exactly 32 bits in length. The bits are transmitted in the sequence shown from left to right, Fig. 39-3.

If the audio data contains 20 or fewer bits, subframe format B is used. If the audio data contains 21 to 24 bits, subframe format A is used. In either case if data containing less than 20 or 24 bits is used, extra zeros are added to the LSB to bring the total number of bits to 20 or 24. Since the data is in two’s complement form, it is important that the MSB, representing the signal polarity, always be located in bit 27.

The preamble is used to indicate if the audio to follow is channel one or two, and to indicate the start of a block of 192 frames.

If 20 or less audio bits are carried, then AES3 allows 4 bits of other data to be carried by the AUX bits.

The validity bit is zero if it is permissible to convert the audio bits into analog, and one if the conversion should not be done. Neither state should be considered a default state.

The user bit may be used in any way for any purpose. A few possible formats for using this bit are specified by the standard. Use of one of these formats is indicated by the data in byte one, bits 4 through 7 of the channel status information. If the user bit is not used it defaults to zero.

The channel status bit carries information about the audio signal in the same subframe, in accordance with a scheme that will be described later.

The parity bit is added to the end of each subframe and is selected so the subframe contains an even number of ones and an even number of zeros. This is called even parity. It allows a simple form of error checking on the received signal.

### 39.2.2 Frame Format

A subframe from channel two follows a subframe from channel one. The pair of subframes in sequence is called a frame.

In normal use frames are transmitted at exactly the sampling rate.
Again the data is transmitted in the sequence shown from left to right.

The parts shown as X, Y, and Z above represent the three versions of the preamble portion of each subframe. When version Z is used, it indicates the start of a block of 192 frames. When version X or Z is used, it indicates that the channel data to follow is from channel one. When version Y is used, it indicates that the channel data to follow is from channel two.

Blocks are used to organize the transmission of channel status data, Fig. 39-4.

39.2.3 Channel Coding

AES3 needs to be able to be transmitted through transformers. Transformers can’t pass direct current (dc). Ordinary binary data can stay at 1 bit level for any arbitrary length of time, and thus by its nature can contain a dc component. Therefore a coding scheme is needed that eliminates this possibility.

We must also be able to recover the sampling rate clock from the AES3 signal itself. It was desired not to have to rely on a separate connection to carry the sampling rate clock. Since ordinary binary can stay at a given bit level for an arbitrary length of time, it is not possible to extract the clock from such a signal.

It was also desired to make AES3 insensitive to polarity reversals in the transmission media.

To meet these three requirements, all of the data except the preambles is coded using a technique called biphase-mark.

The binary data shown in the source coding portion of the diagram above has the sequence 100110.

The clock marks shown are at twice the bit rate of the binary source coding, and specify a time called the unit interval (UI), Fig. 39-5.

The channel coded data sequence has a transition at every boundary between bits of the original source coding, whether or not the source coding has such a transition. This allows extraction of the original clock rate from the received signal since there always is a transition at every source bit boundary.

If the source coding data is a one, the channel coding will insert a transition in the middle of the source coding bit time. If the source coding data is a zero, the channel coding will not insert any additional transition.

The combination of these channel coding characteristics provides the desired features. There is no dc component, so the signal may be transmitted through transformers. The sampling rate clock may be extracted from the signal. The signal is insensitive to polarity reversals since the source data state is carried by the presence or absence of an additional signal transition rather than the coded data state itself.

39.2.4 Preambles

The single portion of the subframe that is not encoded using biphase-mark coding is the preamble. In fact the preambles are deliberately designed to violate the biphase-mark rules. This is done to allow easy identification of the preamble and to avoid any possibility that some data pattern could by chance duplicate a preamble.

This also allows the receiver to identify the preamble and synchronize itself to the incoming audio within one sample period. This makes for a robust reliable transmission scheme.

As mentioned in the Frame Format section above, there are three different possible preambles. Each preamble is sent at a clock rate equal to twice the bit rate of the source coding. Thus the eight states of each preamble are sent in 4 bit time slots at the beginning of each subframe.
Chapter 39

The state of the beginning of the preamble must always be opposite that of the second state of the parity bit that ends the subframe before it.

You will note that the two versions of each preamble are simply polarity reversed versions of each other.

In practice, due to the nature of the positive parity used for the bit before the preamble, and the biphase coding, only one version of each preamble will ever be transmitted. However, to preserve the insensitivity to polarity inversions, AES3 receivers must be able to accept either version of each preamble.

Like biphase-mark coding, the preambles are dc free and allow for clock recovery while differing from valid biphase-mark coding at least twice.

The clock rate shown above is at twice the source bit rate. Note that the second state of the parity bit is always zero, and therefore the preamble will always start with a transition from zero to one. Also note that in this preamble, as in all possible preambles, there are at least two places where there is no transition at a bit boundary thus violating the rules for biphase-mark coding and providing positive identification of the preamble.

The sequence of channel status bits for each channel starts in the frame with Preamble Z.

39.3 AES3 Implementation

39.3.1 AES3 Transmitters

As a minimum, an AES3 transmitter must encode and transmit the audio words, validity bit, user bit, parity bit, the three preambles, and a minimum version of the channel status.

The minimum version of channel status will have byte 0 bit 0 set to one to specify this is a “professional use of channel status block” and all the other bytes set to their default values.

Some AES3 receiving devices might have problems with such a minimum version of channel status for two reasons. First, many receivers expect to see a properly encoded CRC in byte 23, and will therefore show a CRC error when receiving the default 0’s instead of a CRC. Second, some receivers might expect to see the sampling frequency in byte 0 bits 6–7, and not have provision for manual override or auto set of the sampling frequency.

Even if some addition information is included in the channel status beyond what is listed as a minimum above, unless all the information considered standard below is included, the interface must still only be called a minimum implementation of AES3.

A standard implementation will include everything specified as minimum above plus will encode and transmit all the information in bytes 0, 1, 2, and 23 of the channel status.

An enhanced implementation provides additional capabilities beyond the standard implementation.

All transmitters must be documented as to which of the channel status capabilities they support.

39.3.2 AES3 Receivers

All receivers must document the level of implementation provided and the actions that will be taken by the receiving device based on the information received.

39.3.3 Electrical Interface

AES3 uses a balanced 110 Ω electrical interface based on the International Telegraph and Telephone Consultative Committee (CCITT) Recommendation V.11. It is
designed for use at distances up to “a few hundred meters.”

If improved performance beyond that of CCITT V.11 is desired, it is suggested but not required that the circuit in Fig. 39-8 be used.

Series capacitors $C_2$ and $C_3$ block external dc from flowing through the transformers. This protects the transformers from damage or performance degradation if dc is applied to them. The AES42 (AES3-MIC) Digital Interface for Microphones Standard calls for digital microphones to be powered by $10 \text{ V}_{dc}$ digital phantom power that is a variation on the phantom power scheme used for analog microphones. This provides another excellent reason to provide dc blocking on all AES3 inputs and outputs, transformer based or not, to prevent damage if such a phantom power scheme were to be applied. Structured wiring using Cat5 or high rated cable and RJ45 connectors is now a permitted alternative interconnect scheme for AES3 signal. These interconnects are also used for Ethernet, which may have power over Ethernet (PoE) applied. They are also used for plain old telephone service (POTS), which will have 48 V battery and 90 V ring signals. If structured cabling is used for AES3, consideration must be given to the survivability of the line driver and receiver circuits if accidentally interconnected to PoE or POTS lines.

Transformers will make possible higher rejection of common mode interfering signals, electromagnetic interference (EMI), and grounding problems than common active circuits. The European Broadcasting Union (EBU) in its version of this standard (EBU Tech. 3250-E) requires the use of transformers. This is the major difference between the standards. It is common to see the AES3 Standard referred to as the AES/EBU Standard even though that is not strictly correct since AES3 makes the transformers optional, while the EBU requires them.

![Figure 39-7. AES3 Channel Status Data Format. Note both the bits and bytes are numbered starting with 0.](image-url)
Table 39-1. Channel Status Data Format Details (Continued)

| Bit 5 | Source sampling frequency unlocked. |
| Bit 6–7 | Encoded Sampling Frequency (See Notes 2, 3 and 4.) |
| State | No sampling frequency indicated. This is the default. |

Note 1. Other than the use of the Channel Status block of information, the rest of the data format is identical between the AES3 “professional use” Standard and the IEC 60958-3 “consumer use” Standard. The electrical format is different, however. For these reasons it should never be assumed that a “consumer use” receiver would function correctly with a “professional use” transmitter, or vice versa.

Note 2. It is not a requirement that the sampling frequency used be indicated by these bits, nor is the use of one of the sampling frequencies that can be indicated by these bits. If the transmitter does not support sampling frequency indication, the sampling frequency is unknown, or the sampling frequency is not one that can be indicated by these bits, then the bits should be set to 0 0. Bits 3–6 of Byte 4 of the Channel Status may indicate other possible sampling rates.

Note 3. If a sampling rate is indicated, it may be modified by the status of Bit 7 of Byte 4 of the Channel Status.

Note 4. If Bits 0–3 of Byte 1 indicate single channel double sampling frequency mode, then the sampling frequency indicated by Bits 6 and 7 of Byte 0 is doubled.

</tbody>
</table>

Bits 0–3 Channel number if bit 7 is 1. Channel number is value of bits 0–3 (bit 0 is LSB) plus 1.

Note 1. It is intended that the defined multichannel modes will identify mappings between channel numbers and function. Standardized mappings have yet to be defined.

Note 2. Some equipment may only consider the channel status data carried in one of the two subframes. Therefore if both subframes specify the same channel number, subframe 2 has a channel number one above channel 1 unless single channel double sampling frequency mode is in use.

Note 3. If bit 7 is 1, bits 0–3 correspond to the consumer mode channel status specified in IEC 60958-3. Consumer mode channel A is equivalent to channel 2, and Consumer mode channel B to channel 3 and so on.

</tr>
</tbody>
</table>

Cabling to be used for AES3 is specified as 110 Ω balanced twisted pair with shield. The impedance must be held over a frequency range from 100 kHz to 128 times the maximum frame rate to be carried. The line driver and line receiver circuits must have an impedance of 110 Ω ±20% over the same frequency range. While the acceptable tolerance of the cable impedance is not specified, it is noted that tighter impedance tolerances for the cable, driver, and receiver will result in increased distance for reliable transmission, and for higher data rates. If a 32 kHz sampling rate mono signal were carried in single channel double sampling frequency mode, the interface frequency range would only extend to 2.048 MHz. If a 48 kHz sampling frequency two-channel signal were to be carried, the interface frequency range would extend to 6.144 MHz, or about the 6 MHz bandwidth commonly quoted for AES3. However, if a 192 kHz sampling frequency two-channel signal were to be carried, the interface frequency range would extend to 24.576 MHz. As you can see, some uses of AES3 can extend the frequency range far beyond 6 MHz. If you are using a mode that has extended interface frequency, make sure that the transmitter, interconnect system, and receiver are all designed to meet specifications over the entire frequency range in use.

When AES3 was originally introduced it was thought that ordinary analog audio shielded twisted pair cable would be acceptable for carrying AES3 digital audio, and indeed that is often the case for shorter distances. However, the impedance and balance of common audio cable vary widely, and it was quickly determined that purpose built AES3 cable performed significantly better for AES3 than ordinary analog audio cable. It was later determined that such AES3 rated cable often also performed significantly better as analog audio cable than ordinary cable, so today we commonly see AES3 rated cable used in both analog and digital applications.

While the AES3 Standard makes mention of interconnect lengths of “a few hundred meters,” in practice distances beyond about 100 m often require the use of equalization to compensate for losses in the cabling. If such equalization is used, it must never be applied to the transmitter, but only to the receiver.

As an alternative to purpose built AES3 rated digital audio cable, structured wiring meeting Category 5 or greater is acceptable. Such cabling can be of either shielded twisted pair (STP) or unshielded twisted pair (UTP) construction. To deliver satisfactory performance, only one cable type (Category 5 or higher STP, Category 5 or higher UTP, or AES3 digital audio rated)
may be used for the entire path from driver to receiver. If Category 5 or greater UTP is used, distances of 400 meters unequalized or 800 meters with equalization are possible.

### 39.3.4 Line Drivers

Just like AES3 cabling, line drivers are specified as having a balanced output with an impedance of 110 \( \Omega \pm 20\% \) over the entire frequency range from 100 kHz to 128 times the maximum frame rate. The driver must be capable of delivering an output level between 2–7 V (measured peak to peak) into a 110 \( \Omega \) resistive termination directly across its output terminals with no cable present. The balance must be good enough so that any common mode output components are at least 30 dB lower in level than the balanced output signal.

The rise and fall times of the output, as measured between the 10–90\% amplitude points, must be no faster than 5 ns, and no slower than 30 ns into a 110 \( \Omega \) resistive termination directly across its output terminals with no cable present. A fast rise and fall time often improves the eye pattern at the receiver, but a slower rise and fall time often results in lower electromagnetic interference (EMI) radiated. Equipment must meet the EMI limits of the country in which it is used.

Equalization must not be applied at the driven end of the line.

### 39.3.5 Jitter

All digital equipment has the potential for introducing jitter, or small timing variations in the output signal. Extreme amounts of jitter can actually cause data errors. More moderate amounts of jitter may not change the actual data transmitted, but can lead to other ill effects. An ideal D/A would ignore the jitter on the incoming signal and perfectly produce the analog output based solely on the data carried. Unfortunately many real-world A/D and D/A converters are far from ideal, and but it became clear this was not good practice and the allow jitter to change or modulate the output. Therefore keeping jitter low can have significant audible benefits.

AES3 divides the jitter at the output of a line driver into two parts intrinsic and pass through. The pass through portion of the jitter is due to jitter in the timing reference used. If such an external timing reference is used AES3 requires that there never be more than 2 dB of jitter gain at any frequency. The external timing reference may be derived from an AES3 input signal, or from a digital audio reference signal (DARS), which is an AES3 signal used as a clock reference as specified in AES11. If cascades of digital devices are built where each device uses as its clock reference the AES3 signal received from the previous device in the chain, it is possible for the pass through jitter to eventually increase the output jitter to an unacceptable level.

Many of today’s better A/D and D/A converters provide jitter attenuation from the timing reference, Fig. 39-9.

Intrinsic jitter is measured with the equipment’s own internal clock and with the equipment locked to an effectively jitter free external reference clock. Intrinsic jitter is measured through a minimum-phase one-pole high-pass filter whose -3 dB down point is 700 Hz, and which accurately provides that characteristic down to at least 70 Hz. The pass band of the filter has unity gain. Measuring at the transition zero crossings and through the filter the jitter must be less than 0.025 unit intervals (UI), Fig. 39-5.

### 39.3.6 Line Receivers

Just like AES3 cabling and line drivers, line receivers are specified as having a balanced output with an impedance of 110 \( \Omega \pm 20\% \) over the entire frequency range from 100 kHz to 128 times the maximum frame rate. The receiver must be capable of accepting an input level of 2–7 V (measured peak to peak). Early versions of AES3 required the receiver be able to accept 10 V. Only one receiver may be connected to an AES3 line. Early versions of AES3 permitted multiple receivers, standard was modified.
An AES3 receiver must correctly interpret data when a random data signal that is not less than $V_{\text{min}} = 200 \text{ mV}$ and $T_{\text{min}} = 0.5 T_{\text{nom}}$, as shown in Fig. 39-10, is applied to the receiver. If cable lengths of over 100 m are to be used, optional receiver equalization may be applied. The amount of equalization needed depends on the cable characteristics, length, and the frame rate of the AES3 signal. The AES3 Standard suggests that at a 48 kHz frame rate an equalizer with a boost that rises to a maximum of 12 dB at 10 MHz would be appropriate.

The receiver must introduce no errors due to the presence of common mode signals as large as 7 Vp at any frequency from dc to 20 kHz. This is not enough range to protect an AES3 receiver from the application of 10 Vdc digital phantom power as specified in the AES42 (AES3-MIC) Digital Interface for Microphones Standard.

The receiver must introduce no data errors from jitter that does not exceed 10 unit intervals (UI) at frequencies below 200 Hz decreasing to not exceeding 0.25 UI at frequencies over 8 kHz. Of course the recovered clock from such a high jitter signal may cause other problems, but at least the data must be decoded correctly.

### 39.3.7 AES3 Connectors

The connector for AES3 signals is what is commonly called the XLR, and is standardized in IEC 60268-12 as the circular latching 3 pin connector. Outputs are on male connectors and inputs are on female connectors just as in common analog usage of this same connector. The shield or ground connection is on pin 1, and the signal connections are on pins 2 and 3. With AES3 digital signals, the relative polarity of pins 2 and 3 is unimportant.

To avoid confusion with analog audio signal connectors, AES3 suggests that manufacturers label AES3 outputs “digital audio output,” or “DO;” and AES3 inputs “digital audio input,” or “DI.”

An alternative modified XLR connector has been proposed to help make clear that the signal on the connector is digital and not analog, and via a keying scheme reducing the chances of accidental interfacing of inputs and outputs that are incompatible. There has been much discussion in the AES about changing to this
connector, either for all AES3 signals, or at least for AES42 (AES3-MIC) digital microphone signals, but no consensus has been reached. It should also be noted that since the analog audio bandwidth usually does not significantly exceed 20 kHz, and the AES3 spectrum does not go below 100 kHz, it is possible for a single cable to carry both an analog audio signal and an AES3 signal at the same time. The proposed modified XLR connector could also allow such a dual use condition.

If Category 5 or greater UTP or STP is used, the RJ45 connector must be used. Pins 4 and 5 of the RJ45 are the preferred pair, with pins 3 and 6 the suggested alternative pair. It is suggested that if adaptors from XLR to RJ45 are used, pin 2 of the XLR should connect to pin 5 (or other odd numbered pin) of the RJ45, and pin 3 of the XLR should connect to pin 4 (or other even numbered pin) of the RJ45 connector.

39.4 AES-3id

AES-3id is a variant on AES3 where the signal is carried over unbalanced 75 Ω coaxial cable instead of over 110 Ω balanced cable. It can allow the transmission of AES3 information over distances of up to 1000 m. Analog video distribution equipment and cable may often be suitable for transmission of AES-3id data. This of course is a great convenience in video facilities.

At distances of up to 300 m, receiver equalization may not be needed. Equalization must never be applied at the line driver end.

The AES-3id information document provides extensive tables and circuit diagrams showing active and passive circuits for AES-3id transmission. Canare, among others, sells passive adapters between 110 Ω balanced AES3 and 75 Ω unbalanced AES-3id.

AES-3id was written based on the assumption of the sampling rates specified in AES3-2003 and not on double or quadruple rates as are sometimes used today. The basic techniques of AES-3id should extend to these higher rates, however.

The following information is based on AES-3id-2001. It is always advisable to obtain the latest revision of the information document.

39.4.1 Line Driver

AES-3id line drivers must have an impedance of 75 Ω and exhibit a return loss in excess of 15 dB from 100 kHz to 6 MHz. Obviously if frame rates in excess of 48 kHz as allowed by AES3 were to be used, wider bandwidths would be required. Much but not all modern video gear will have the bandwidth to correctly handle higher sampling rates.

The peak to peak output voltage into a 75 Ω 1% tolerance resistor must be between 0.8 V and 1.2 V, with a dc offset not to exceed 50 mV. The rise and fall times should be between 30 ns and 44 ns. These output voltage, dc offset, and rise and fall times have been chosen for compatibility with analog video distribution equipment. Lower dc offset values are desirable for longer transmission distances.

39.4.2 Interconnect System

AES-3id cable must be 75 ±3 Ω over the range from 100 kHz to 6 MHz. It is to be equipped with BNC connectors as described in IEC 60169-8 but with an impedance of 75 Ω instead of 50 Ω.

39.4.3 Line Receiver

AES-3id line receivers must have an impedance of 75 Ω and exhibit a return loss in excess of 15 dB from 100 kHz to 6 MHz. The receiver must be capable of correctly decoding signals with input levels of 0.8 V and 1.2 V (measured peak to peak).

An AES-3id receiver must correctly interpret data when a random data signal that is not less than \( V_{\text{min}} = 320 \, \text{mV} \) and \( T_{\text{min}} = 0.5 \, T_{\text{nom}} \) as shown in Fig. 39-11 is applied to the receiver. For reliable operation at distances in excess of 1000 m, a receiver that operates correctly with a \( V_{\text{min}} = 30 \, \text{mV} \) may be required.

![Figure 39-11](image.png)

**Figure 39-11.** AES-3id Eye diagram. \( T_{\text{nom}} = 0.5 \) unit interval (UI) (see Fig. 39-5); \( T_{\text{min}} = 0.5 \, T_{\text{nom}}; \) \( V_{\text{min}} = 320 \, \text{mV} \). The eye diagram is one of the most powerful tools used to examine the quality of received data. The larger the open area of the eye the better. The limits shown are the most closed an eye should ever be for correct reception of the AES-3id data.
39.5 AES42 (AES3-MIC)

AES42 (AES3-MIC) is a variant on AES3 designed to meet the needs of interfacing microphones that have direct digital outputs. The first most significant difference is that the transmitter and receiver use center tapped (on the cable side) transformer, which allow a digital phantom power (DPP) of +10 (+0.5, –0.1) Vdc at 250 mA to be supplied to the microphone. No more than 50 mVp-p ripple is allowed on the DPP. The microphone may draw no less than 50 mA, or more than 250 mA from the DPP, and may not present a load in excess of 120 nF to the DPP. The microphone must not be damaged by the application of any of the analog microphone phantom powers specified by IEC 61938 including common 48 V phantom. The techniques described by this standard may be applied to portable AES3 output devices other than microphones, however, AES42 only covers microphones.

Optionally a modulation from +10 to +12 V (resulting in a peak current of 300 mA) may be applied to the DPP for remote control purposes. This modulated signal thus travels in common mode from the AES3-MIC input back to the AES3-MIC microphone over the same cable that is carrying the AES3 audio data from the microphone to the AES3-MIC input. Because it is sent in common mode, the data rate must be far slower than that of AES3 to avoid interference. If the AES3 frame rate (FR) is 44.1 kHz or 48 kHz, the bit rate of the remote control signal is FR/64 bits per second (bit/s). For a FR of 88.2 kHz or 96 kHz the remote control bit rate is FR/128 bit/s. For a FR of 176.4 kHz or 192 kHz the remote control bit rate is FR/256 bit/s. As a result, the remote control bit rate is 750 bit/s if the AES3 FR is 48 kHz, 96 kHz, or 192 kHz, and 689.06 bit/s if the FR is 44.1 kHz, 88.2 kHz, or 176.4 kHz.

The remote control signals are sent as required, except if used for synchronization, in which case they will be sent on a regular basis of not less than six times per second.

The following information is based on AES42-2006. It is always advisable to obtain the latest revision of the standard.

39.5.1 Synchronization

There are two primary possible modes of operation for a microphone meeting the AES42 Standard, Fig. 39-12.

Mode 1 allows the microphone to free run at a rate determined by its own internal clock. No attempt is made to lock the microphone’s clock rate to an external clock, and if such a lock is desired, sample rate conversion must be performed external to the microphone. This technique is the simplest way for an AES3-MIC microphone to operate, and does not require the use of the optional remote control signal.

Mode 2 uses the remote control signal to send data back to the microphone that allows its sampling rate to be varied, and phase locked to an external reference. The mode 2 microphone (or other AES3-MIC device) contains a voltage controlled crystal oscillator (VCXO), which has its frequency controlled by a digital to analog converter (DAC). The DAC receives control information via the remote control signal from the AES3-MIC receiving device. The receiving device compares the current sample rate of the microphone to the external reference and uses a phase locked loop (PLL) to generate a correction signal, which is sent back to the microphone. This results in the sampling rate of the microphone becoming frequency and phase matched to the reference signal. If multiple microphones or other AES3-MIC mode 2 sources are locked to the same reference, this has the additional advantage of providing a consistent and near zero phase relationship between the sampling times of the various sources. When multiple microphones sample correlated signals, for example, in stereo or multichannel recording techniques, this results in stable imaging.

If the receiver does not support mode 2 operation, the mode 2 microphone automatically reverts to mode 1 operation.

39.5.2 Microphone ID and Status Flags

AES42 defines the use of the user data channel in AES3 to optionally allow the microphone to identify itself and send back status information. Imagine the benefits in a complex setup of not having to worry which input a given mic is plugged into. The receiving device could use the microphone ID information to automatically route the microphone to the correct system input, no matter to which physical input it was connected.

39.5.3 Remote Control

AES42 defines three possible sets of remote control instructions, simple, extended, and manufacturer specific. If a device supports the extended instruction set, it must also support the simple instruction set. If a device supports at least the simple instruction set, it must have predetermined default settings it enters if no instructions are received on power up. If a device has switches on it, those will have priority over received instructions.
39.5.4 Simple Instruction Set

The simple instruction set is sent as a 2 byte signal with a minimum of 1 byte break between commands sent. Each byte is sent MSB first.

39.5.5 Direct Commands

Table 39-2 shows the direct commands.

x x x x All other states are under consideration.
1 1 1 1 1 Command 34.

Extended Command 4 data Byte

Bits 0–1 Light Control.

Bit 0 1
State 0 0 No light, default.
1 0 Light 1.
0 1 Light 2.
1 1 Both lights.

Bits 2–3 Test Signal.

Bit 2 3
State 0 0 No test signal, default.
1 0 Test signal 1 (under consideration).
0 1 Test signal 2 (under consideration).
1 1 Test signal 3 (under consideration).

Bit 4 ADC Calibration.

0  No calibration, default.
1  Calibrate ADC

Bit 5 Reset

0  No reset, default.
1  Reset.

Note 1. Signed two’s complement notation is used to encode the channel weights. Bit 6 is the sign extension = –2^6, bit 5 = 2^5 . . .

Bit 0 = 2^6.

Note 2. If XY is selected, then AES3 Channel 1 carries the Left audio channel, AES3 Channel 2 carries the Right audio channel, and bits 0–6 control the XY balance. If MS is selected, then AES3 Channel 1 carries the Mid or sum signal, AES3 Channel 2 carries the Side or difference signal, and bits 0–6 control the MS width.

Extended Command 5 Data Byte

Bits 0–3 Dither and noise shaping.

Bit 0 1 2 3
State 0 0 0 0 No dither or noise shaping, default.
x x x x All other states are under consideration.

Bits 4–7 Sampling frequencies.

Bit 4 5 6 7
State 0 0 0 0 48 kHz, default.
1 0 0 0 44.1 kHz.
0 1 0 0 96 kHz multiple = 2.
1 1 0 0 88.2 kHz multiple = 2.
0 0 1 0 192 kHz multiple = 4.
1 0 1 0 176.4 kHz multiple = 4.
x x x x All other states reserved.

Extended Command 6 Data Byte

Bits 0–6 XY balance, (Notes 1, 2).

Bit 0 1 2 3 4 5 6
State 0 0 0 0 0 0 0 Left 0.5, Right 0.5, Center, default.
1 1 1 1 1 1 0 Left 0.5, Right 0.5, Left (A) channel only.
0 1 0 0 0 0 1 Left 0.0, Right 1.0, Right (B) channel only.
0 0 0 0 0 0 1 Same as for 1 0 0 0 0 1.

Bits MS width (Notes 1, 2).

0–v6

Bit 0 1 2 3 4 5 6
State 0 0 0 0 0 0 0 Mid 0.5, Side 0.5, Stereo, default.
1 1 1 1 1 1 0 Mid 1.0, Side 0.0, Mono.
1 0 0 0 0 1 Mid 0.0, Side 1.0, Difference only.
0 0 0 0 0 1 Same as for 1 0 0 0 0 1.

Bit 7 XY or MS Select (Note 2).

0  XY stereo, default.
1  MS stereo.

Note 1. Signed two’s complement notation is used to encode the channel weights. Bit 6 is the sign extension = –2^6, bit 5 = 2^5 . . .

Bit 0 = 2^6.

Note 2. If XY is selected, then AES3 Channel 1 carries the Left audio channel, AES3 Channel 2 carries the Right audio channel, and bits 0–6 control the XY balance. If MS is selected, then AES3 Channel 1 carries the Mid or sum signal, AES3 Channel 2 carries the Side or difference signal, and bits 0–6 control the MS width.

Extended Command 7 Data Byte

Bits 0–7 Equalization Curve Select.

Bit 0 1 2 3 4 5 6 7

Note 1. Signed two’s complement notation is used to encode the channel weights. Bit 6 is the sign extension = –2^6, bit 5 = 2^5 . . .

Bit 0 = 2^6.

Note 2. If XY is selected, then AES3 Channel 1 carries the Left audio channel, AES3 Channel 2 carries the Right audio channel, and bits 0–6 control the XY balance. If MS is selected, then AES3 Channel 1 carries the Mid or sum signal, AES3 Channel 2 carries the Side or difference signal, and bits 0–6 control the MS width.
39.5.6 Remote Control Pulse Structure

The remote control pulses are added to the DPP voltage and have a peak to peak amplitude of 2 ±0.2 V. They carry information in the form of pulse width modulation.

For AES3 frame rates (FR) of 48 kHz or multiples thereof the remote control data rate is 750 bit/s, while for FR of 44.1 kHz or multiples thereof the remote control data rate is 689 bit/s.

A logical 1 is represented by a pulse width of 
\[
(7 \times 64) / (8 \text{ FR}),
\]
and must follow the preceding pulse at an interval of 
\[
(1 \times 64) / (8 \text{ FR}).
\]
A logical 0 is represented by a pulse width of 
\[
(1 \times 64) / (8 \text{ FR}),
\]
and must follow the preceding pulse at an interval of 
\[
(7 \times 64) / (8 \text{ FR}).
\]
Thus in both cases the total time used by a bit is 64 FR, a byte is 
\[
(8 \times 64) / (8 \text{ FR}),
\]
and the combination of the command and data bytes is 
\[
(16 \times 64) / (8 \text{ FR}),
\]
if the FR is 44.1 kHz or 48 kHz.

It is possible that in the future an extended command byte may be added preceding the existing command and data bytes. In any case the entire sequence of extended command byte (if defined in the future), command byte, and data byte is sent with no interruptions in the flow of pulses.

The minimum interval between the end of one command and data bytes block and the beginning of the next is 
\[
(8 \times 64) / (8 \text{ FR})
\]
or a 1 byte interval. This allows detection of the end of the command and data bytes and for the data to be latched into the microphone.

The command byte is transmitted first, immediately followed by the data byte. Within each byte the MSB is transmitted first and the LSB last.

The rise and fall times of the pulses (measured from the 10% and 90% amplitude points) is to be 10 μs ±5 μs, over the entire specified load range of 
\[
dc = 50–250 \text{ mA}, C_{load} = 0–170 \text{ nF including the cable capacitance},
\]
Fig. 39-13.

39.5.7 Synchronization

A mode 2 AES3-MIC transmitter contains a VCXO and a DAC that set its operating frequency. The corresponding PLL resides in the AES3-MIC receiver. The receiver sends a regular stream of control voltage commands to the microphone using Direct Command 3 of the simple instruction set. The commands are repeated not less than once every 
\[
s / 6 \text{ s},
\]
and can have 8 to 13 bits of resolution. The ADC and DAC must have an accuracy of ±1/2 LSB, and be monotonic.

If on power up a mode 2 AES3-MIC transmitter does not see synchronization commands sent to it by the receiver, it will run in mode 1 at its default sampling rate or at the rate specified by the extended instruction set if supported. If while running a mode 2 AES3-MIC transmitter stops receiving synchronization commands, it should hold the last value of control voltage sent to it until synchronization commands are restored.

Mode 2 transmitters identify themselves to mode 2 receivers by means of a command that is part of the user data bits in the AES3 data stream. When a mode 2 capable receiver sees this signal it switches to mode 2 operation.

AES42 specifies the mode 2 AES3-MIC receiver characteristics for 48 kHz or 44.1 kHz operation. Since there is a linear relationship between comparison

![Figure 39-13. AES42 command and data byte bit structure at a 48 kHz frame rate (FR).](image-url)
frequency and loop gain, operation at higher frequencies will require either frequency division down to 48 kHz or 44.1 kHz, or a corresponding reduction of the loop gain.

The phase comparator is a frequency-phase (zero-degree) type, and the PLL has a proportional, integrating, differentiating (PID) characteristic. The proportional constant $K_p$ is 1 LSB at 163 ns time error (2.8° at 48 kHz). The integration time constant $K_i$ is 1 LSB/s at 163 ns time error. The differential constant $K_d$ is 1 LSB at 163 ns/s change of time error. The differential signal maximum gain is 8 LSB at 163 ns time error (fast change). The master reference clock must have an accuracy of ±50 ppm or better.

The AES3-MIC mode 2 transmitter must have a VCXO basic accuracy of ±50 ppm, a minimum tuning range of ±60 ppm + basic accuracy, a maximum tuning range of ±200 ppm, and a tuning slope that is positive with $f_{\text{max}}$ for control data = 0xFF. The control voltage low pass filter has a dc gain of unity, a stage 1 filter that is first order with a corner frequency of 68 mHz (0.068 Hz) and maximum attenuation for frequencies greater than 10 Hz of 24 dB constant, and a stage 2 filter that is first order with a corner frequency of 12 Hz. Means may be used to raise the corner frequencies when the rate of tuning change is great. This will allow faster lockup on power on.

AES42 provides schematics showing how such a mode 2 control system might be implemented.

### 39.5.8 Microphone Identification and Status Flags

AES42 compliant transmitters may send status information to the receiver using the user data bit as defined in AES3. The channel status block start preamble is used to identify the start of blocks of 192 bits of user data. Each subframe contains user data. This allows different information to be sent in each subframe that is associated with that subframe.

In monophonic microphones where the audio data is repeated in both subframes, the user data must also be repeated.

Microphone status data is sent in MSB form in pages of 192 bits each. The pages are organized into 24 bytes. Byte 0 of all pages always contains the same data, including a page identifier, and time critical bits. This assures the delivery of the time critical bits no matter which page is being sent. Page 0 is sent continuously with each additional page being sent at least once per second. The receiver may request additional pages using the page request command in Extended Command data byte 4.

In order for the receiver to properly interpret the user data, the transmitter must set byte 1 bits 4–7 of the AES3 channel status data to 0 0 0 1. This indicates the user data bit is in use, and it is organized into 192 bit blocks starting with the AES3 subframe Z preamble.

#### 39.5.8.1 Organization

All status bytes are sent MSB first, Table 39-3.

### Status Data Page 0 Bytes 9–23—Reserved

All bits of Page 0 Bytes 9–23 are reserved and should be set to 0.

### Status Data Page 1 Bytes 1–12—Manufacturer Identification

Manufacturer identification information should be sent in 7 bit ASCII form using only printable characters in the range of 00, and 20 to 7E Hex, and starting in byte 1. The use of nonprintable characters in the range of 01 to 1F Hex is not allowed. Each byte has a 0 of reserved usage in bit 7, followed by the MSB of the ASCII code in bit 6, through the LSB in bit 0. This allows 12 characters for manufacturer identification. Fill any unused bytes with zeros.

### Status Data Page 1 Bytes 13–20—Microphone Model Identification

Microphone model identification information should be sent in 7 bit ASCII form using only printable characters in the range of 00, and 20 to 7E Hex, and starting in byte 13. The use of nonprintable characters in the range of 01 to 1F Hex is not allowed. Each byte has a 0 of reserved usage in bit 7, followed by the MSB of the ASCII code in bit 6, through the LSB in bit 0. This allows 8 characters for microphone model identification. Fill any unused bytes with zeros.

### Status Data Page 1 Bytes 21–23—Reserved

All bits of Page 1 Bytes 21–23 are reserved and should be set to 0.

### Status Data Page 2 Bytes 1–8—Microphone Serial Number

Microphone serial number information should be sent in 7-bit ASCII form using only printable characters in the range of 00, and 20 to 7E Hex, and starting in byte 1. The use of nonprintable characters in the range of 01 to 1F Hex is not allowed. Each byte has a 0 of reserved usage in bit 7, followed by the MSB of the ASCII code in bit 6, through the LSB in bit 0. This allows 12 characters for microphone serial numbers. Fill any unused bytes with zeros.

### Status Data Page 2 Byte 9—Microphone Hardware Revision Main Counter

The information is sent as two binary coded decimal (BCD) digits. The L-nibble or lower nibble is sent with its LSB in bit 0, and MSB in bit 3. The U-nibble or upper nibble is sent with its LSB in bit 4, and MSB in bit 7. Numbers less than 10 are coded with a leading 0 in the U-nibble.

### Status Data Page 2 Byte 10—Microphone Hardware Revision Index Counter
39.5.9 XLD Connector for AES3-MIC Applications

AES42 describes but does not require the use of a new connector called the XLD for AES3-MIC applications. It is a variant on the common XLR-type connector with the addition of keying. This connector was designed by Neutrik and is not in production as of this writing.

The reason for this connector is to prevent accidental interconnection between analog and digital circuits, and in particular between analog and AES3 circuits. The keying was designed to be field removable so if someone were required to use the same cabling for both analog and digital applications that would still be possible, Figs. 39-14–Fig. 39-18.

A number of those involved with the AES42 effort felt that some such connector that prevents accidental interconnections is mandatory given the use of the relatively high current DPP. They feared it might damage analog outputs to which it might be accidentally connected. Others favored a different connector than the XLR because of the years of experience troubleshooting mismated analog and digital circuit connections. It was pointed out that this issue would be better addressed by the group responsible for AES3 revisions. There was also a group that felt that given the large amount of existing infrastructure using the XLR for AES3 circuits, any change was unacceptable. As a compromise, the standard was issued with the proposed new XLD connector described but not required.

According to AES42 the issue of what connector to use for AES3-MIC applications is under consideration by the AES Standards Committee. Meanwhile, the XLR-3 as currently specified for AES3 may be used. If a new connector is selected for AES3 applications, then
that connector will be allowed for AES3-MIC as well. If a connector different from the XLR is desired currently, then that connector must be the XLD, Fig. 39-18.

The black-white-black-white pattern on the zebra ring and associated wiring and the bumps on the surface of the ring serve to identify a connector that carries an AES3 digital audio signal, and that may be carrying DPP, Fig. 39-19. It also indicates that associated circuitry will not be damaged by the application of DPP. Cables so marked are designed to carry AES3 digital signals.

### 39.6 IEC 60958 Second Edition

This standard is based on three different sources, the AES3 and EBU Tech. 3250-E professional digital audio interconnection standards, and the consumer digital interface specification from Sony and Phillips (SPDIF).

The standard is broken into four parts, 60958-1 Ed, which contains general information on the digital interface; 60958-2 (unchanged from the first edition) on the serial copy management system; 60958-3 Ed2, which contains the consumer interface specific information; and 60958-4 Ed2, which contains information on the professional interface.

Since the professional interface is covered under the section on AES3 above, in this section we will only review how the consumer interface specified in 60958-3 differs from AES3.

Table 39-4 is based on Edition 3 of IEC 60958. It is always advisable to obtain the latest revision of the standard.
39.6.1 Electrical and Optical Interface

Two types of interface are specified, unbalanced electrical and optical fiber.

Three levels of timing accuracy are specified and indicated in the Channel Status. Level I is the high accuracy mode, requiring a tolerance of ±50 ppm. Level II is the normal accuracy mode, requiring a tolerance of ±1000 ppm. Level III is the variable pitch mode. An exact frequency range is under discussion, but may be ±12.5%.

By default, receivers should be capable of locking to signals of a Level II accuracy. If a receiver has a narrower locking range, it must be capable of locking to signals of a Level I accuracy, and must be specified as a Level I receiver. If a receiver is capable of normal operation over the Level III range, it should be specified as a Level III receiver.

Table 39-4. IEC 60958 Edition 2 Standard

Channel Status General Format

<table>

</tr>
</tbody>
</table>

Note 1. Other than the use of the Channel Status block of information, the rest of the data format is identical between the AES3 “professional use” Standard and the IEC 60958-3 “consumer use” Standard. The electrical format is different, however. For these reasons it should never be assumed that a “consumer use” receiver would function correctly with a “professional use” transmitter, or vice-versa.

Note 2. If the copyright status is unknown for this application, the state of this bit may alternate at a rate between 4 Hz and 10 Hz.

Channel Status Format for Consumer Use Digital Audio

If Byte 0 bit 1, and bits 6–7 are all 0, then the following applies.

Byte 1—Category Code

Contains the category code indicating the type of equipment generating the signal. Category codes are given in the annexes to the Standard. Bit 0 contains the LSB and bit 7 the MSB. Used in conjunction with the copyright bit to control allowable copying of material.

Bits 4–5 Clock Accuracy.
39.6.1.1 Unbalanced Line

Connecting cables are unbalanced, shielded, with an impedance of 75 Ω ±26.25 Ω over the frequency range from 100 kHz to 128 times the maximum frame rate. The line driver has an impedance of 75 Ω ±15 Ω at the output terminals over the frequency range from 100 kHz to 128 times the maximum frame rate. The output level is 0.5 ±0.1 Vp-p, measured across a 75 ±1% Ω resistor across the output terminals without any cable connected. The rise and fall times measured between the 10% and 90% amplitude points should be less than 0.4 UI. The jitter gain from any reference input must be less than 3 dB at all frequencies.

The receiver should be basically resistive with an impedance of 75 Ω ±5% over the frequency range from 100 kHz to 128 times the maximum frame rate. It should correctly interpret the data of a signal ranging from 0.2 to 0.6 Vp-p.

The connector for inputs and outputs is described in 8.6 of Table IV of IEC 60268-11, and popularly known as the RCA connector. Male plugs are used at both ends of the cable. Manufacturers should clearly mark digital inputs and outputs.

39.6.1.2 Optical Connection

This is specified in IEC 61607-1 and IEC 61607-2, and popularly known as the TOSLINK connector.

39.7 AES10 (MADI)

The AES10 Standard describes a serial multichannel audio digital interface, or MADI. The abstract says it uses an asynchronous transmission scheme, but the overall protocol is better described as isochronous. It is based on the AES3 Standard, but allows thirty two, fifty six, or sixty four channels of digital audio at a common sampling rate in the range of 32 to 96 kHz, with a resolution of up to 24 bits to be sent over a single 75 Ω coaxial cable at distances up to 50 m. Transmission over fiber is also possible. Like the other schemes we have looked at it only allows one transmitter and one receiver.

Table 39-5 is based on AES10-2003. It is always advisable to obtain the latest revision of the standard.

MADI used the bit, block, and subframe structure of AES3 with the exception of the subframe preambles. Instead it substitutes four bits according to Table 39-5. MADI sends all its active channels in consecutive order starting with channel zero. Each active channel has the active channel bit set to 1. Inactive channels must have all their bits set to 0 including the channel active bit. Inactive channels must always have higher channel numbers than any active channel.

The channels are transmitted serially using a nonreturn-to-zero inverted (NRZI) polarity free coding. Each 4 bits of the data are turned into 5 bits before encoding. Each 4 bits of the data are turned into 5 bits before encoding. Each 4 bits of the data are turned into 5 bits before encoding.
Each 32 bit channel data is broken down into eight words of 4 bits each following this scheme:

<table>
<thead>
<tr>
<th>Word</th>
<th>Channel Data Bits</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0 0 1 2 3</td>
</tr>
<tr>
<td>1</td>
<td>4 5 6 7</td>
</tr>
<tr>
<td>2</td>
<td>8 9 10 11</td>
</tr>
<tr>
<td>3</td>
<td>12 13 14 15</td>
</tr>
<tr>
<td>4</td>
<td>16 17 18 19</td>
</tr>
<tr>
<td>5</td>
<td>20 21 22 23</td>
</tr>
<tr>
<td>6</td>
<td>24 25 26 27</td>
</tr>
<tr>
<td>7</td>
<td>28 29 30 31</td>
</tr>
</tbody>
</table>

The 4 bit words are turned into 5 bit words as follows:

<table>
<thead>
<tr>
<th>4 Bit Data</th>
<th>5 Bit Encoded Data</th>
</tr>
</thead>
<tbody>
<tr>
<td>0000</td>
<td>11110</td>
</tr>
<tr>
<td>0001</td>
<td>01001</td>
</tr>
<tr>
<td>0010</td>
<td>10100</td>
</tr>
<tr>
<td>0011</td>
<td>10101</td>
</tr>
<tr>
<td>0100</td>
<td>01010</td>
</tr>
<tr>
<td>0101</td>
<td>01011</td>
</tr>
<tr>
<td>0110</td>
<td>01110</td>
</tr>
<tr>
<td>0111</td>
<td>01111</td>
</tr>
<tr>
<td>1000</td>
<td>10010</td>
</tr>
<tr>
<td>1001</td>
<td>10011</td>
</tr>
<tr>
<td>1010</td>
<td>10110</td>
</tr>
<tr>
<td>1011</td>
<td>10111</td>
</tr>
<tr>
<td>1100</td>
<td>11010</td>
</tr>
<tr>
<td>1101</td>
<td>11011</td>
</tr>
<tr>
<td>1110</td>
<td>11100</td>
</tr>
<tr>
<td>1111</td>
<td>11101</td>
</tr>
</tbody>
</table>

The now 5 bit words are transmitted (left to right) as follows:

<table>
<thead>
<tr>
<th>Word</th>
<th>Channel Link Bits</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0 1 2 3 4</td>
</tr>
<tr>
<td>1</td>
<td>5 6 7 8 9</td>
</tr>
<tr>
<td>2</td>
<td>10 11 12 13 14</td>
</tr>
<tr>
<td>3</td>
<td>15 16 17 18 19</td>
</tr>
<tr>
<td>4</td>
<td>20 21 22 23 24</td>
</tr>
<tr>
<td>5</td>
<td>25 26 27 28 29</td>
</tr>
<tr>
<td>6</td>
<td>30 31 32 33 34</td>
</tr>
<tr>
<td>7</td>
<td>35 36 37 38 39</td>
</tr>
</tbody>
</table>

Unlike the coding used for AES3, this coding allows dc on the link.

AES10 uses a synchronization symbol, 11000 10001 transmitted left to right, which is inserted at least once per frame to ensure synchronization of the receiver and transmitter. There are no defined locations for the insertion of this symbol, but it may only be inserted at the 40 bit boundaries between data words. Enough synchronization symbols should be interleaved between channels transmitted, and after the last channel has been transmitted, to fill up the total link capacity.

### 39.7.1 NRZI Encoding

The 5 bit link channel data is encoded using NRZI polarity free encoding. Each high bit is converted into a transition from the bit before, while each low bit results in no transition. In other words a 1 turns into a 1 to 0 or 0 to 1 transition, while a 0 results in a static 1 or 0.

### 39.7.2 Sample Frequencies and Rates

MADI allows operation with sampling rates in any of three ranges:

- 32 to 48 kHz, ±12.5%, 56 channels.
- 32 to 48 kHz nominal, 64 channels.
- 64 to 96 kHz, ±12.5%, 28 channels from the nominal frequency.

Higher sampling rates such as 192 kHz require the use of multiple audio channels per sample.

Data is transmitted across the link at a constant 125 megabits per second irrespective of the number of channels in use. The data transfer rate is 100 megabits per second. The difference is due to the 4 data bit to 5 link bit encoding used.
Actual data rates used will vary. Fifty six channels at 48 kHz + 12.5% or 28 channels at 96 kHz + 12.5% results in a data rate of 96.768 megabits per second, while 56 channels at 32 kHz – 12.5% results in a data rate of 50.176 megabits per second.

### 39.7.3 Synchronization

Unlike AES3, MADI does not carry synchronization information. Therefore a separate AES3 signal must be provided to both the transmitter and receiver for synchronization purposes.

A MADI transmitter must start each frame within 5% of the sample period timing of the external reference signal. A MADI receiver must accept frames that start within 25% of the sample period timing of the external reference signal.

### 39.7.4 Electrical Characteristics

Either 75 $\Omega$ coax or optical fiber is allowed for the transmission media. Optical interfacing is described below.

The line driver has an impedance of 75 $\Omega \pm 2$ $\Omega$ average output level when terminated into 75 $\Omega$ is 0 V ±0.1 V. The peak-to-peak output voltage is between 0.3 V and 0.6 V into 75 $\Omega$. Rise and fall times between the 20% and 80% amplitude points must be no longer than 3 ns, and no shorter than 1 ns with a relative timing difference to the average of the amplitude points of no more than ±0.5 ns.

Interestingly there is no input impedance specified for the receiver, although the example schematic shows a 75 $\Omega$ termination.

When a signal meeting the limits shown in Fig. 39-20 is applied to the input of a MADI receiver, it must correctly interpret it.

Cabling to interconnecting MADI devices must be 75 $\Omega \pm 2$ $\Omega$ and have a loss of less than 0.1 dB/m over the range from 1–100 MHz. Cables are equipped with 75 $\Omega$ BNC-type male connectors and have a 50 m maximum length. Chassis connectors are female.

At the receive end of the cable the eye pattern must be no worse than what is shown in Fig. 39-20. Equalization is not allowed.

The cable shield must be grounded to the chassis at the transmitter. If the shield is not grounded directly to the chassis at the receiver, it must be grounded above 30 MHz. This can be achieved by capacitively coupling the shield to the chassis through a suitable low inductance capacitor of around 1.0 nF.

#### Figure 39-20. AES10 eye pattern for minimum and maximum input signals where $t_{nom} = 8$ ns, $t_{min} = 6$ s; $V_{max} = 0.6$ V; $V_{min} = 0.15$ V. The MADI receiver must correctly interpret signals within this eye diagram as applied to its input.

### 39.7.5 Optical Interface

Graded-index fiber with a core diameter of 62.5 nm, nominal cladding diameter of 125 nm, and a numerical aperture of 0.275 is to be used with ST1 connectors. This will allow links of up to 2000 m.

### 39.8 Soundweb

All of the interconnect schemes we have looked at so far have been point to point, and not networked. Soundweb is a good example of a simple yet useful networking scheme that is part of a family of signal-processing devices from BSS Audio. In the following discussion we will only consider the digital audio networking aspect of Soundweb. The chapter on virtual systems describes the sound-processing aspects of this family of products.

Unlike the standards-based digital audio interconnect methods discussed so far, the protocol for Soundweb is not published and is available only in products from a single manufacturer, BSS Audio. Nonetheless it is in wide use, and needs to be examined from an applications viewpoint.

Each Soundweb component has network in and out connectors for interconnecting the devices. Most devices have just 1 in and 1 out, but their active hub has three in and three out connectors. Each of the six network connectors on a hub may be used to terminate one end of a chain. Virtual wiring inside the hub is then used to interconnect the 6 networks as desired.

An output is connected to an input with a Category 5 (Cat 5) data cable of up to 300 m in length. By using special fiber converters that distance can be extended to
2 km. The maximum number of units is dependent on the distance, but they say that usually up to fifteen units can be cascaded in a single chain.

Even though Soundweb uses Cat 5 cabling and the same “RJ-45” connectors as used for Ethernet networking, it is important to note that Soundweb is not using the Ethernet protocol, just the same cable and connectors as used by Ethernet.

Referring to Fig. 39-21, there are several things to note. First, the physical wiring must always be from output to input. Although signal flows in both directions over each cable, the output and input terminology shows the direction of primary signal flow. Second, even though the physical topology is a chain, the virtual signal flow topology is a loop. Up to eight audio channels may be passed from device to device over each virtual signal flow link. This requires planning since if, for example, you wanted to get a signal from B to A above, you would have to pass the signal from B to C, connect it inside C to an output channel, pass it from C to D, connect it inside D to an output channel, and then pass it from D back to A. As a result you are using one of the eight available channels on each of three links in order to pass the signal back one box. Planning your circuit topology carefully will reduce the need to send signals backwards.

39.9 Nexus

The Stage Tec Nexus is another proprietary digital audio networking system. It is a very high-quality system using fiber optic interconnections, providing a very flexible system. Redundant interconnections allow very high reliability. A very wide variety of input and output devices are available to insert into the Nexus frames. Both analog and digital inputs and outputs are available.

One of the most interesting aspects of the Nexus system is the ability of the programmable devices in a system to learn what they should be doing from other devices in the system. If a device fails in a running system, when the replacement device is plugged in, it determines what it should be doing from the other devices in the network. The instructions for all the devices are stored in multiple places in the system to enable this capability.

39.10 IEEE 1394 (FireWire)

FireWire is an attractive networking scheme since it provides both isochronous and asynchronous capabilities in the same network. However, this same diver-
Crestron have embraced it for audio/video system control.

Yet with all these advantages, Ethernet per se is poorly suited to carry real-time audio since it is by nature an asynchronous system. Kevin Gross of Peak Audio decided that there had to be a way to overcome the limitations of Ethernet for transmission of real-time information such as audio and video. His solution, called CobraNet®, was granted a patent, and has been licensed by many major professional audio companies for inclusion in their products including: Biamp, Creative Audio, Crest Audio, Crown, Digigram, EAW, LCS, Peavey, QSC, Rane, and Whirlwind.

More recent entrants into digital audio networking include Aviom, EtherSound, and Dante. All of the above make use of at least some portion of Ethernet technology.

Before we can examine these audio networking technologies, we need to get a good understanding of Ethernet.

### 39.11.1 Ethernet History

In 1972 Robert Metcalf and his colleagues at the Xerox Palo Alto Research Center (PARC) developed a networking system called the Alto Aloha Network to interconnect Xerox Altos computers. Metcalf changed the name to Ethernet in 1973. While the Altos is long gone, Ethernet has gone on to become the most popular networking system in the world, Fig. 39-22.

This system had a number of key attributes. It used a shared media, in this case a common coaxial cable. This meant that the available bandwidth was shared among all the stations on the cable. If any one station transmitted, all the other stations would receive the signal. Only one station could transmit at any instant in time and get the data through uncorrupted. If more than one station attempted to transmit at the same time, this was called a collision, and resulted in garbled data.

In a shared media Ethernet network there will be collisions as a normal part of operation. As a result a mechanism for preventing collisions, detecting those it could not prevent, and recovering from them was required.

This mechanism is called *carrier-sense multiple access with collision detection* (CSMA/CD). In other words, while any station can transmit at any time (multiple access), before any station can transmit it has to make sure no other station is transmitting (carrier-sense). If no other station is transmitting, it can start to transmit. However, since it is possible for two or more stations to attempt to transmit at the same time, each transmitting station must listen for another attempted transmission at the same time (a collision). If a station transmitting detects a collision, the station transmits a bit sequence called a jam to insure all transmitting stations detect that a collision has occurred, then is silent for a random time before attempting to transmit again. Of course no retransmission can be attempted if another station is transmitting. If a second collision is detected, the delay before retransmission is attempted again increases. After a number of tries the attempt to transmit fails.

Now since the signals travel at the speed of light (approximately) down the coax cable, and since a station at one end of the cable has to be able to detect a collision with a transmission from a station at the other end of the cable, two requirements had to be imposed. First, there was a limitation on how long the cable could be. This was imposed to limit the time it could take for a transmission from a station at one end of the cable to reach the most distant station. Second, there was a minimum length imposed on the data packet transmitted. This made sure that stations that were distant from each other would have time to realize that a collision had occurred. If the cable were too long, or the packet were too short, and the stations at the ends of the cable were to both transmit at the same time, it would be possible for them to both finish transmitting before they saw the packet from the other station, and never realize that a collision had occurred, Fig. 39-23.

### 39.11.2 Ethernet Packet Format

Every Ethernet device in the world has a globally unique media access control or MAC address. Manufacturers apply to the Institute of Electrical and Elec-
tronics Engineers (IEEE) and are assigned a block of MAC addresses for their use. Each manufacturer is responsible to make sure that each and every device it ships has a unique MAC address within that range. When it has used up 90% of its addresses it can apply for an additional block of addresses.

A MAC address is 48 bits, or 6 bytes long, which allows for 281,474,976,710,656 unique addresses. While Ethernet is extremely popular, we have not begun to run out of possible MAC addresses.

An Ethernet packet starts with the MAC address of the destination. That is followed by the MAC address of the station sending the packet. Next come 2 bytes called the EtherType number or protocol identifier, which identify the protocol used for the payload. Again the IEEE assigns these numbers. The protocol identifier assigned for CobraNet®, for example, is 8819 in hexadecimal notation.

The data payload can range from a minimum size of 46 bytes to a maximum size of 1500 bytes. The protocol identifier specifies the content of the payload and how it is to be interpreted. Data of less than 46 bytes must be extended or padded to 64 bytes, while data of more than 1500 bytes must be broken into multiple packets for transmission.

The frame check sequence (FCS) is a 4 byte long cyclic redundancy check (CRC) calculated by the transmitting station based on the contents of the rest of the Ethernet packet (destination address, source address, protocol, and data fields). The receiving station also calculates the FCS and compares it with the received FCS. If they match, the data received is assumed to have been received without corruption. There is a 99.9% probability that even a 1 bit error will be detected.

As you can see, the smallest possible Ethernet packet is 64 bytes long, and the longest is 1518 bytes long.

### 39.11.3 Network Diameter

The maximum allowable network diameter, Fig. 39-24, that will permit Ethernet’s collision detection scheme to work is dependent on:

- The minimum packet size (64 bytes),
- The data rate (these last two together determine the time duration of the minimum size packet), and
- The quality of the cable (which determines the speed of propagation down the cable).

In 1980 the IEEE standardized Ethernet as IEEE 802.3. This initial standard was based on the use of 10 mm 50 Ω coaxial cable. Many variations quickly appeared.

- 10Base5—This was the original Ethernet, also called thinnet or thick Ethernet because of the large diameter coaxial cable used. It ran at 10 MBit/s, baseband, with a maximum segment size of 500 m (hence 10Base5).
- 10Base2—Designed as a less expensive Ethernet, it was called thinnet or thin Ethernet due to the thinner RG-58 50 Ω coaxial cable used. It ran at 10 MBit/s, baseband, with a maximum segment length of 200 m.
- 1Base2—A slower variant of thinnet. It ran at 1 MBit/s, baseband, with a maximum segment length of 200 m.
- 10Broad36—Very rare, this ran over a RF cable plant similar to cable TV distribution systems, and was built with cable TV distribution components.

All of these variants suffer from a common problem. Since they use a shared media that had to physically connect to every station in the network, a problem at any point along the backbone could disable the entire network. Clearly a different approach was needed to protect the shared media from disruption.

In 1990 a new technology called 10Base-T was introduced to solve these problems. Instead of the vulnerable shared media being strung all over the entire facility, it was concentrated into a box called a repeater hub, Fig. 39-25. The media was still shared, but protected. It had an allowable network diameter of 2000 m, and used the same packet structure. Each station was connected to the hub with twisted pair cable, with two pairs used. One pair carried the signal from the station to the hub, while the other pair carried the signal from the hub to the station. Category 3 (Cat3) unshielded twisted pair (UTP) was used with transformer isolation at both ends of each pair. The maximum length of a single cable run was restricted to
100 m. Longer runs up to 2000 m were possible using a fiber version called 10BaseF. Cat3 cable was more durable and less expensive than the coax formerly required. Of greatest importance, a problem with a cable only affected a single station, and would not bring down the entire network.

Since then, 100BaseT or Fast Ethernet has been introduced. It runs at ten times the data rate of 10Base-T, or 100 MBit/s. Since the data rate is ten times as high as 10Base-T, and the minimum packet size is the same, the maximum network diameter had to be reduced to 200 m. This is the most common form of Ethernet today although Gigabit Ethernet is catching up quickly. CobraNet® uses Fast Ethernet ports but can be transported over Gigabit Ethernet between switches.

Within Fast Ethernet there are several varieties. 100Base-T4 uses all 4 pairs of a Cat3 UTP cable. 100Base-TX uses 2 pairs of a Cat5 cable. This is the most common variety of Fast Ethernet. Both of these varieties allow single cable runs of 100 m. 100Base-FX uses multimode fiber, and allows single runs of up to 2000 m. A version of Fast Ethernet to run over single-mode fiber has not been Standardized, but many manufacturers sell their own versions, which allow distances of as much as 100,000 m in a single run.

Many Fast Ethernet devices sold today not only support 100Base-TX, but also 10Base-T. Such a dual speed port is commonly called a 10/100 Ethernet port. It will negotiate automatically with any Ethernet device hooked to it and connect at the highest speed both ends of the link support. The technique for this negotiation is described below.

Gigabit Ethernet is now available, and the price has dropped so much it is more and more replacing Fast Ethernet. As you might have guessed it runs at a rate ten times as fast as 100BaseT, or 1000 MBit/s. The first versions ran over optical fiber, but now a version that runs over Cat5 UTP cabling is available. It does, however, use all four pairs in the cable. Gigabit Ethernet increases the minimum packet size from 64 bytes to 512 bytes in order to allow the network diameter to stay at 200 m. Ethernet ports that support 10/100/1000 MBit/s speeds and auto-negotiate to match the highest speed the connected device can support are now common.

Within Gigabit Ethernet there are also several varieties. 1000Base-LX (L for long wavelength) can be used with either multimode or single-mode optical fiber. 1000Base-SX (S for short wavelength) is used with multimode fiber only. 1000Base-SX is less expensive than 1000Base-LX. 1000Base-LH (LH for long haul) is not an IEEE standard, but is supported by many manufacturers. Manufacturers make different versions depending on the distance to be covered. 1000Base-T runs over Cat5 cable using all four pairs. The maximum single cable run is 100 m.

A version of Ethernet that will run at ten times the speed of Gigabit Ethernet is available and the price has been dropping.

Several manufacturers power their products over Ethernet cabling. There is now an IEEE Standard for Power over Ethernet (PoE) and most manufacturers sending power to their products over the Ethernet cabling have gone to this standard.

Wireless Ethernet to the IEEE 802.11 Standard has become very popular and inexpensive. It provides a variable data rate based on distance and environmental conditions. The best case data rate for 802.11n (the latest as of this writing) is 300 MBit/s, but typical data rates are closer to 74 MBit/s.

39.11.5 Ethernet Topology
The Ethernet topology shown in Fig. 39-25 as a collapsed backbone is commonly called a star topology, since every station connects back to the common hub. It is also permissible to tie multiple stars together in a star of stars, Figs. 39-26 and 39-27.

Using fiber to interconnect the stars can increase the distance between clusters of stars, Fig. 39-28.

39.11.6 Ethernet Equipment
This will become clearer when we examine the internal functions of the repeater hubs we have been talking
A hub has ports that connect either to stations or other hubs. Any data that comes in a port is immediately sent out all the other ports except the port it came in on, Fig. 39-29. An audio analogy would be a mix-minus system.

One of the factors keeping the size of the network from growing is that all of these star and star of stars topologies still have the same network diameter limitation. One way to build a bigger network is to isolate data in one star from that in another, and only pass between stars packets that need to reach stations in the other star. Collisions that occur in a given star are not passed to the other stars since only complete packets addressed to a station in the other star are passed on. This isolates each star into a collision domain of its own, so the network diameter limitation only applies within a given collision domain.

The device that provides this function between a pair of collision domains is called a bridge. As the technology became cheaper multiport bridges started to appear that were called switches. As switches become popular and bridges fade from use, you will sometimes see a bridge referred to as a two-port switch, Fig. 39-30.
Ethernet switches receive a packet into memory. They examine the destination address and decide which of their ports has attached to it the station with the address in question. Then if the destination is not on the same port as the packet was received from, the switch forwards the packet to only the correct port. Packets where the destination address is on the same port as the packet was received from are discarded.

Switches determine which addresses are connected to each port by recording the source address of every packet received, and associating that address with the port from which it was received. This information is assembled in a look up table (LUT) in the switch. Then as each packet is received, the switch checks to see if the destination address is in the LUT. If it is, the switch knows where to send that packet and only sends it out the appropriate port. If a destination address is not in the LUT, the switch sends that packet out every port but the one from which it was received. Since most Ethernet stations respond to packets received addressed to them, when the response is sent the switch learns which port that address is on. Thereafter packets addressed to that station are only sent out the correct port.

If a given MAC address is found on a different port than was contained in the LUT, the LUT is corrected. If no packet is received from a given MAC address within a timeout window of perhaps 5 minutes, its entry in the LUT is deleted. These characteristics allow the switch to adapt and learn as network changes are made.

Packets intended to go out a given port are never allowed to collide inside the switch. Instead each outgoing packet is stored in a first in first out (FIFO) buffer memory assigned to a given port, and transmitted one at a time out the port.

While most data passing through a switch behaves as described above, there is one type of packet that does not. Most data packets are addressed to a specific destination MAC address. This is called unicast addressing. There is a specific address called the multicast or broadcast address. Packets with this address in their destination field are sent to all stations. Therefore, these packets are sent out all ports of a switch except the port they came in on.

Switches are not the shared media of the early coaxial cable Ethernet varieties, or the newer repeater hubs. Instead by storing the packets, examining the addresses, selectively passing the packets on, and FIFO
buffering the outputs, they break the network diameter limitation.

Switches have another difference from repeater hubs. Repeater hubs and stations connected to them operate in half duplex mode. In other words a given station can only receive or transmit at different times. If a station that is transmitting in half duplex mode sees a received signal, that tells it a collision has occurred. Since switches store and buffer the packets, they can operate in full duplex mode with other switches or with stations which can operate full duplex. When a station is connected to a switch in full duplex mode it can receive at the same time as it transmits and know that a collision can’t occur since it is talking to a full duplex device which does not allow collisions to occur internally, Fig. 39-31.

Full duplex operation has the added benefit of doubling the communications bandwidth over a half duplex link. A half duplex fast Ethernet connection has 100 MBit/s of available bandwidth which must be split and shared between the packets going each direction on that link. This is because if packets were going both directions at once, that by definition would be a collision. A full duplex link on the other hand has no problem allowing packets to flow in both directions at once, so a fast Ethernet link has 100 MBit/s capability in each direction.

The internal packet routing function inside a switch is called the switch fabric or switch cloud. Switches which contain enough packet routing capability in their cloud to never run out, even if all ports are receiving the maximum possible amount of data, are known as “nonblocking” switches.

Proper Ethernet network design includes ensuring that no packet may go through more than 7 switches on its way from the source to the destination.

When switches were first introduced their expense limited their application to the few situations which required their capabilities. Today the price of switches has come down until they are hardly any more expensive than repeater hubs. As a result the repeater hub is becoming a vanishing part of Ethernet history, Fig. 39-32.

The device that provides this function between a pair of collision domains is called a bridge. As the technology became cheaper multiport bridges started to appear which were called switches. As switches became popular and bridges faded from use, you will sometimes see a bridge referred to as a two-port switch.

Ethernet switches receive a packet into memory. They examine the destination address and decide which of their ports has attached to it the station with the address in question. Then if the destination is not on the same port as the packet was received from, the switch forwards the packet to only the correct port. Packets where the destination address is on the same port the packets were received from are discarded.

Switches determine which addresses are connected to each port by recording the source address of every packet received, and associating that address with the port from which it was received. This information is assembled in a look up table (LUT) in the switch. Then as each packet is received, the switch checks to see if the destination address is in the LUT. If it is, the switch knows where to send that packet and only sends it out the appropriate port. If a destination address is not in the LUT, the switch sends that packet out every port but the one from which it was received. Since most Ethernet
stations respond to packets received addressed to them, when the response is sent the switch learns which port that address is on. Thereafter packets addressed to that station are only sent out the correct port.

If a given MAC address is found on a different port than was contained in the LUT, the LUT is corrected. If no packet is received from a given MAC address within a timeout window of perhaps 5 minutes, its entry in the LUT is deleted. These characteristics allow the switch to adapt and learn as network changes are made.

Packets intended to go out a given port are never allowed to collide inside the switch. Instead each outgoing packet is stored in a first in first out (FIFO) buffer memory assigned to a given port, and transmitted one at a time out the port.

While most data passing through a switch behaves as described above, there is one type of packet that does not. Most data packets are addressed to a specific destination MAC address. This is called unicast addressing. There is a specific address called the multicast or broadcast address. Packets with this address in their destination field are sent to all stations. Therefore, these packets are sent out all ports of a switch except the port they came in on.

Switches are not the shared media of the early coaxial cable Ethernet varieties, or the newer repeater hubs. Instead by storing the packets, examining the addresses, selectively passing the packets on, and FIFO buffering the outputs, they break the network diameter limitation.

Switches have another difference from repeater hubs. Repeater hubs and stations connected to them operate in half duplex mode. In other words a given station can only receive or transmit at different times. If a station that is transmitting in half duplex mode sees a received signal, that tells it a collision has occurred. Since switches store and buffer the packets, they can operate in full duplex mode with other switches or with stations that can operate full duplex. When a station is connected to a switch in full duplex mode it can receive at the same time as it transmits and know that a collision can’t occur since it is talking to a full duplex device that does not allow collisions to occur internally.

Full duplex operation has the added benefit of doubling the communications bandwidth over a half duplex link. A half duplex fast Ethernet connection has 100 MBit/s of available bandwidth that must be split and shared between the packets going each direction on that link. This is because if packets were going both directions at once, that, by definition, would be a collision. A full duplex link, on the other hand, has no problem allowing packets to flow in both directions at once, so a fast Ethernet link has 100 MBit/s capability in each direction.

Of course a repeater hub-based fast Ethernet network has only 100 MBit/s of total bandwidth available for the entire network since it uses a shared media. A network based entirely on fast Ethernet switches has 100 MBit/s of bandwidth available in each direction on each link that makes up the network, assuming that all the stations are capable of full duplex operation. When you combine no collisions with full duplex operation, a switched network can run much faster than a repeater hub-based network.

The internal packet routing function inside a switch is called the switch fabric or switch cloud. Switches that contain enough packet routing capability in their cloud to never run out of internal bandwidth, even if all ports are receiving the maximum possible amount of data, are known as nonblocking switches.

Proper Ethernet network design includes ensuring that no packet may go through more than seven switches on its way from the source to the destination.

When switches were first introduced their expense limited their application to the few situations that required their capabilities. Today the price of switches has come down until they are hardly any more expensive than repeater hubs. As a result the repeater hub is becoming a vanishing part of Ethernet history.

39.11.7 Ethernet Connection Negotiation

It is important to understand how different Ethernet devices negotiate connections between themselves in order to understand why some combinations of devices will work and others won’t.

If a 10 MBit/s Ethernet device is not transmitting data, its output stops. After a period of no data transmissions, it will begin sending normal link pulses (NLPs). These allow the device at the other end of the link to know that the connection is still good, and it serves to identify the device as a 10 MBit/s device.

100 MBit/s devices on the other hand always send a signal even when no data is being transmitted. This signal is called a carrier, and serves to identify the device as a 100 MBit/s device.

10/100 Ethernet devices often use a technique called autonegotiation to establish the capabilities of the device at the other end of the link, before the link is established. This process determines if the other device is capable of full or half duplex operation, and if it can connect at 10 MBit/s, 100 MBit/s, or Gigabit speeds. Data is conveyed using fast link pulses (FLPs), which are merely sequences of NLPs that form a message.
If at the end of the autonegotiation process a 10 MBit/s link is established, both devices will send NLPs when idle. If a 100 MBit connection was established, both devices transmit carrier signals.

Autonegotiating devices also utilize parallel detection. This enables a link to be established with a nonnegotiating fixed speed device, and for a link to be established before a device detects the FLPs. The state diagram in Fig. 39-33 shows how the different possible end conditions are reached. Notice that a 100 MBit device can never parallel detect into a full duplex link.

Fiber optic links do not pass the FLPs needed for autonegotiation though they do pass the carrier. One consequence of this is that if full duplex operation over a fiber link is desired, either manual configuration is required, or an intelligent media converter is required. Such a converter includes circuitry to autonegotiate the link at each end of the fiber.

If a 10/100 NIC were to connect to a 10 MBit/s repeater hub, the 10 MBit/s hub sends NLPs that are detected by the NIC. Seeing the carrier, the 10/100 NIC goes to 100 MBit/s half duplex operation, and link is established. This is correct since hubs are half duplex devices.

If a 10/100 NIC were to connect to a 100 MBit/s switch, the switch sends FLPs that are detected by the NIC. After interpreting the FLPs, the 10/100 NIC goes to 100 MBit/s full duplex operation, and link is established. This is correct since 100 MBit/s is the highest common rate, and switches can operate full duplex.

A media converter can be thought of as a two-port repeater that converts from one type of media to another. The most common such conversion is from copper to fiber. There are two basic types of media converters, simple and intelligent.

Simple media converters have no intelligence and just convert electrical signals to light and back. These simple media converters can’t pass or detect FLPs. Therefore, they can’t pass the signals needed for autonegotiation from one end to the other, nor are they capable of autonegotiating with the ports at each end on their own.

Intelligent media converters add electronics at each end of the fiber link that are able to generate and interpret FLPs. As a result such a converter can either autonegotiate with the port at each end, or be manually configured. They are also capable of both half and full duplex operation.

Figure 39-33. Ethernet autonegotiation state diagram. 10 = 10 MBit/s, 100 = 100 MBit/s, HD = half duplex, FD = full duplex. The dashed lines show the parallel detection that can take place while waiting for the FLPs to be recognized. Note that if parallel detection sets up a 100 MBit half duplex connection, then a full duplex connection can never be established.

39.11.8 Managed Switches

All switches have the capabilities described so far. Some switches add significant additional capabilities. Switches with just the basic capabilities are known as unmanaged switches, and have become very inexpensive. Unmanaged switches operate automatically, and do not require special settings for their operation. Managed switches provide the capability to control the switch’s internal settings.

Common control techniques include a dedicated serial port for control, and Telnet, Web access using a normal Web browser, or Simple Network Management Protocol (SNMP). The last three control methods function over the network. Some managed switches provide all four methods of control. The control capabilities available using each method will often differ. The methods that work over the network will usually require that first the switch is accessed via the serial port, and an IP number assigned to the switch. After that the other control methods can reach the switch over the network at the assigned IP address.
Not all managed switches will provide all the additional capabilities that will be mentioned. Check with the manufacturer of the switch to determine its exact capabilities.

39.11.9 Virtual Local Area Network (VLAN)

Virtual Local Area Network (VLAN) capability allows certain switch ports to be isolated from the other ports. This allows dividing up a larger switch into several virtual smaller switches. While this capability may not matter if all the data is unicast, if there is any multicast or broadcast traffic, there might be significant benefit to isolating that traffic to just certain ports. Some switches may allow data from several VLANs to share a common link to another switch without the data being mingled. Both switches must support the same method for doing this for it to work. Most today use a technique called tagging to allow isolated VLANs to share a common physical link between switches.

39.11.10 Quality of Service (QoS)

Quality of service (QoS) allows priority to be given to certain data trying to leave a switch over other data. For example, if we are sending audio over Ethernet using CobraNet®, we would not want there to be any dropouts in the audio if there was a momentary spike in normal computer data traffic through the switch. Such a dropout could occur if a surge in computer data traffic took up bandwidth needed for audio transmission and delayed the reception of the audio packets.

Several means can be used to specify to the switch which traffic is to be given priority. Priority can be given to traffic on a certain VLAN, or that received from certain ports, or that received from certain MAC addresses, or even traffic containing a specific protocol identifier.

39.11.11 Routing

Ethernet switches normally don’t examine the payload portion of the Ethernet packet. Routers are capable of looking inside the payload and routing Ethernet packets based on Internet Protocol (IP) addresses that might be found inside some Ethernet payloads. Such a router, or a routing function built into some switches, can allow packets to flow between normally independent networks or VLANs. This can be very useful, for example, to allow a central SNMP management system to monitor and control all the network devices in a facility even if they are in independent isolated networks or VLANs.

39.11.12 Fault Tolerance

39.11.12.1 Trunking

Trunking or link aggregation allows two or more links between switches to be combined to increase the bandwidth between the switches. Both switches must support trunking for this to work. While the algorithm used to share the traffic between the links works for many types of data, it does not for all possible types of data. You may find situations where adding a second link and activating trunking between two switches does not provide any significant increase in available bandwidth, Fig. 39-34.

Figure 39-34. Example of trunking between two switches.

Trunking does provide increased fault tolerance, particularly if the links aggregated run through different physical paths between the two switches. If one link is lost, the other link or links will continue to carry traffic between the switches.

39.11.12.2 Spanning Tree

Spanning tree provides automatic protection from inadvertent loops in a network’s topology. The cost for this protection is a delay in the activation of a connection made to a port where spanning tree is activated while the switch tries to determine if there is a path out that
port that eventually returns to the same switch. If it finds no such path, it will activate the port. The delay might be on the order of 30 seconds to a minute. If it finds a path back to itself on the port, it will disable that port. Whenever a connection to a port is made or lost, and the port has spanning tree active, the switch will reexamine all the ports for loops and activate those where loops are not found.

In any network, damage to the cabling is one of the more common causes of network failures. Spanning tree can be used to reduce the impact of such failures on network operation, Fig. 39-35.

When managed switches with spanning tree capability are used it is common to deliberately build the network with loops. The switches will find the loops and disable enough of the links between switches to insure the network topology is a star of stars and stable. If one of the active links is later disabled, perhaps due to physical damage to the cable or the failure of another switch, then one or more of the currently disabled links will automatically be restored to operation. This provides an inexpensive way to increase the reliability of a network.

Fig. 39-36 shows one possible network topology that can be stable if spanning tree is used. Such a network design can be quite robust, and accommodate multiple failures while maintaining operation.

One difficulty with designing a network that uses spanning tree is that we can’t know which links will be disabled and which will stay active. This makes it difficult to predict the amount of traffic a given link will carry.

While spanning tree used with the correct network topology can increase system reliability, it does not respond instantly to failures or changes in network topology. At times it may take several minutes for operation to be restored after a failure.

39.11.12.3 Meshing

At this time meshing is only available on some Hewlett Packard (HP) Procurve switches. Meshing is an attempt to combine the best portions of trunking and spanning tree into a new protocol. Unlike spanning tree, meshing does not disable any links. Instead it keeps track of packets and prevents them from being recirculated around loops. When there are multiple possible routes for a packet to take to its destination, meshing attempts to send the packet by the most direct route.

One of the most significant advantages of meshing is that recovery from failures of links or switches is far faster than spanning tree, and may be accomplished in seconds rather than minutes.

39.11.12.4 Rapid Spanning Tree

More recently a new protocol has brought much of the advantages of meshing and other proprietary technologies into the general market. It allows restoration of a network typically in seconds rather than minutes.

Figure 39-35. A loop around three switches. Spanning tree would disable one of the three links between the switches, and allow the network to be stable.
39.11.13 Core Switching

At its simplest a core switch can be thought of as the central switch in a star of stars configuration. Data that needs only to travel between devices local to each other is switched through the edge switches and never goes through the core switch. Core switches often run at ten times the data rate of the edge switches. For example if the edge switches are fast Ethernet, they will each have a gigabit uplink port that connects back to the gigabit Ethernet core switch.

Besides allowing ten times the data traffic, another reason to use the next higher-speed protocol in the core switch is that the latency through the higher-speed link and switch is only 1/10 as long as if the higher speed was not used.

Some core switches will be equipped with routing capabilities to allow easy central control of all the VLANs using SNMP management.

Core switches are often built to higher-quality standards than ordinary switches since such a core switch can be a single point of failure in the network.

To prevent a single point of failure and greatly increase the fault tolerance of the network, it is possible to use a pair of core switches, each of which connects to all of the edge switches. The network will continue full operation even if one of the core switches or any link to a core switch was to fail.

39.11.14 Ethernet Wiring

Proper design of an Ethernet cable plant is important for reliable operation, ease of maintenance, and maximum performance.

A typical Ethernet network cable path or link is shown in Fig. 39-37. The items that make up the cable plant include:

- Cabling connecting nodes—this can be Cat5 or fiber optic cable.
- Wiring closet patch panels.
- Station cables—the cable that runs from node to wall plate.
- Wall plates—the data or information outlet close to the node.

![Figure 39-37. Ethernet typical cable plant showing the entire link from one Ethernet device to another.](image)

It is considered good design practice to include the intermediate patch points as shown. This gives the cable plant operator flexibility in accommodating expansion and configuration changes.

There are two main types of cables used in Ethernet networks: Cat5 cable and fiber optic cable. The following sections will describe these cable types, as well as the issues associated with each.

39.11.14.1 UTP Cable Grades

Unshielded twisted pair (UTP) cables are graded in several categories.

- Quad: nontwisted four conductor formerly used for telephone premise wiring.
- Category 1: No performance criteria UTP.
- Category 2: Rated to 1 MHz (old telephone twisted pair).
- Category 3: Rated to 16 MHz (10Base-T and 100Base-T4 Ethernet, current FCC required minimum for telephone).
- Category 4: Rated to 20 MHz (token-ring).
- Category 5: Rated to 100 MHz—now withdrawn as a Standard and replaced by Cat5e.
- Category 5e: Improved Cat5 with tighter tolerances. (100Base-TX and 1000Base-T Ethernet).
- Category 6: Rated to 250 MHz.
- Category 7: Shielded cabling mostly used in Europe.
When used with quality equipment there usually is not a lot of advantage for fast Ethernet networks in using cable with a rating beyond Cat5e. Future higher speed networks, or marginal equipment on fast Ethernet may benefit from improved cable.

Unless specified differently by the manufacturer, most UTP has a minimum bend radius of 4 times the cable diameter or about 1 inch.

Cat5e is inexpensive unshielded twisted pair (UTP) data grade cable. It is very similar to ubiquitous telephone cable but the pairs are more tightly twisted. It should be noted that not all Cat5e cable is UTP. Shielded Cat5 also exists but is rare due to its greater cost and much shorter distance limitations than UTP Cat5e.

**39.11.14.2 Distance Limitations**

On fast Ethernet systems, Cat5e cable runs are limited to 100 m due to signal radiation and attenuation considerations. A Cat5e run in excess of 100 m may be overly sensitive to electromagnetic interference (EMI).

**39.11.15 Connectors**

Cat5 cable is terminated with an RJ-45 connector. Strictly speaking this nomenclature is incorrect since it designates a particular telephone usage of the connector rather than the connector itself. Since 8 position 8 contact nonkeyed modular connector is difficult to say and write, we are stuck with the common usage of RJ-45, Fig. 39-38.

There are two different types of contacts in RJ-45 connectors. There is the *bent tyne* contact, intended for use with solid core Cat5, and then there is the *aligned tyne* contact used with stranded Cat5 cable. Errors can occur when using an incorrect cable/connector combination. Fig. 39-39 shows an end-on view of a single contact in a modular connector. The aligned tyne contact (on left) must be able to pierce through the center of the wire, therefore it can only be used on stranded wire. The bent tyne contact has the two or three tyne tips offset from each other to straddle the conductor; therefore, it can be used on solid or stranded wire.

Cable openings in modular connectors can be shaped for flat, oval, or round cable. Cat5 cable does not usually fit properly into connectors made specifically for flat telephone cable, Fig. 39-40.

Cheap modular connectors may not have proper gold plating on the contacts, but instead only have a gold flash. Without proper plating, the connectors may quickly wear and corrode, causing unreliable connections.
AMP makes quality modular connectors, but the secondary crimp point is located in a different position from everyone else’s connectors. Fig. 39-41 shows a standard crimp die and an AMP plug. Point “A” is the primary crimp point, and should fold the primary strain relief tab in the plug down so that it locks against the cable jacket. At the opposite end of the plug, the contacts are pressed down into the individual conductors. The “B” secondary crimp point secures the individual conductors so that they do not pull out of the contacts.

AMP puts this crimp in a different location from all other manufacturers. If AMP connectors are used in a standard crimper they will either jam, bend, or break the crimp die. If standard connectors are used in an AMP crimper, the die will usually break. Once either type of plug is properly crimped onto the wire, they are interchangeable and will work properly in any mating jack, Fig. 39-41.

Some plugs are made with inserts that guide the wires. These can make the job of properly assembling the connector easier. Some connectors made with inserts may also provide better performance than Cat5, Figs. 39-42 and 39-43.

39.11.15.1 Pairing, Color Codes, and, Terminations

Cat5 cable consists of four twisted pairs of wires. To minimize the crosstalk between the pairs, each pair is twisted at a slightly different rate. For fast Ethernet, one pair is used to transmit (pins 1 and 2) and another pair is used to receive (pins 3 and 6). The remaining two pairs are terminated but unused by fast Ethernet. Although only two of the four twisted pairs are used for fast Ethernet, it is important that all pairs be terminated, and that the proper wires be twisted together. Standards set forth by EIA/TIA 568A/568B and AT&T 258A define the acceptable wiring and color-coding schemes for Cat5 cables. These are different from the USOC wiring Standards used in telecommunications, Figs. 39-44 and 39-45.

Note that there are two conflicting color code standards for data use of the RJ-45 connector. Both work just fine, but to avoid problems make sure that one of the standards is selected and used uniformly throughout a facility.
Often when installers accustomed to telephone wiring install data cabling they will incorrectly use the telephone USOC (Universal Service Ordering Code) wiring scheme. This will result in a network that either does not work, or has very high error rates, Fig. 39-46.

**Figure 39-46.** USOC (Universal Service Order Code), the wiring scheme used for telephones. This must not be used for data! The eight contact connector uses all pairs for four lines. The six contact connector uses only center one–three pairs for one, two, or three line phones.

Normal Ethernet cable wiring such as shown in Fig. 39-47 is used for interconnecting unlike devices. In other words it is used to connect the Network Interface Card (NIC) in a station to a switch or repeater hub. Connections between like devices such as a pair of NICs, or between switches, repeater hubs, or switch to repeater hub require a “crossover” cable wired per Fig. 38-48. This is because the data transmit pair must connect to the receive input, and vice versa.

**Figure 39-48.** Ethernet standard (T568B colors) crossover cord. Pairs 2 and 3 are reversed end to end. Used for connections between like devices (NICs, switches or repeater hubs).

It is very easy to tell the difference between a crossover cable and a straight-through cable by looking at the conductors in the RJ-45 connectors. If the wiring is identical at both ends, you are holding a straight-through cable, if it is different, you most likely have a crossover cable.

Some hubs and switches have uplink ports that can eliminate the need for crossover cables. Such a port is wired with pairs 2 and 3 reversed internally. Make sure that when connecting two switches or repeater hubs so equipped, you only use the uplink port at one end. Another caution is that often such an uplink port is not an independent port but is wired internally to one of the normal ports. In such a case make sure that only one of the pair of ports is used.

Some switches employ an autoselect crossover feature. This allows the use of either a straight-through or a crossover cable on any port. The switch automatically senses which cable type is in use and adjusts the electronics to suit the cable.

Stranded patch cable sometimes has different colors.

39.11.16 Fiber Optic Cable

There are two basic varieties of fiber optic cable, single-mode and multimode. Both are used in Ethernet network designs. Two fibers are needed to make an Ethernet connection, one fiber for transmit, and one for receive, Fig. 39-49.

Multimode fiber is built of two types of glass arranged in a concentric manner. Multimode fiber allows many modes, or paths, of light to propagate down the fiber optic path. The relatively large core of a multimode fiber allows good coupling from inexpensive LED light sources, and the use of inexpensive couplers and connectors, Fig. 39-50.

Two sizes of multimode fiber are available. 62.5/125 μm is used primarily in data communications, and 50/100 μm is used primarily in telecommunications applications. The standard for transmission of 100 Mbit Ethernet over 62.5/125 μm multimode fiber is called 100Base-FX. 100Base-FX has a 2 km distance limitation.

Single-mode fiber optic cable is built from a single type of glass. The cores range from 8 μm to 10 μm, with 8/125 μm being the most commonly used. There is only a single path of light through the fiber, Fig. 39-51.

While single-mode fiber cable costs approximately the same as a multimode cable, the cost of the optical transmitters and receivers is significantly more for a single-mode installation than multimode. Single-mode fiber has a core diameter that is so small that only a single mode of light is propagated. This eliminates the main limitation to bandwidth, but makes coupling light into the fiber more difficult.

Although multimode fiber cable has a specific distance limitation of 2 km, distance limitations of single-mode fiber vary according to the proprietary system in use. All are in excess of 2 km with some allowing 100 km. There is currently no Ethernet standard for single-mode fiber.

39.11.16.1 Fiber Optic Connectors

There are two common types of fiber optic connectors, SC and ST, Fig. 39-52. The ST, or straight tip, connector is the most common connector used with fiber optic cable, although this is no longer the case for use with Ethernet. It is barrel shaped, similar to a BNC connector, and was developed by AT&T. A newer connector, the SC, is becoming more and more popular. It has a squared face and is thought to be easier to connect in a confined space. The SC is the connector type found on most Ethernet switch fiber modules and is the connector of choice for 100 Mbit and gigabit Ethernet. A duplex version of the SC connector is also available, which is keyed to prevent the TX and RX fibers being incorrectly connected.
There are two more fiber connectors that we may see more of in the future. These are the MTRJ and MTP. They are both duplex connectors and are approximately the size of an RJ-45 connector.

39.11.16.2 Cabling and Network Performance

A number of factors can degrade the performance of an Ethernet network, and among these is a poor cable plant. Cabling problems and a susceptibility to EMI can actually lead to packet loss. The following sections present cabling considerations that will help to insure a high-quality cable plant installation.

The Cat5 specifications require that no more than ½ inch of the pairs be untwisted at each termination. It is good practice to never strip more of the outer jacket of the cable than is required, and to keep the cable pairs twisted at their factory twist rates until the point they must separate to enter the terminations.

As with audio cabling, there are certain proximity specifications to be aware of when designing your network cable routes. Fig. 39-53 lists some UTP proximity guidelines. For fiber optic cable runs, proximity is not a concern due to fiber’s inherent immunity to EMI and RFI.

39.11.17 Cable Installation

39.11.17.1 Cable Ties and UTP

Another factor that can degrade the installation quality is snug cable ties. Ties should never be pulled tight enough to deform or dent the outer jacket of the UTP cable. Doing so produces a slight change in the cable impedance at the point under the tie, which can lead to poor network performance. If tight ties are used at even intervals down the cable length, the performance degradation is even worse.

For best performance with minimum alien crosstalk between cables, they should not be bundled or combed into a straight and neat harness, but instead be allowed to lie randomly and loosely next to each other.

39.11.17.2 Pull Force and Bend Radius

A common myth is that fiber optic cable is fragile. In fact, an optical fiber has greater tensile strength than copper or steel fibers of the same diameter. It is flexible, bends easily, and resists most of the corrosive elements that attack copper cable. Some optical cables can withstand pulling forces of more than 150 pounds! The fact is, Cat5 cable may be more fragile than optical cables: tight cable ties, excessive untwisting at the connector, and sharp bends can all degrade the cable’s performance until it no longer meets Cat5 performance requirements. While fiber may have a reputation for being more fragile than it really is, it still has limitations, and as such, care should be taken when installing both Cat5 and fiber optic cables. Here are some guidelines for Cat5 and fiber optic bend radius and pull force limitations.

39.11.17.3 Cat 5

All UTP cables have pull force limitations much lower than those tolerated in the audio industry. If more than 25 lbs of force is applied to Cat5 cable during installation, it may no longer meet specification. Like most audio cables, UTP cables also have minimum bend radius limitations. Generic Cat5 allows a minimum bend radius of four times the cable diameter or 1 inch for a ¼ inch diameter cable. Unless specified otherwise by the manufacturer, it is fairly safe to use this as a guideline. Note that this is a minimum bend radius and not a minimum bend diameter.

39.11.17.4 Fiber Optic Cable

The bend radius and pull force limitations of fiber vary greatly based on the type and number of fibers used. If no minimum bend radius is specified, one is usually safe in assuming a minimum radius of ten times the outside diameter of the cable. For pulling force, limitations begin at around 50 lbs and can exceed 150 lbs. In general, it is recommended that you check with the fiber
manufacturer for specifications on the specific cable used in your installation.

39.11.17.5 Cable Testing

All network cable infrastructure, both copper and fiber, should be tested prior to use, and after any suspected damage. The tester used should certify the performance of the link as meeting the Cat5, Cat5e, Cat6, or whatever performance level you thought you had bought.

Inexpensive Cat5 testers are often just continuity checkers and are worse than useless since they can provide a false sense of security that the cabling is fine when in fact it may be horrible.

A tester that can correctly certify a link as meeting all of the Cat5 specifications will cost thousands of dollars, and testers capable of certifying to higher levels are more expensive.

While there are dedicated fiber testers, many of the quality Cat5 testers can accept fiber testing modules.

39.12 CobraNet®

CobraNet® is a technology developed by Peak Audio a division of Cirrus Logic, Inc., for distributing real-time, uncompressed, digital audio over Ethernet networks. The basic technology has applications far beyond audio distribution, including video and other real-time signal distribution.

CobraNet® includes specialized Ethernet interface hardware, a communications protocol that allows isochronous operation over Ethernet, and firmware running on the interface that implements the protocol. It can operate on either a switched network or a dedicated repeater network.

To the basic Ethernet capabilities, CobraNet® adds transportation of isochronous data, sample clock generation and distribution, and control and monitoring functions.

The CobraNet® interface performs synchronous to isochronous and isochronous to synchronous conversions as well as the data formatting required for transporting real time digital audio over the network.

A CobraNet® interface provides conversion from synchronous to isochronous and back, and formats the data to meet Ethernet requirements. This allows it to provide real-time digital audio across the network.

As shown in Fig. 39-54, CobraNet® can transport audio data, and carry and use control information as well as allowing normal Ethernet traffic over the same network connection. Simple Network Management Protocol (SNMP) can be used for control and monitoring. In most cases normal Ethernet traffic and CobraNet® traffic can share the same physical network.

![Figure 39-54. CobraNet® Data Services showing the different types of data flowing through the Ethernet network.]

39.12.1 CobraNet® Terminology

**CobraNet® Interface.**

The hardware or hardware design with associated firmware provided by Peak Audio to CobraNet® licensees and affiliates.

**CobraNet® Device.** A product that contains at least one CobraNet® interface.

**Conductor.** The particular CobraNet® interface selected to provide the master clock and transmission arbitration for the network. The other CobraNet® interfaces in the network function as performers.

**Audio Channel.** A 48 kHz sampled digital audio signal of 16, 20 or 24 bit depth.

**Bundle.** The smallest unit for routing audio across the network. Each bundle is transmitted as a single Ethernet packet every isochronous cycle, and can carry from zero to eight audio channels. Each bundle is numbered in the range from 1 to 65,535. A given bundle can only be transmitted by a single CobraNet® interface. There are two basic types of bundles.

**Multicast Bundle.** Bundles 1 through 255 are multicast bundles and are sent using the multicast MAC destination address. If a transmitter is set to a multicast bundle number it will always transmit regardless of whether a receiver is set to the same bundle number. Multiple receivers can all pick up a multicast bundle.

**Unicast Bundle.** Bundles 256 through 65,279 are unicast bundles and are sent using the specific MAC destination address of the receiver set to the same bundle number. Only a single receiver can receive each
of these bundles. If no receiver is set for this bundle number the bundle will not be transmitted.

### 39.12.2 Protocol

CobraNet® operates at the data link layer (OSI Level 2). It uses three distinct packet types, all of which are identified in the Ethernet packet by the unique protocol identifier (8819 hex) assigned by the IEEE to Peak Audio. CobraNet® is a local area network (LAN) technology and does not utilize Internet Protocol (IP), which is most important in wide area networks (WAN).

### 39.12.3 Beat Packet

Beat packets are sent with the multicast destination MAC address 01:60:2B:FF:FF:00. They contain the clock, network operating parameters, and transmission permissions. The beat packet is sent by the Conductor and indicates the start of the isochronous cycle. Because the beat packet carries the clock for the network, it is sensitive to delay variations in its delivery to all the other CobraNet® interfaces. Failure to meet the delay variation specification can keep the other devices from locking their local clocks to the master clock in the Conductor. The beat packet is usually small on the order of 100 bytes, but grows with the number of active bundles.

### 39.12.4 Isochronous Data Packet

One isochronous data packet is transmitted for each bundle each isochronous cycle, and carries the audio data. It can be addressed to either unicast or multicast destination addresses depending on the bundle number. Since the CobraNet® interfaces buffer the data, out of order delivery within an isochronous cycle is acceptable. To reduce the impact of the Ethernet packet structure overhead on the total bandwidth consumed, data packets are usually large on the order of 1000 bytes.

### 39.12.5 Reservation Packet

Reservation packets are sent with the multicast destination MAC address 01:60:2B:FF:FF:01. CobraNet® devices usually send a reservation packet once per second. This packet is never large.

### 39.12.6 Timing and Performance

In order for CobraNet® to provide real-time audio delivery, certain maximum delay and delay variation requirements must be put on the performance of the Ethernet network, Fig. 39-55.

If the network loses a beat packet it will cause an interruption in proper operation of the entire CobraNet® network. If an isochronous data packet is lost, a 1 ms dropout will occur only in the audio carried by that particular bundle. A single such dropout may be inaudible or may make a “tick” in the audio. Large numbers of dropouts may sound like distortion.

39.12.7 Bundle Identification

Audio is carried over CobraNet® networks in bundles. Bundles may contain from zero to eight audio channels. Each bundle consists of a stream of packets of one of three types specified in Fig. 39-56.

39.12.8 Multicast Bundles

In a given network or VLAN there can only be a single instance of a given multicast bundle number at a time. The conductor will only allow one CobraNet® transmitter to be active during any isochronous cycle on a given multicast bundle number.

Multicast bundles are always multicast addressed, and are always transmitted even if no receiver has selected that bundle. Since they are multicast, they will appear on every port of a network or VLAN, even on switched networks. Therefore, the receiver does not have to submit a reverse reservation request to the conductor in order to receive a multicast bundle since the bundle will always appear at its input.

Caution must be used with multicast bundles and switched networks so as not to overwhelm the ports with multicast traffic. It is generally suggested to not use more than four multicast bundles on a given switched network or VLAN at the same time.

Multicast bundles can serve as a common denominator to allow interoperability with CobraNet® devices, which can only be configured from their front panel switches.

39.12.9 Unicast Bundles

In a given network or VLAN there can only be a single instance of a given unicast bundle number at a time. The conductor will only allow one CobraNet® transmitter to be active during any isochronous cycle on a given unicast bundle number.

Unicast bundles may be either unicast or multicast addressed based on the transmitter’s reception of one or more reverse reservation requests for its bundle number. The txUnicastMode variable is used to control the transmitter’s ability to switch to multicast on a unicast bundle number. The default setting of the txUnicastMode variable disables the ability to transmit multicast on a unicast bundle number. With the default setting, if more than one receiver requests a given unicast bundle number, only the first receiver to get its reverse reservation request in will get that bundle. With the default setting, unicast bundles can’t be used for point to multipoint routing, instead multicast bundles must be used.

Some CobraNet® devices allow the same audio to be transmitted on more than one bundle at a time. This can provide an alternative way for a single CobraNet® device to unicast to as many as four receiving devices at the same time.

Unicast bundles are only transmitted if a receiver has requested that bundle. This allows a receiver to select

<td>Only transmitted when at least one receiver is identified via reverse reservation.</td>
</tr>
</tbody>
</table>

Figure 39-56. CobraNet® bundle types. The bundle number specifies the type of bundle. There can only be a single transmitter for any given multicast or unicast bundle number at a time on the same network or VLAN. The three bundle types have different characteristics. Multicast bundles will be routed to every port in a switched network, or to every port in a VLAN, so use them sparingly. It is generally suggested that no more than four multicast bundles be used at any one time in a given switched network or VLAN within a switched network.
which of many sources it wishes to receive, and only the source selected will transmit onto the network.

### 39.12.10 Private Bundles

Individual CobraNet® transmitters® control their own private bundles. Unlike multicast and unicast bundles, there may be more than one private bundle with the same bundle number on a network or VLAN at the same time. This is because a private bundle is specified using the transmitter’s unique MAC address in addition to the bundle number.

Private bundles may be either unicast or multicast addressed based on the transmitter’s reception of one or more reverse reservation requests for its bundle number and MAC address. The `txUnicastMode` variable is used to control the transmitter’s ability to switch to multicast on a private bundle number. The default setting of the `txUnicastMode` variable disables the ability to transmit multicast on a private bundle number. With the default setting, if more than one receiver requests a given private bundle number from the same transmitter, only the first receiver to get its reverse reservation request in will get that bundle. With the default setting, private bundles can’t be used for point to multipoint routing, instead multicast bundles must be used.

Some CobraNet® devices allow the same audio to be transmitted on more than one bundle at a time. This can provide an alternative way for a single CobraNet® device to send private bundles to as many as four receiving devices at the same time.

Private bundles are only transmitted if a receiver has requested that bundle. This allows a receiver to select which of many sources it wishes to receive, and only the source selected will transmit onto the network.

### 39.12.11 Bundle Assignments

Over CobraNet®, all audio channels are packaged into groups called bundles for transmission over the Ethernet network. The usual assignment is eight audio channels of 20 bit depth into one bundle. This is the maximum size possible, although using less audio channels is possible. In general for most efficient utilization of network bandwidth, maximum-size bundles are suggested. In the rest of this section we will be talking about maximum-size bundles. If 24 bit audio channels are used the maximum is seven audio channels packaged into a single bundle due to the maximum allowable Ethernet packet size.

A CobraNet® system is coordinated by one of the devices called the conductor. When two or more CobraNet® devices are interconnected properly, one of the devices will be elected the network conductor based on a priority scheme. The conductor indicator will light on the CobraNet® device that is serving as the conductor.

Each CobraNet® device has the ability to send and receive a fixed number of bundles. The bundle number tells the CobraNet® conductor which specific CobraNet® device is trying to communicate with which other CobraNet® device(s) over the network. Use of bundle numbers removes the necessity of the user having to tell the devices the Ethernet hardware (MAC) addresses of the other devices with which it is trying to communicate. As long as the CobraNet® devices are all set to the same bundle number, the CobraNet® system takes care of all the rest of the technical details of setting up an audio path over Ethernet between the devices.

A given bundle may have only one transmitter that places it onto the network. Unicast bundles may have only a single receiver. Multicast bundles may have multiple receivers.

In an ordinary Ethernet data network it is possible to mix both repeater hubs and switches and have the network continue to work. This is not the case with CobraNet®! For a CobraNet® network, you must either use all repeater hubs, or all switches in the network. This is because the CobraNet® protocol changes depending on which type of network it is operating over. However, non-CobraNet® devices may be attached to a switched CobraNet® network via repeater hubs.

On a repeater hub-based network, there is a fixed maximum of eight bundles per network. Any bundle may be placed onto the network from any port, and will appear at every other port on the network. The bundles usually used in a repeater hub network are numbered in the range from 1 to 255 decimal, and are called multicast bundles. Such bundles are always transmitted in a multicast mode, and may be received by any of the CobraNet® devices on the network.

As long as the limit of eight total bundles is not exceeded, it does not matter which channel numbers in the range of 1 to 65,279 are used.

It is not suggested to mix ordinary computer data on a repeater network with CobraNet®, as this could result in dropouts in the audio.

On a switched network, there is no fixed maximum number of bundles possible. The number will be determined by the network design. Again, bundles from 1 to 255 decimal are multicast bundles and, since they are multicast, will usually be sent to every port in the
network. It is not suggested to use more than four multicast bundles in a switched CobraNet® network. There are special cases where more could be used, which we will go into later.

Bundles from 256 to 65,279 decimal are called unicast bundles. These are addressed to a single destination unit and are usually sent unicast. A switch will send these channels only out the ports leading to the CobraNet® device to which they are addressed. Unlike multicast bundles, unicast bundles will not be transmitted unless a receiver is requesting that bundle. This allows destination controlled routing, where the receiver selects one of several possible transmitters to receive, and only the selected transmitter is activated.

It is possible to have far more than eight total bundles active on a switched network if most of those channels are sent unicast using unicast bundles. A given port on a fast Ethernet switch can only send eight bundles out without running out of bandwidth. Those bundles will consist of every multicast bundle on the network, plus any unicast bundle addressed to a CobraNet® device connected either directly or through other switches to this port on the switch.

Some switches have gigabit Ethernet ports in addition to the fast Ethernet ports. The gigabit ports can be used to transfer data between switches with 10 times the bandwidth of a fast Ethernet port and can carry ten times as many bundles as fast Ethernet can. Gigabit Ethernet also transfers data at ten times the speed of fast Ethernet, and thus can have as little as \( \frac{1}{10} \) the forwarding delay. This can become very important in larger networks.

Unlike repeater hub-based networks, CobraNet® over a switched network does allow coexistence with ordinary computer data on the same network, because there are no collisions with the audio. There is the possibility that CobraNet® traffic on the network will cause problems for 10 Mbit/s Network Interface Cards (NICs) used for computer data traffic. Recall that multicast bundles are sent to all switch ports in the same network. Since 8 bundles will fill a fast Ethernet (100 Mbit/s) switch port, if that port is connected to a 10 Mbit/s NIC (most fast Ethernet switch ports are dual speed 10/100 ports) then it is easy to see that multicast data from CobraNet® can saturate the 10 Mbit NIC and make it drop the computer data packets it needs.

There are several possible solutions: one easy solution is to upgrade the NIC to 100 Mbit/s full duplex.

1. Another possibility is to use little if any multicast bundles.

2. Most managed switches have multicast filtering features. These allow you to exclude multicast traffic from a specified port. If your data is carried by the Internet protocol (IP), it is usually safe to filter all multicast traffic except the FF:FF:FF:FF:FF:FF destination address used by the address resolution protocol (ARP) associated with IP.

3. Obviously separate physical networks for audio and data will solve the problem. Separate networks can also be created using VLANs, which are supported by most managed switches. All traffic in a given VLAN, even multicast traffic, is isolated to only those ports which are part of the VLAN. You can typically partition up to eight different VLANs, and assign ports to them as you wish. Uplink ports used to connect two switches can be connected to multiple VLANs, and the traffic from those VLANs is multiplexed onto that link, and then demultiplexed at the other end.

VLANs can also be used in some cases when you need to use more multicast bundles than is allowable on a given CobraNet® network. By splitting the network into two virtual networks you have the ability to run twice as many multicast bundles.

Another solution that can be used with some CobraNet® devices, is transmitting the same audio information on two, three, or four unicast bundles to specific destinations instead of a single multicast bundle. Please note that not all CobraNet® devices have this capability. Some devices can only transmit two bundles, while others can transmit four. Some devices only accept eight audio inputs, while others accept sixteen. Obviously if a device accepts sixteen audio inputs and can only transmit two bundles, it can’t use this technique.

Also be aware that different CobraNet® devices can receive different numbers of bundles, and select only certain audio channels from those bundles to use or output.

Follow this procedure when designing a CobraNet® network:

1. Make a list of all the audio sources and their locations.
2. For each source, list the destination(s) to which it needs to go.
3. Group the audio sources at a location into bundles with no more than eight audio channels in a given bundle (or seven if 24 bit).
4. Determine if each bundle can be unicast, or if it must be multicast.
5. Make sure you don’t have more than four multicast bundles in a network. If you need more than four multicast bundles:

- Consider using multiple switched networks or VLANs.
- Consider transmitting several unicast bundles instead of one multicast bundle.
- Use the following rules to see if you can send more than four multicast bundles on a given network or VLAN:
  - Carefully map the number of bundles sent to each port of the system. The total of multicast and unicast Bundles arriving at each switch port may not exceed eight.
  - If a half-duplex device that can only transmit two bundles, and is set to transmit using both its bundles is part of the network, then you must make sure that the network conductor is not transmitting a multicast bundle. This may require changing the default conductor priority of one or more devices in the system to assure this condition is met.
  - Map the bundles carried by every link in the system to make sure that the limit of 8 bundles each direction on a given fast Ethernet connection is not exceeded.

39.12.12 CobraCAD®

Fortunately there is an easier way to do steps 5 and 6 above. CobraCAD® can be downloaded for free from the Cirrus Logic Web site. CobraCAD® is a new software tool that provides a simple graphical user interface for the design and configuration of CobraNet® networks.

It allows you to draw your proposed CobraNet® network design using any of the CobraNet® devices on the market as of when the version you are using was released. You may also use any of a large selection of Ethernet switches.

After drawing the physical Ethernet interconnections, you next draw the bundle connections between the CobraNet® devices.

Then just press the Design Check button, and CobraCAD® will perform a design rule check. Designs that pass this check are extremely likely to work in the real world. There are still a few things CobraCAD® can’t check for, so be sure to read the information and disclaimers in the Help system.

You may also want to check Cirrus Logic’s CobraNet® Web site at: http://www.cobranet.info/ for the most recent version.

39.12.13 CobraNet® Hardware

At the heart of the CobraNet® interface, as shown in Fig. 39-57, is the digital signal processor, or DSP. It runs the software that together with the hardware provide all CobraNet® and Ethernet functions. It stores all the audio and Ethernet information as needed in stacks in the SRAM, converts the incoming synchronous audio into isochronous packets for transmission over the network, and converts isochronous packets from the network back into synchronous audio outputs. The DSP provides all interface functions to and from the device in which it is installed, and controls all other parts of the CobraNet® interface including the sample clock.

The sample clock is a voltage controlled crystal oscillator (VCXO), which is under the control of the DSP. If the CobraNet® interface is serving as the conductor, the sample clock is fixed in frequency and serves as the master clock for the network. In all other interfaces on the network, the sample clock is adjusted by the DSP so that it locks to the frequency of the network master clock.

The CobraNet® interface provides its clock signal to the device it is part of, but can also receive a clock signal from the device and use that signal as the network master clock if the interface is the conductor.

The CobraNet® interface can provide up to thirty two synchronous digital audio signals to the device, and accept up to thirty two synchronous digital audio signals from the device for transmission across the network.

The serial port can accept serial data which is then bridged across the network and appears at all other CobraNet® devices on the network.

The host interface allows bidirectional communication and control between the CobraNet® interface DSP and the processor of the host device in which the interface is located. Detailed information on the connections and signals on the CobraNet® interface to the host are available in the CobraNet® Technical Datasheet found in pdf form on the Cirrus Logic’s CobraNet® Web site at: http://www.cobranet.info/.

39.13 Aviom

Aviom uses the Physical Layer of Ethernet. In other words it is transported over Cat5e cable with RJ-45 connectors. It does not use any other parts of Ethernet,
but instead uses its own protocol. Aviom says on its Web site, “A-Net manages data differently than Ethernet does,” which has advantages as well as disadvantages. Aviom at this time offers two different versions of its technology, Pro16 and Pro64. Pro16 is limited to point to point connections while Pro64 is more flexible. Pro64 allows up to sixty four audio channels and lets all devices see all sixty four channels. The Aviom protocols are low latency and simple allowing inexpensive but effective products such as its personal monitor mixers, which have revolutionized personal in-ear monitoring onstage and in studios. A single Cat5e cable to a small box by each musician carries sixteen audio channels and power, and allows the musician to make his own monitor mix exactly as he wishes.

39.14 EtherSound

EtherSound, as the name implies, does comply with the 802.3 Ethernet standard, but EtherSound networks are usually not built the same way Ethernet networks are. Ethernet networks are built using a star or star of stars topology, where each edge device connects to a switch port. Other than the simple case of a two device network, Ethernet edge devices do not directly connect to each other. Other than rare Ethernet edge devices with redundant ports, most Ethernet edge devices have only a single Ethernet port. Ethernet devices are never wired in a daisy-chain or cascade. EtherSound, on the other hand, provides in and out Ethernet ports on its edge devices, and in many cases builds networks by daisy-chaining its edge devices. This can result in simpler network designs, but also means that if a device fails in the middle of a daisy-chain it splits the rest of the devices into two isolated chains. EtherSound can also use switches in a more conventional star topology, but then devices downstream of the switch can’t send audio back to the devices before the switch. The devices can be wired in a ring for fault-tolerance, and daisy-chain, star, and ring topologies can be mixed in the same network.

EtherSound has low latency and can support multiple sampling rates mixed in the same network. In order to get this low latency, EtherSound traffic must not be mixed with ordinary Ethernet traffic on the same network or VLAN. In EtherSound, 96 kHz streams occupy two EtherSound channels, while 192 kHz streams take four.
Digital Audio Interfacing and Networking

39.15 Dante

A new entry into the digital audio networking world is Dante from Audinate. Unlike the other real-time digital audio networking protocols, Dante makes use of the new IEEE 1588 real-time clocking standard to solve many of the issues facing those who would use Ethernet for audio transport. Dante also uses the standard UDP/IP data transport standards. This allows it to use standard Ethernet ports on a computer, for example, instead of requiring dedicated hardware to interface a computer to the audio network. Dante supports multiple latencies, sampling rates, and bit depths in the same network.

39.16 QSC

QSC Audio has introduced a new Ethernet-based digital audio networking scheme in some of its new products. It allows standard Ethernet ports on a computer to serve as audio transport ports, and does not require dedicated hardware for audio I/O. It is designed to take full advantage of Gigabit Ethernet and other advances in Ethernet technology, and to stay fully compatible with Ethernet as it evolves. Among the advantages it brings to audio networking are high channel counts, low latency, and the ability to operate over many switch hops. It uses automatic configuration techniques to greatly simplify the process of setting up an audio network and make it fast and easy.

40.1 Digital Audio Storage

There are numerous applications for digital audio storage, that for day-to-day use, and that which is preserved for future generations. We will first address the applications and workings of message repeaters as they are used on a daily basis. Secondly, we will discuss the specifics of archiving audio information.

40.2 Message Repeaters

Message repeaters have come a long way in 40 years. The original repeater was a person sitting at a microphone making an announcement over a public address system at or about the right time. This system had both advantages and disadvantages. The message could be changed at any time, and if area switching was available, different messages could be sent to different areas in real time. Different messages could not be sent at the same time. Another disadvantage was requiring dedicated personnel 24 hours a day, seven days a week. In an emergency, an individual was required to stay at the microphone and announce in a calm and persuasive voice—a difficult thing to do at best.

With the introduction of tape recorders, messages could be prerecorded and played back manually or automatically. Unless a multichannel recorder or multiple recorders were used, only one message could be played at one time. To play different recorded messages required recording them in series and locating the desired message by fast forwarding the tape, time consuming in an emergency situation. With the design of lubricated tape, continuous loop tape recorders were used. This eliminated the requirement of rewinding but also meant the message could not be repeated until the tape had taken its course. Tape stretch and breakage was always a possibility. Auto-rewind cassette players were also used but had the same problem of reel-to-reel machines, they had to be rewound.

The late 1970s brought about the introduction of tape recorders using solid state equipment. Digital message repeaters have the following advantages over the previous systems.

- Reliability.
- Flexibility.
- Solid state reproduction quality.
- User-recordable messages.
- Programmable, often user-programmable, locally or remotely.
- Remotely controllable.

40.3 How Message Repeaters Work

The use of digital signal processors (DSPs) has greatly simplified digital circuitry and made it possible to design digital message repeaters (see Chapter 39).

A digital message repeater in its simplest form is shown in Fig. 40-1. In this system, a permanent message is digitized by the manufacturer and stored in the digitized message storage circuit. To change the message requires sending the unit back to the manufacturer for reprogramming.

Upon contact closure, the control circuitry transfers the digitally stored message to the digital to analog converter (D/A) circuitry where it is changed into an analog circuit. The analog signal is only approximate at this time so a filter is used to smooth the waveform and limit the frequency response. Normally this type of unit has a frequency response from 300 Hz–3 kHz or the basic telephone response. The filtered output is then directed to the audio output circuitry where it is amplified, made balanced or unbalanced, and matched for the proper output impedance.

![Figure 40-1. Digital message repeater.](image-url)

An intelligent digital message repeater, such as an Instaplay™ by ALARMCO is shown in Fig. 40-2. In this system, messages can be recorded from a microphone (Mic), Aux. Input (AUX) (e.g., a CD or MP3 player), or standard touch tone telephone (control Phone). The analog input is then filtered and converted to a digital signal (A/D conversion circuitry) and stored (digitized message storage). Several thousand messages can be stored and individually replaced at any time. By using flash memory, sound quality is assured by storing audio data using 16 or 24 bit samples in the Instaplay™. Audio and programming data may also be downloaded digitally. With memory and intelligent firmware, each new recording can be longer or shorter than the original with all unused memory available for the recording.

To simplify recording from a control phone (either locally or remotely) [Control Phone and Telephone Network Interface], prerecorded instructions are stored in the announcer in digitized form [Command Prompt Audio Storage]. These instructions guide the user.
through each step. The telephone’s keypad is used to respond to the prompts.

Installers can create a schedule for the playback of messages with the scheduler [Internal Program Storage] supplied by the manufacturer. Using this scheduler, the announcer can automatically switch from one playlist to another at various times throughout the day or week. The announcer insures not only that announcements are made, but also made on time.

With an intelligent announcer, the installer can specify [User Program Storage] where a message should be played [Audio Outputs] as well as the time delay between the announcements over each output channel.

Instaplay™ always knows when it’s talking. By activating one of the numerous relays, [Output Relays], the installer is able to use the announcer to direct other activities, such as turning on lights or to trigger other announcers. The installer can control these relays by entries on a playlist [User Program Storage].

During playback, selected messages can be played in any order (including repeats), as specified by the installer [User Program Storage]. Background music, such as Muzak, can be played between messages [Music Feedthrough] with many message repeaters. An intelligent message repeater, however, can interrogate the software [User Program Storage] and decide whether to duck down or mute the background music during each individual message.

With intelligent message repeating messages can be triggered externally in numerous ways [Contact Closure Control Inputs, Serial Communications Link, Control Phone], and to play a message sequence or queue new messages. In addition, intelligent repeaters allow customers to record new messages, modify schedules, playlists and other programming parameters either locally or remotely. When accessing the announcer remotely, [Telephone Network Interface], a security code can be employed. A queue is a sequence of message files that has been selected to be played through a particular channel. A playlist is a command list that queues the messages to play in a defined sequence and channel and includes the ability to operate external devices. It also has the ability to start and stop messages from an external trigger.

Instaplay™ gets its native intelligence from its embedded firmware [Internal Program Storage]. Supplied by the manufacturer, these programs not only define the internal operation of the machine, but also define default parameters, such as how often to repeat a recorded message or how to act when a request is received.

40.4 Message Repeater Usage

Message repeaters are used in many venues:

- Hospitals.
- Schools.
- Factories.
- Amusement Parks.
- Retail Stores.
- Tourist Attractions.
- Transportation Services.
- Information Providers/Broadcast Services.
- Message on Hold.
- Museums.

40.4.1 Hospital Applications for Message Repeaters

Message repeaters have been sold into numerous hospitals. One common application is to broadcast different messages into separate locations in the hospital. The messages may be divided into all area announcements, or those that are announced only in public areas or patient areas. For example, visiting hour reminders are broadcast into all areas of the hospital, including patient’s rooms. No smoking reminders might be announced only in lobbies, cafeterias, and waiting rooms, while doctor calls would only be announced in patient areas.

In addition, with a scheduler, message repeaters can be used to announce when visiting hours are about to end and when visiting hours begin again.

Hospitals around the country are trying unique ways of increasing their patient satisfaction. Many hospitals are now using message repeaters to play “Brahms Lullaby” when a baby is born. It adds a little smile to everyone’s face.
A message repeater can also be connected to controlled doors such as in geriatric and psychiatric wards to tell nurses of unauthorized door openings. Voice messages can announce immediately throughout the building which door is open, so personnel do not have to go to a central alarm panel to see which door is ajar, a much more effective and faster method than visual indications.

When a Code Blue Dispatch happens, message repeaters can instantaneously repeat the message as often as required without requiring dedicated personnel.

40.4.2 Factory Floor Applications for Message Repeaters

Just-in-time manufacturing is a very popular way for companies to cut expenses. Some companies have documented savings of over one million dollars annually in reduced inventory expenses by having components delivered where required just-in-time. This way, unused parts don’t require valuable and expensive floor space, nor does the production line ever slow due to lack of components. Many of the largest factories in the country, such as Motorola, General Motors, and Xerox, have been practicing this method of cost reduction for many years.

Message repeaters can be used to broadcast a message when certain parts need to be restocked. Messages can be triggered manually by having the assembly operator push a button, or automatically with a sensor to trip the message when the weight of the bin containing components becomes too light, sending a verbal message to stock.

Repeaters can also be used to announce lunch time, scheduled breaks, safety reminders, company announcements, and so forth. They can be configured to know when someone is entering (versus exiting) a hard hat area. A warning message can be announced on entering. A message reminding visitors to return their hard hats and protective eyewear can also be announced on exiting the area.

Another interesting use of a message repeater is the elimination of acoustical feedback in noisy environments. By recording the message or page on a message repeater and playing it back as soon as the recording is finished, the microphone-amplifier-loudspeaker-room feedback loop is broken and feedback is eliminated and pages can be automatically repeated. With PageDelay™ from ALARMCO, pages can be monitored as they are being recorded. Inappropriate pages can easily be canceled before they are aired.

40.4.3 Retail Store Applications for Message Repeaters

Message repeaters are ideal for in-store assistance requests. In-store assistance is becoming increasingly popular with retailers because it allows them to cut the expense of large staffs while still delivering service to customers who need it. Often the signs asking customers to “Press the button for assistance in this department” is connected to a message repeater.
Convenience stores have a captive audience when it comes to customers who are pumping gas. Message repeaters can trigger different advertising messages when someone drives up to the gas pump. Studies have proven that sales increase dramatically with this type of advertising. Repeaters can be configured to play the appropriate message to shoppers as they enter or exit a store.

Message repeaters are used in some stores to do targeted in-store advertising. Special repeaters allow messages to influence the customers when they are near the point-of-purchase. Targeting is done by using sensors to trip the control circuit, thereby giving advertising messages when someone enters a particular aisle or department. Even more specific targeting can be accomplished, for example, when someone reaches for a brand name product, as detected by a motion sensor, a message can be played to try the store brand.

Customized modes of operation form an elegant solution for in-store use. Specific options could include individual timers that would allow each department manager to specify the amount of time before the message repeater transmits another message triggered from the same department. A second audio output channel allows office or security personnel to know when someone needs assistance in sensitive areas, such as someone in the area carrying a handgun. Message repeaters can allow any department zone to be enabled or disabled from a central location, such as the front office. If a child is playing with a button, the store manager can temporarily disable that button until the child moves on.

With a built-in scheduler, message repeaters can announce appropriate closing times each day. Sophisticated software allows a single intelligent message repeater to perform many of these functions simultaneously.

### 40.4.4 School Applications for Message Repeaters

School closing or shortened day announcements for snow days etc. can be recorded and played back over the school PA system and the local town access TV channel.

Also class change announcements and activities announcements can be prerecorded and transmitted day or night automatically through the internal scheduler. A message repeater can also be set up as a dial-in line for sports schedules, latest news, and so forth.

Often school gyms or auditoriums are used after hours. Due to fire regulations, many do not have security gates to separate the used area from the rest of the school. A message repeater, triggered by a light beam or motion detector, can energize a message repeater to notify people that they are walking into a closed area, while simultaneously alerting personnel or security staff. In the event of a lock down situation, message repeaters quickly and reliably direct students and staff in safety measures.

### 40.4.5 Transportation Services Applications for Message Repeaters

To ease the burden on the driver, bus route stops can be manually selected, controlled, and played on a message repeater or they can be completely computer controlled. Message repeaters on tour buses are often used to eliminate the necessity of a tour director and to give a running dialogue of the tour route. Usually the driver controls the repeater by pushing a switch when he or she is ready for the next message to be announced.

Message repeaters on mass transit loading platforms can announce train arrivals and departures, safety messages, and upcoming schedule changes. The Statue of Liberty Ferry chose Alarmpco’s Instaplay™ to intelligibly announce tour information and required safety messages, Fig. 40-3.

![Figure 40-3. Instaplay message repeater. Courtesy ALARMCO.](image)

### 40.4.6 Information/Broadcast Services Applications for Message Repeaters

USIA Voice of America uses message repeaters in a number of European countries to retrieve messages that are broadcast over a worldwide satellite network. The broadcast messages are downloaded in various languages into the appropriate repeater. Local radio stations in the individual countries dial into the repeater and download the messages, which are in turn broadcast over the radio stations. Intelligent message repeaters have the ability to record remotely from a line level input, thereby allowing the remote telephone to control them, while they are recording from the satellite.

Because messages can be easily changed, they are ideal for radio broadcast directions, Traveler Advisory Radio (such as AlertAM from Information Station
specialists), news broadcast services, and visitors information services. They are also widely used for employment hotlines, movie theater schedules, sports score lines, and weather information lines.

40.4.7 Message-on-Hold Applications for Message Repeaters

Telephone on-hold equipment is operating whenever we hear anything but silence when we are put on hold. There are three basic categories of on-hold equipment:

- Tuners/radios, where the on-hold program is a radio broadcast.
- Cassette players, where the on-hold program is on an endless loop cassette.
- Digital playback systems, where the on-hold program is stored on solid state memory chips.

Each system has advantages and disadvantages. While the tuner/radio is probably the least expensive method of playing on-hold programs, employing radio programs on-hold has a few pitfalls. For instance, radio programs include licensed music and retransmission is illegal for all but very small businesses without paying licensing fees. The tuner/radio might also be transmitting competitive ads.

Cassette players allow end users to either make their own on-hold program, or have it made by a professional on-hold studio. The disadvantages to cassette players are tape and head wear from dragging the tape across playback heads and the necessity for head cleaning and demagnetization every few weeks to slow head wear.

Digital playback units came into use in the 1980s, primarily because of their high reliability. When the program is loaded into solid state digital memory chips, it can be played back continuously with no moving parts and no wear and tear. The program sounds the same on the millionth play as it does on the first.

The programming and messages for on-hold players can be recorded either locally or remotely. Local recording and programming requires someone on-site to record the message or load cassette tapes. Some of the more intelligent systems allow for remote downloading of the programming and messages using satellite systems, FM subcarrier audio channels, a standard telephone line, a modem, or the Internet. During playback, these remote download units have all the reliability advantages of other digital on-hold equipment. They have the additional advantage over conventional tape download equipment that they are completely hands-off at the installation site. They require no intervention from on-site store personnel, who may be unwilling or unable to load in the tape.

Digital on-hold players employ memory chips to store the program. To produce a frequency response from 20 Hz–20 kHz would require a tremendous amount of memory. Telephone lines normally will not transmit a greater frequency response than 300 Hz–3.5 kHz, therefore it is not practical to increase the response and the equipment cost to cover a much wider range.

As is the case with CDs, digital on-hold units sample the incoming signal many times a second to store the signal into digital memory. Theoretically, the greater the samples per second—i.e., the sampling rate—the better the sound quality. Sampling rate is usually expressed in kilobits per second (Kbps). Toll quality telephone performance (the best performance any telephone network will allow) is 64 Kbps so there is no need to produce on-hold units with a sampling rate greater than 64 Kbps.

Sampling rate is only one measure of the audio quality of a digital downloadable on-hold unit; a network of filters and frequency compensators also contributes to the sound quality.

In most cases, nontechnical employees connect the on-hold equipment to the line and load new taped music/messages. Some units require no controls, no level setting, and no start/stop control because the units employ microprocessors to control all aspects of the download/play process.

The Bogen HSR series unit is an example of a full microprocessor-controlled on-hold system. Various models have a 4, 6, 8, or 12 minutes of memory capacity. The HSR’s automatic operation assesses the start and stop point of the audio, sets record levels, downloads, and goes into play mode automatically. The unit also incorporates a one-play trigger mode for making a single message such as store closing.

The Mackenzie Laboratories, Inc. Dynavox series are on-hold systems that can also be used as storecasters. One series has a 3.4 kHz bandwidth for telephones and the other series has a 6.8 kHz bandwidth for storecast and other wide-band requirements. The bit rate increases from 96 to 196 Kbps and the sampling frequency increases from 8 to 16 kHz with the increasing frequency response. Audio storage requires 16 MB DRAM (dynamic random-access memory) to record 32 minutes at 96 Kbps and 16 minutes at 196 Kbps. These units have a noise floor and dynamic range of greater than 70 dB.

Intelligent message repeaters, such as the Instaplay™ series by ALARMCO, can provide on-hold music and messages, storecasting messages, triggered customer
assistance messages, and automatic store closing announcements—all with a single announcer. In addition, this type of repeater can also play existing background music through, thereby eliminating the need for customers to purchase a cassette with recorded music.

### 40.4.8 Museum Applications for Message Repeaters

Message repeaters with multiple inputs are ideal for museum displays that require several messages associated with a single display. For example, messages that are tailored to either adults or children, short messages or detailed messages, or multiple language messages.

Museums can be exciting with interactive displays and audiovisuals replacing the static placards of the past. Today visitors are accustomed to a multimedia environment where programming captures their attention with entertainment mixed in with an educational message.

The original museum audio systems included narrations and sound effects. Loudspeakers were mounted in front of the exhibit, often at knee level. The source was often continuous loop tapes that could not be rewound and they ran continuously so if the listener came in during the message he or she would have to listen to the end before the beginning. If the tape had automatic stop at the end of the narration, the listener could push the start button and hear the message from the beginning. Of course anyone coming in after the dialogue was started would have to listen to the end before restarting it. Often multitrack playback tape machines were used so the listeners could pick their language of choice. While not the best system, it was a step beyond placards.

Around 1957, visitors carried a reel-to-reel tape recorder over their shoulder. With this system they not only heard the message but also got their exercise for the day.

#### 40.4.8.1 Inductive Loop Systems

Another early system, and still used by some museums today, is to transmit the signal on a wire inductive loop antenna that surrounds the audience area. The listeners wear a receiver and earpiece and as long as they are within the boundary created by the loop, they can hear. As they step outside of the loop, the signal disappears. They can then go to the next exhibit, step into its loop, and hear the dialogue. An advantage of the system is it is simple and reliable and works with hearing aids. The drawbacks are:

- Poor frequency response making it useful only for voice.
- As the signal is analog and operates much like an AM radio station, the volume and sensitivity vary with the distance of the listener to the loop.
- Affected by external electrical noise such as lighting, electric motors, and SCR lamp dimming circuits.
- Requires a wire loop around the area of interest, sometimes rather difficult to install and hide.

For more information on magnetic induction loop systems, see Chapters 41.2 and 42.2.1

#### 40.4.8.2 Infrared Systems

Another type of system by Sennheiser and others uses infrared (IR) transmission. In this system the message is transmitted via wireless infrared using amplitude and frequency modulation processes. They come in either narrow band for multichannel setups or wideband for high quality.

The area of reception is confined to line-of-site or an individual room. Through reflections, however, it can bounce around corners into other unwanted areas. While they can cover large areas effectively, they are limited when it comes to multiple exhibits in a confined area. Another problem with IR is its poor operation in the sun or very bright areas.

Dual channel systems normally operate subcarriers of 95/250 kHz or 2.3/2.8 MHz. The emitters are placed around the room to give even coverage and they may be daisy-chained for easy installation.

For more information on infrared systems, see Chapters 41.3 and 42.2.5.

#### 40.4.8.3 RF Systems

Today RF systems are most often used, making the systems much more versatile and simpler to install. These systems range from simple to quite complex. The following systems are only a smattering of what is available but give an indication of the features available.

Acoustiguide has been in business for over 50 years. Its major system is the Acoustiguide 2000 Series and includes three AG 2000 players—the Wand, the Mini, and the Maxim.

All three systems use MP3 and Windows Media Audio 4.0 for full production sound, and their own software called Vocoder for voice only.
The **Wand** is 12.5 inches long, 2.5 inches wide, and 0.75 inch deep and weighs 9.2 oz, Fig. 40-4. It can hold up to 500 selectable languages or programs or up to 8000 messages. The controls include Play, Clear, Pause, Fast Forward, Rewind, Volume Up, and Volume Down. It can play for 12 h continuous without charging and can accommodate surveys, games, and educational question-and-answer formats. Battery charging can be accomplished in 3 hours in the charging/programming rack.

Because of the design of the **Wand**, it is easy to encourage corporate sponsorship including rotating logos on the LCD screen and the flat areas on the casing are good for applying logos and graphics.

The **Mini** has many of the same features as the **Wand**. The **Mini** is ideal for highly produced audio programs that blend narration, archival audio, large interviews, music, and sound effects making exhibits come to life. The **Mini** comes with headsets or single earpieces. The unit is 5.6 inches long, 2.6 inches wide and 0.75 inch deep and weighs 5 oz. The controls are the same as with the **Wand**. It will also play for 12 h without charging and can be fully recharged in 3 h.

The **Maxim** can hold 200 h of stereo sound or over 2000 h of voice in either linear, random access, or combination tours. It can hold 500 different programs and over 12,000 messages on each unit to provide tours on different subjects or foreign languages. The unit is 7 inches long, 3.9 inches wide, and 1.5 inches deep and weighs 15 oz. It has the same controls as the **Wand** and the **Mini**.

The Acoustiguide storage racks recharge the batteries and include a programming card that is about the size of a credit card. The programs can be either written by the client or by Acoustiguide which can provide creative and production services. The programs are downloaded from the Internet or from CDs onto a laptop computer. As new material is written, recorded, and digitized, it is put on the program card, which automatically updates the players as they are being charged.

To operate the system the visitor is given a player. A staff member sets up the player for the language and the complexity of the tour. The tour could be long or abbreviated to control traffic when the museum is crowded or can be set up for adults or children. The visitor can adjust volume at each area to compensate for noise level. When the visitor is at an exhibit, he or she punches in the number corresponding to the exhibit as shown on a placard. The visitor can then pause the program, rewind it, or fast forward it.

Acoustiguide’s newest unit is a compact screen-based player, developed and designed specifically for on-site interpretation of museums and visitor venues. The Opus series allows institutions to provide visitors access to various digital resources—video, images, and animation, plus the traditional audio, Fig. 40-5.
The high-performance computing capabilities of Opus include sophisticated graphic images and digital movies as its processing speed and memory capacity enable delivery of high-resolution video files and CD-quality sound.

The administrative user interface allows for simple additions and deletions of content, as well as more complex functions, such as integration of timed audio with video and images.

Opus comes in two formats: Opus Click™ and Opus Touch™. The click format utilizes a keypad while the touch format utilizes a touchscreen. The systems incorporate the following:

- Remote triggering and synchronization.
- Remote content activation via IR and RF technologies.
- Synchronization to external multimedia or show control systems.
- Data collection and visitor surveys.
- Software tracks user click stream.
- Customized surveys can be incorporated into the guide’s audio/visual content.
- Produces easy-to-read reports.
- Visitors can bookmark items of interest either for on-demand printing via MyCollection™ or other postvisit services such as e-mailing information home.
- Map-driven or object-driven modes.
- Full color TFT LCD screen.
- Large, expandable memory.
- Compatible with a complete range of audio, video, image and animation multimedia formats.
- Dual-listening mode, via internal speaker and/or through headset/earpiece.
- Up to 12 h of usage between charges.
- Remote activation via IR and RF.
- Opus Content Management System—easy setup and install, can be used by client.
- Dual-listening mode.
- A fold-out loudspeaker, each player can be used either as a true wand or as a headset unit.
- Headphone integrated into strap.
- MP3 stereo sound quality.
- Range of sixteen stepped volume levels.
- 500 h of multilingual audio content.
- MP4 and JPEG visual quality.
- QVGA resolution (320 × 240 pixels) and 65,536 color depth.
- 28 h of video, or 10,000 images.
- 2 GB memory; expandable.
- Holds multiple languages and tours.
- Guides can contain any combination of audio, images, animation, or video clips.
- Graphically rich user interface with menu selection and navigation functions.

Another system is made by Tour-Mate. Its SC500 Listening Wand is 13 inches long, 1.8 inches wide, and 1 inch deep and weighs 8 oz. A carrying strap is attached inside the wand for added strength and so it that it cannot be unclipped by the user. The system is powered by a rechargeable nickel metal hydride battery pack which will deliver 10 h of continuous play from a full charge and can be recharged in 3–4 h, Fig. 40-6.

![Figure 40-6. Typical charger/programmer.](image)

The maximum capacity of the system is 24 h of mono sound or 12 h of stereo sound. The message can be expanded on-site. The wand can store several tours and/or versions of the tour. The software permits a staff member to type in a code that locks out all tours but the desired one. A keystroke permits one to see what version of the tour has been selected.

The Tour-Mate editing capability software is windows compatible. The editing software permits the user to input tour messages or message segments and to perform such functions as: cut, paste, parametric equalization, normalization, variable gain, variable compression, insert message queues, and program message sequences.

MyGuide by Espro is a system much like the previous two. It uses a wand that has the tour narration downloaded from the storage-rack/power supply recorded through a flash memory card. This system runs for 10 h between charging and can have up to 4 h of audio capacity. The bandwidth is between 300 Hz and 4 kHz so it is particularly useful for voice only.

ExSite MP3 system by Espro can have up to 72 h of multilingual content, uses a wide alphanumeric and graphic LCD screen, and can be synchronized to external multimedia presentations such as DVD and video. It can also collect and analyze visitor usage data.
The system can be used with the unit’s built-in speaker or with plug-in earphones.

*GroupGuide* by Espro is a portable system for group tours where the visitor wears a personal receiver with headphones, and the guide wears a transmitter with microphone.

AKG, Sennheiser, and Williams Sound also have tour systems using wireless microphones and wireless receivers. All of these systems as the *GroupGuide* are useful for guided tours.

### 40.4.8.4 Sophisticated Systems

One sophisticated system is *GuidePORT™* by Sennheiser. To operate *GuidePORT*, the museum is set up into zones or cells, Fig. 40-7. These zones may be separate rooms or floors or a section of a large room. Audio files associated with the exhibit in a cell and their corresponding identifier unit are created and/or stored on a standard PC. The files are uploaded by *GuidePORT* software to multichannel RF (radio frequency) wireless cell transmitters located in each individual cell. Each cell transmitter stores the audio for its particular zone. The audio (prerecorded and/or live stream) for that particular cell is downloaded into the visitors’ receivers when they enter the cell.

![Diagram of GuidePORT system layout](image)

**Figure 40-7.** GuidePORT system layout for a typical museum. Courtesy Sennheiser Electronics.

*GuidePORT*’s charger system can store and charge ten wireless receivers. Chargers can be linked to accommodate 5,000+ receivers. Receivers can operate for up to 8 h between charges. The charger system is linked to the control unit (PC) to allow programming the receivers for language and/or level.

To enable management of a frequently changing exhibit environment, Sennheiser has engineered a list-based audio configuration software so the museum management can control the audio tours by simply updating the master audio list as exhibit items and corresponding identifiers are moved.

Discreet wireless antennas are strategically placed throughout the exhibit to allow receivers and cell transmitters to interoperate. The system is designed to operate on license-free dedicated radio frequencies in the 2.4 GHz ISM band that are ideal for digital audio and resistant to outside radio interference.

Battery-operated or externally powered wireless identifier units are hidden near or behind each exhibit. The wireless architecture behind the *GuidePORT* system allows for quick and easy setup of the museum because, as an exhibit is moved, the associated identifier is moved along with it making it easy to rearrange an exhibit space.

The visitors are given a lightweight receiver that fits in the palm of their hand or can be hung around their neck, and a headset. The receiver is programmed by a staff member to the language and level the visitor desires. The system is hands free so the visitor is not required to press buttons to match exhibit placards. The visitors proceed into the exhibit at their own pace and as they move from exhibit to exhibit, the system automatically dissolves the audio from the previous message to the new one. Visitors can adjust the volume and pause or repeat information they would like to hear again, Fig. 40-8. The headphones fit all age groups and can include a sponsor logo.

When the visitor enters a zone, audio files for all of the exhibits within that zone are downloaded into the visitor’s receiver. The identifiers automatically trigger the receiver when a visitor is within a specified range of the displayed item to play the corresponding audio file. The trigger range, along with other parameters of the identifier, can be programmed via an infrared enabled Palm™ compatible PDA.

*GuidePORT* can integrate live audio into the presentation. The visitor can listen to live demonstrations, concerts, movies, and video presentations with synchronized sound just by walking into the area. The visitor can leave the area and walk to a new area and the audio program will automatically change.

All stationary components of *GuidePORT* are located in a central location. Cell transmitters interface with their base station PC via USB ports. A larger facility can network multiple base station PCs, including through an existing network. Antennas are connected using standard shielded Cat5 cable. Audio files may be created anywhere in any standard format, which are then converted to .WAV files before they are
imported into the GuidePORT system. The base station PC and/or central control unit is only needed when configuring or reconfiguring the system, and could be substituted with a temporary PC or notebook.

### 40.5 Narrow Beam Loudspeaker System

The directivity (narrowness) of any wave producing source depends on the size of the source compared to the wavelengths it generates.* Audible sound has wavelengths ranging from a few inches to several feet, and because these wavelengths are comparable to the size of most loudspeakers, low- to medium-frequency sound (20 Hz to 10 kHz) generally propagates omnidirectionally. Only by creating a sound source much larger than the wavelengths it’s producing can a narrow beam be created. To accomplish this with standard loudspeakers would require loudspeakers 50 ft in diameter. A narrow beam of sound from a small acoustic source is accomplished by generating a beam of ultrasound, which becomes audible as it travels.

Ultrasound, whose wavelengths are only a few millimeters long, are much smaller than the source, and consequently travel in an extremely narrow beam.

Ultrasound contains frequencies far outside of our range of hearing, and is completely inaudible, but as the ultrasonic beam travels through the air, the inherent properties of the air cause the ultrasound to distort (change shape) in a predictable way. This distortion gives rise to frequency components in the audible bandwidth, which can be accurately predicted, and therefore precisely controlled. By generating the correct ultrasonic signal, we can create, within the air itself, essentially any sound desired.

Note that the source of sound is not the physical device you see, but the invisible beam of ultrasound, which can be many meters long. This new sound source, while invisible, is very large compared to the audio wavelengths it’s generating, so the resulting audio is extremely directional, just like a beam of light.

Often incorrectly attributed to so-called Tartini tones, the technique of using high-frequency waves to generate low-frequency signals was in fact pioneered by physicists and mathematicians developing techniques for underwater sonar over 40 years ago.

Dr. F. Joseph Pompei, then a researcher at MIT, solved the problems of using ultrasound as an audible source that plagued earlier researchers. His design of the Audio Spotlight® sound system has become the very first, and still the only, directional loudspeaker system which generates low-distortion, high-quality sound in a reliable, professional package, Fig. 40-9. Fig. 40-10 shows the sound field distribution with equal-loudness contours for a standard 1 kHz tone. The center area is loudest at 100% amplitude, while the sound level just outside the illustrated beam area is less than 10%.

Audio Spotlight systems are much less sensitive to listener distance than traditional loudspeakers, but maximum performance is attained at roughly 1–2 m (3–6 ft) from the loudspeaker.

Typical levels are 80 dB SPL at 1 kHz for the AS-16, and 85 dB SPL for the AS-24 models. The larger AS-24 can output about twice the power and has twice the low-frequency range of the AS-16.

The most common use of the Audio Spotlight system is to deliver sound to a specific, isolated area. Just as with lighting, the Audio Spotlight system is best accomplished by generating a beam of ultrasound, which becomes audible as it travels.

mounted directly above the listener, aimed downward Fig. 40-11, which provides maximum localization. The speaker panel can also be mounted on a wall, and angled downward, to reach the listener.

Multiple Audio Spotlight systems can be used to create a larger field of sound, or to increase the sound intensity in a given region. Just like visual spotlights, beams of sound can be aimed next to each other, to shape the sound field Fig. 40-12A, or multiple speaker panels can be aimed to one position Fig. 40-12B. Just as with light, sound from these systems will combine to increase output substantially.

While the beam generated by the Audio Spotlight system is very narrow, the beam will reflect from surfaces (and listeners) in your environment. To sound waves, solid surfaces are much like mirrors are to light. Therefore, to reduce reflections, an acoustically absorbing surface (such as carpet, padding, or curtains) should be used to catch the beam and reduce the reflection. Generally, this is most important only in very quiet spaces, where there is little background noise to mask minor scattered energy. Also, like light, reflections can be used as projection of audible sound. By directing the beam against a surface, one can create very interesting virtual loudspeaker effects. The beam will generally maintain its directivity after projection, so it is best to insure that the listener is in the path of the reflected beam.

The loudest sound area is directly in front of the speaker panel at a distance of 1–2 m. Reasonable listening areas are within the darker zones. Sound levels outside the beam are down by over 90%. In all sound systems, audibility is determined by sound level received versus background noise levels. Therefore, the beam will be perceived as more narrow in the presence of background noise, as any scatter from a listener or
floor will be inaudible. This is much like the difference in shining a flashlight in a completely dark room versus one with background lighting.

### 40.5.1 Voice Evacuation/Mass Notification Systems

by Vic Cappetta, Cooper Notification

A logical evolution for message repeaters is the development of voice evacuation systems for life safety applications.

Cooper Notification, with the company’s brands Wheelock®, Safepath® Waves®, and Roam Secure®, offers complete solutions consisting of supervised notification and audio systems, RF control, and network alerting.

Depending on the application, Voice Evacuation and Mass Notification are terms that are often used interchangeably. The term voice evacuation is traditionally used in the fire alarm industry; the term Mass Notification is more recent and has its origins in military installations and an ever-growing presence on college campuses.

The term Mass Notification has been adopted by the U.S. Army Corps of Engineers and is specified and defined in a driving document known as the UFC (Unified Facilities Criteria). Mass Notification requirements are detailed and specific, including intelligibility performance. The intelligibility aspect is gaining more and more momentum as a way of defining clear communications over a loudspeaker system. Basically, intelligibility measurements deal with a percentage of loss of consonant definition (%Alcons method) or may be measured on CIS (combined intelligibility scale) or STI (speech transmission index) platforms.

Voice evacuation is self-explanatory—a system broadcasts recorded or live voice announcements over a loudspeaker system, typically within a building. Mass Notification, which can be the same thing, can also extend to outdoor areas; for example, military bases or university campus environments. The differences can be subtle: the term Mass Notification is more often used when the system is used for more than simple fire messages; for example, severe weather, industrial incidents such as noxious gas release, or bomb threats.

If a Voice Evacuation system is specified as a Fire Alarm system, the system must be UL listed for fire, and the entire system must be monitored for integrity (supervised).

This means that all internal aspects such as power supplies, voice modules, etc., as well as external aspects such as speaker loops must be monitored for shorts, opens, or ground fault. These conditions must be reported as troubles to the system headend.

The UFC basically defers to NFPA (National Fire Protection Association) for its technical requirements; therefore Mass Notification systems are typically supervised and resemble fire alarm notification systems in many respects. Some differences include the use of amber strobes instead of clear strobes in order to differentiate between fire notification and other life threatening events such as a bomb threat.

Traditional notification (horn strobes) or Voice Evacuation systems may be grouped together and accessed/initiated by radio frequency (RF). Cooper Notification’s WAVES® product line offers command and control capability that allows system operators to access traditional Wheelock® horns and horn strobes, or individual and multiple Safepath® systems from a PC-based command and control security point. Systems may be addressed by zone and prerecorded messages or live voice announcements can be initiated. The WAVES® product line also includes large outdoor high-power fixed and/or portable (TACWAVES) horn arrays that can be configured as standalone access points in the system—thereby achieving indoor as well as outdoor coverage. The outdoor horn arrays can be powered by local ac power, or solar charged batteries—eliminating cable installations in large geographical land mass situations, Fig. 40-13.

Mass Notification may also include network alerting, such as blast e-mails to networked PCs and text alerting over cellphones and Blackberries®, as well as alerting pocket pagers.

Cooper Notification’s Roam Secure® product line may be tied into the entire system for a complete notification solution.

#### 40.5.1.1 Case Study

**Scenario.** An incident indicating universal alerting with as much coverage as possible, such as a random act of violence on a college campus.

**Solution.** Mass Notification. Campus security with one action can initiate live or prerecorded messages with flashing strobes over targeted zone loudspeaker systems inside and outside the buildings, while simultaneously broadcasting text messages over LAN networks as well as cell phones and Blackberries®.
40.6 Audio Archival

In addition to message repeating applications, there is a need for long term storage—i.e., to preserve audio and video data for future generations. It has been only the last quarter century that we came out of the dark ages and into the domain of digital storage, Table 40-1.

As the world is changing from analog to the digital domain, the media for archiving must be improved. After all, the medium used 20,000 years ago for written information can still be read today, while today’s media for audio storage lasts only a few years and playback equipment becomes obsolete.

Today, most memory for audio storage is accomplished through solid state technologies. Solid state technologies fall into four broad categories:

1. Electrical memories based on semiconductor IC technology.
2. Magnetic memories based on magnetic materials.
3. Optical memories based on the interaction of light with matter.
4. Molecular, chemical, or biological memory based on changes in the atomic, molecular, or biological level.

Electrical memory is the most used technology for digital audio storage. Information is stored in digital form in various types of memory units. Common
circuits are DRAMs, PROMs, EPROMs, flash EEPROMs, and ROMs.

Dynamic random access memory devices (DRAMs) store information dynamically, that is, as a charge on a capacitor. These designs feature one field-effect transistor (FET) to assess information for both reading and writing and a thin-film capacitor for information storage. Most nonvolatile cells rely on trapped charge stored on the floating gate of the FET. These units can be rewritten many times, the limit being determined by programming stress-induced degradation of the dielectric. Erasure of the charge from the floating grid is accomplished by tunneling or by exposure to ultraviolet light.

DRAMs are volatile, the average memory is about 10 years. Programmable memories can be programmed at least once and some can be programmed a million times. A few nonvolatile memories are programmable just once. These have an array of diodes or transistors with fuses or antifuses in series with each semiconductor cross point.

Electrically programmable read only memory devices (EPROMs) are usually used to describe cells that are electronically written and UV erased. EEPROM is probably the most common technology used. Static random access memory devices (SRAMs) are sometimes connected to EEPROM for storage when power is removed. Flash EPROMs require bulk erasure and therefore cannot be written over by the consumer.

Read only memory (ROM) is the only form of semiconductor storage that is permanently nonvolatile. Even with no power source present, information is retained in a ROM without any information loss.

Optical storage devices, the CD and DVD, are popular for long term archiving for the following reasons:

- Disk medium is highly standardized.
- Disk medium is multimedia (sound, data, still images, moving images).
- Disk medium format has a commercial life expectancy of many decades.
- Disk medium is an efficient and evolving medium.
- Disk medium has good chemical and mechanical resistance.
- Disk medium has good resistance to harsh environmental conditions.
- Disk medium has contactless reading—i.e., nondestructive.
- Disk medium is cost effective.
- Disk medium is an unrecordable system in the ROM version that prevents erasing or overwriting.

Archived CDs must be chemically stable, have good resistance against scratching, breaking, etc., and must be tolerant to extreme conditions of temperature, humidity, and electromagnetic fields. Some companies, such as DIGIPRESS, produce a stable CD. Rather than using a polycarbonate substrate, the CENTURY-DISC ARK from DIGIPRESS has a desalcanized etched tempered glass substrate, which is covered with titanium nitride—a very resistant metal. They can reach a lifetime of over 200 years—not forever maybe, but a great deal better than our present mediums can.

41.1 Interpretation Systems

As the world gets smaller and smaller, communications become increasingly important. Countries must talk to countries, businesses to businesses, and people to people. Only a few years ago, simultaneous interpretation systems were only found in places such as the United Nations and NATO. Today businesses are doing business with partners around the world, religious organizations have international meetings, schools are multilingual, and video and audio conferencing is common place.

Designing and building a simultaneous interpretation system is not just adding a set of earphones and another microphone to a sound system. A simultaneous interpretation system requires sound equipment and an acoustically correct room for the interpreter. The output from the various interpreters is transmitted to the various listeners in their language. This can be done via hardwire and earphones, AM or FM transmission, induction loop, or with infrared transmission systems.

Simultaneous interpretation systems allow a presentation by a talker to be heard and understood in or close to real time by all people in the audience. To accomplish this, the voice of the talker is directed to interpreters in soundproof booths or areas. The interpreters hear the original or floor language on headphones and instantly or simultaneously interpret it into the language they are assigned. The translated signal is then transmitted back into the audience area through the interpreters, microphones and transmission medium to the listeners through their control panel and headsets.

There are two basic types of simultaneous interpretation systems: bilingual and multilingual. Bilingual systems are designed for places where two and only two languages are used, such as in eastern Canada where French and English are used. Bilingual systems are the least expensive and the simplest to set up and use. These systems usually use only one interpreter’s booth with either one or two interpreters.

Multilingual systems are used in the United Nations, large church conferences, boardrooms and schools, just to name a few. These systems are much more complicated and harder to install and use as they require individual interpreter rooms and a means for the listener to switch between languages.

41.1.1. Central Control Unit

The central control unit is the hub of the system. Most systems are microprocessor controlled and/or operated through an IBM compatible PC, Fig. 41-1. The floor language enters the unit at line level and is routed to the interpreters’ booths and a tape recorder if required. The interpreted languages are returned to the central control from the interpreters’ booths where they are prepared for transmitting to the listeners. This could be on hardwire, induction loop, infrared, or any combination of the three. Provision is also made for taping the interpreted language. The unit incorporates various operating modes and interlocks and a means for the interpreter and the operator to communicate with each other.

41.1.2. Interpreter’s Booth

In the multilingual system, each booth normally has two or more interpreters that work as a team to interpret the floor language into the designated language of the booth. If many floor languages are allowed, each booth could require as many as four interpreters. The ISO standard for fixed interpreters’ booths in systems with six to twelve languages recommends three interpreters per booth for the first six booths and four interpreters for the remaining booths, Fig. 41-2. Systems can have from two to thirty two languages, however, twelve seems to be the maximum normally used. Today most systems are digital, which can reduce background noise, distortion, and crosstalk. AGC assures equal listening level on all input channels, and the systems can be chained together with shielded FTP or STP Cat-5e cables, Fig. 41-3.

Booth size is specified by international standards. Permanent interpreters’ booths and equipment are specified under ISO 2603 (1983), which specifies the minimum dimensions of 2.5 m wide × 2.3 m high × 2.4 m deep (8.2 ft × 7.75 ft × 7.87 ft). In booths with four interpreters, the width shall be 3.4 m (11 ft). An 80 cm (31.5 in) high window should extend the full width of the booth with the bottom of the window flush with the console. The room construction should attenuate the live sound so that if the nonreinforced sound does not exceed 80 dB, the inside signal will not exceed 35 dB.

Portable interpreters’ booths are specified by ISO 4043 1981, and sound transmission using infrared is specified by IEC 764. The MB 2932 interpreter booth by Listen Technologies is intended for portable or fixed installations. The booth consists of four window panels, three blind panels, a door panel, a table, and two roof panels. It includes two ventilation fans and exceeds ISO 4043 sound insulation standards, Fig. 41-4.

Simultaneous interpretation systems are not just a simple input to an interpreter’s booth. The system must enable the interpreter to hear the talker and to distribute
the interpreted language back to the language distribution system where it is sent to the various listeners. Beyond this the system must accommodate the following operations:

- One of the most important operations is to route the floor language through any unengaged channels. This is used so whenever the floor language is the same as the interpreted language of that particular booth, the interpreter does not have to interpret or remove his headset or change channels. This gives the interpreter a break.
In the event the interpreter cannot understand the floor language, the console must have a relay facility so the interpreter can select one of the interpreted channels that she can understand, and make an indirect interpretation of that language into the booth designated language.

It is advisable to have some degree of flexibility and control over the output channel of the booth to make fullest use of the capabilities of the team of interpreters in the booth. There must also be a means to prevent inadvertent interference with an engaged channel by another booth.

When necessary, the output of any or all channels must be available for recording, and/or connecting to other feeds for transmission elsewhere.

A final important accessory to the system is visual indicators on the console to identify engaged channels, and a two-way visual/audio system between the system operator and the interpreters' booth to summon the operator for assistance or alert the interpreter of a problem.

Figure 41-5 is an interpreter terminal for two interpreters according to ISO 4043. The unit is a double interpreter terminal for alternating operation and includes two microphone/headphone combinations. The two output channels are directly selectable by the interpreter and relay translations are possible from all languages. The listening area contains volume, bass, treble controls, an incoming channel selector, and an original/relay lever switch. It also has extra communication channels to and from the system operator and status information lights.

Once the language has been interpreted and sent to the master station, it must be routed to the listeners. There are three basic systems of transmitting the signal; the hardwired system, the multichannel FM inductive loop, and the infrared transmission system.

41.1.3. Hard Wired Systems

Hardwired systems are primarily used to transmit interpreted language channels to delegate stations on the conference hall floor. They are most useful in areas such as the United Nations building where the listeners are always seated in the same place and can tolerate the cable to the earphones. A hardwired system is the most reliable, has the best security against eavesdropping and has the best audio performance. As a rule, hardwired systems are cheaper in hardware costs but more expensive in installation costs. In multiconductor cable systems, each channel is amplified and transmitted on a pair of conductors. Each listener usually has a panel located at his or her seat that includes a language selecting switch, a volume control, and an earphone jack. If the conductors are a twisted pair, there is little crosstalk in lines in excess of 1000 m (3280 ft), and farther with shielded cable. Hardwired systems are not particularly good for portable systems as it is not easy or physically safe to lay out cables on the floor to the various listeners. It is important that the user does not place the earphones next to a microphone, unless it is...
shutoff, as they may be on the same channel and cause feedback. Acoustical crosstalk can occur if open back earphones are used because an adjacent live microphone can sometimes pick up the interpreted language.

If many languages are used, it may be better to multiplex the signal rather than use a multiconductor cable. This system would consist of a central modulator with up to twelve channels driving a network of active channel selector units using coaxial cable in a loop-through configuration. Power for the channel selectors is provided by power supplies injecting dc into the network.

Most single cable conference systems with delegate microphone units incorporate a built-in loudspeaker. The loudspeaker signal is derived directly from a common audio line. This simplifies cabling by avoiding the necessity for a second audio line to drive the loudspeakers. This does mean that the input and output signal are on the same line, and would create a closed loop and feedback unless some means of isolating the two signals is employed. This problem is overcome by Auditel with the application of a common mode reverse audio feed (CMRAF), Fig. 41-6. The technique is based on selective rejection of large common mode signals. The output from the microphone preamplifier is a balanced signal and is extracted in the central unit via transformer. After signal processing, the loudspeaker drive signal is injected into the audio pair in common mode form. Since the loudspeaker drive amplifiers and delegate units reject balanced signals the two signals can be carried over the same conductors without interaction or without compromising the signal quality.

### 41.1.4. FM Interpretation Systems

FM products can be used for language interpretation by connecting a stationary FM transmitter to an audio system transmitting an FM signal to a portable receiver for assistive listening and a language interpreter. In addition to the portable receiver, the interpreters use a portable transmitter and an over-the-head microphone and earphone unit. This combination allows them to hear the audio clearly in an adjoining area while speaking their translations in a normal tone of voice. Their translations are sent via FM back to participants’ receivers. It is important to have transmitters and receivers with multiple channels allowing users to find clear channels even in a crowded venue with extensive FM use.
41.2 Multichannel FM Induction Loop

The induction loop system is a development of the audio loop for assisted hearing that has been around for many years. This system has the advantage of being less expensive than the infrared system and more portable than the hardwired system. It is not affected by line-of-sight limitations and does not require visible radiator panels as is required by infrared systems. Originally these systems operated on the AM band, however, today’s induction loop systems operate on the FM band for better quality and less noise and interference.

A closed loop antenna is installed around the perimeter of the area if the room is small, 30 ft × 60 ft (9 m × 18 m), Fig. 41-7A, or as a zigzag or circular pattern in larger areas with a 10 ft × 15 ft (3 m × 4.5 m) pitch Figs. 41-7B and 7C. The zigzag or circular system should always be on or in the floor rather than in the ceiling because the field strength above and below the loop is reduced as the horizontal strength is increased. The antenna should be placed in aisles where pickup is not essential.

The loop consists of a single conductor with a minimum cross section area of 2.5 mm². Loop inductance should be about 1.5 μH/m. This translates to 1.5 mH for a 1000 m loop. For best signal, the FM transmitter should be capable of delivering 100 mArms per channel to the antenna. It is common to install the loop on or in the floor rather than in the ceiling because the seated listener is usually closer to the floor, and ceilings are apt to have a lot of metal that shorts out the signal. If the antenna is installed permanently in conduit in the floor, nonmetallic conduit, such as PVC, must be used.

An FM modulated-carrier transmits the signal. The band for the carrier frequencies is limited to 15–150 kHz by international Telecom regulations in most areas except North America. This bandwidth limits the number of voice channels to about eight. The radiation is primarily magnetic and pretty much confined to within the area defined by the loop, therefore the system has reasonable security. Audio quality is
restricted to a 3–4 kHz bandwidth that is adequate for voice only. Table 41-1 gives the technical specifications for an eight channel inductive loop system by Auditel.

Inductive loop systems are inexpensive and easy to install and therefore usually preferred in large portable and multiple venues where cost is important. Different systems in adjacent areas can cause crosstalk and security can become a problem if a listener can get close to the loop. Steps can be taken, such as using an out-of-phase loop around the room about 3 ft beyond the periphery of the transmission loop, to reduce horizontal coverage, Fig. 41-7D. To reduce vertical interference where one system is directly above another, a double zigzag antenna system can be used, Fig. 41-7E. This antenna system will reduce the unwanted signal to 50 dB below the wanted signal when the separation distance is 10 ft (3 m) as opposed to 20 ft (6 m) with a standard antenna.

The induction loop receivers normally operate on batteries so the listener can be located or move anywhere within the induction loop. The receivers use a ferrite rod antenna, have a battery status indicator, a volume control, and a channel selector switch. Most units use alkaline batteries and get upwards of 500 h between battery changes. High fidelity headsets are not required because the overall frequency response is so limited.

### 41.3 Infrared Systems

An infrared system is a modern version of the wireless system. InfraRed was designed by Sennheiser in the seventies as a medium for wireless audio transmission. It was initially used as a broad band system for home entertainment and later for assisted hearing systems. It is applied to multichannel audio systems using narrow band modulation techniques in the 930 nanometer wavelength band. Rather than using radio frequencies for transmitting the signal, it uses infrared frequencies, which are confined to line-of-sight or reflections off of objects. These objects can be mirrors, glass ashtrays, or any other brightwork. Infrared goes through glass windows and is absorbed by objects and walls that are dark green or black. It is important that the walls of a room using infrared be light colored and have a minimum number of windows.

Two different transmission techniques are used: the pulse modulated system and the FM multiplexed system. The pulse modulated system has an advantage in that the amount of emitted radiation required is independent of the number of channels, however, it usually has poorer audio quality than the FM multiplexed system. Pulsed systems do not meet IEC audio standards and can be affected more by high-frequency fluorescent lights.

Most systems used today are based on modulated carrier techniques using FM. The operating frequencies for wide-band two-channel infrared systems are 95 kHz and 250 kHz with peak deviation of ±50 kHz. Narrow-band systems operate on twelve or more channels between 55 kHz and 1335 kHz (excluding 455 kHz) with 40 kHz channel spacing and peak deviation of ±7 kHz. These standards are specified in the IEC 76 international standard and insure compatibility between manufacturers. General specifications for infrared systems are given in Table 41-2. The system comprises three sections: the transmitter, the emitter (sometimes both are combined in one unit), and the receiver. The transmitter imparts the audio signal onto a subcarrier that the emitter converts into infrared light. The receiver decodes the infrared signal to retrieve the original audio, Fig. 41-8.

The signal enters the listening area via infrared radiators. The IR light emitting diode can cover an area of 70 ft² and has a coverage angle of ±25 degrees. The

diode incorporates a collecting lens which bends the infrared light to hit the diode, Fig. 41-9. Increasing the number of diodes increases the IR intensity and the area of coverage multiplies by the number of diodes in the panel. The diodes have a continuous operating life of 100,000 h before the light output diminishes to 70% of its original value.

**Transmitters:**

- Frequency response (−3 dB): 50 Hz–8 kHz 50 Hz–13 kHz
- Max. distortion at 1 kHz: <1.0% <1.0%
- Signal/noise (A weighting): >55 dB >70 dB

**Receivers:**

- Frequency response (−3 dB): 50 Hz–8 kHz 100 Hz–9 kHz
- Max. distortion (at 1 kHz): <2.5% <1.0%
- SNR (A weighting): >55 dB >63 dB

**Emitter Panels:**

- Frequency response (−3 dB): 30 Hz–710 kHz

**Figure 41-8.** Light emitting diode (LED). Courtesy Sennheiser Electronics.

Depending on the size of the room, its shape, and surface characteristics, a single small radiator or multiple large radiators may be required. Auditel Systems Limited states that the number of radiators required for a SNR of >40 dB can be calculated using the following equation:

\[
N = \frac{area(m^2) \times number of channels}{D} \tag{41-1}
\]

where,
This does not take into account the wall surfaces, niches, and obstructions and it assumes that at least 95% of the radiation is usable. Sennheiser states its large radiator can cover 11,000 ft²/number of channels in the system.

Layout of the panels is also important. Every seat must have a view of a panel. The range and coverage of a radiator are influenced by its orientation to the surface to be illuminated. A panel that is located so its pattern is parallel to the floor will have a long footprint with decreasing signal with distance. A panel that is aimed straight down will have a circular pattern that has about the same signal everywhere.

Total infrared power is proportional to the number of diodes in the panel. Power can be doubled by using two panels at the same location or using a panel with twice as many diodes. It is often best to use more than one radiator to eliminate dead spots in the area. If the overlapping areas have reduced signal, the two signals can add to bring the SNR ratio up to an acceptable level.

The infrared signal is received by the listener through a belt pack or integral headset type of receiver. The body pack receiver is about 125 mm × 60 mm × 28 mm (4.9 inches × 2.3 inches × 1.1 inches) and weighs 100 g (3.5 oz) and incorporates a channel selector switch, volume control, and earphone jack. The integral headset receiver hangs from the ears down below the wearer’s chin. It includes a channel selector and volume control, weighs 2.1 oz, and can deliver 110 dB, Fig. 41-10.

Security from eavesdropping is good since an unwanted receiver cannot see the transmitter or its reflections. Interference between rooms is also good since infrared cannot go through solid walls. Infrared systems are affected by other infrared sources such as sunlight and incandescent and fluorescent lights. Infrared is never usable in direct sunlight but can often be used in shaded areas if high-power transmitters are used. Rooms with intense incandescent and fluorescent lighting may require high-power transmitters. Because it is line-of-sight, objects, including people between the transmitter and the receiver, can cause dropout unless at least two transmitters are covering the same area.

Infrared systems are used for portable systems, where a large room can be subdivided, and for fixed installations. This system is more expensive than the induction loop but has much better audio quality, and is not as susceptible to electrical interference. Infrared is the system of choice today.

41.4 Tour Group Systems

A tour group FM system consists of a portable FM transmitter and portable FM receivers. A microphone, often worn over the head, is connected to the transmitter and broadcasts the presenter’s voice to everyone in the audience or group. The portable transmitter allows the audio to be delivered without having to carry a microphone or be plugged into the wall. Participants wear a portable FM receiver with an earphone to hear the presentation. An unlimited number of receivers can be used with one transmitter as long as the participants are within the broadcast range, typically up to 150 ft (45.7 m).

The transmitter and the receivers are tuned to the same channel and depending on the frequency, three–eight channels can be used simultaneously. This allows for multiple tours to be conducted at a time and/or provide language interpretation. Currently tour group products are available in 72 MHz, 216 MHz, and 863 MHz.

Transmitters and receivers offer a mix of features and functionality for channel selection, programming, power, signal strength, and use. Portable transmitters and receivers are typically battery powered with standard alkaline or NiMH batteries.
Tour group systems are excellent for factory tours, museums, outdoor events, wireless microphone applications, classroom or training, or personal use. Anywhere you need to amplify sound but don’t have (or want) an installed sound system.

41.4.1. FM Transmitter

A typical portable FM transmitter is shown in Fig. 41-11. The specifications for this transmitter are:

**General**
- Number of channels: 19 wide-band, 38 narrow-band.
- Channel tuning capable of being locked.
- SNR: 70 dB or greater.
- Output power: adjustable to quarter, half, or full.
- Audio frequency response: 50 Hz–15 kHz ±3 dB.
- Includes: a microphone sensitivity switch.
- Includes: a mute switch.
- Operates on two AA batteries.
- Includes: an LCD display that indicates battery level, channel, channel lock, low battery, battery charging, programming, and RF signal strength.
- Includes: automatic battery charging circuitry for recharging NiMH batteries.

**Radio Frequency**
- RF frequency range: 216.0125–216.9875 MHz.
- Frequency accuracy: ±0.005% stability from 32 to 122°F.
- Transmitter stability: 50 PPM
- Transmitter range: 0 to 150 ft (45.7 m).
- Output power: less than 100 mW (216 MHz).
- Antenna: the microphone cable.

**Audio**
- System frequency response: 50 Hz–10 kHz ±3 dB 216 MHz.
- SNR: SQ enabled; 80 dB; SQ disabled 60 dB.
- System distortion: <2% harmonic distortion (THD) at 80% deviation.
- Microphone input: unbalanced, +4 dBu maximum, −10 dB nominal input level adjustable, impedance 10 kΩ.
- Microphone sensitivity: three position switch: high, middle, and low in 6 dB increments.
- Line input: unbalanced, −10 dBu nominal input level, −3 dBu maximum, impedance 10 kΩ
- Microphone power: 3 Vdc bias.

**Controls**
- User controls: power, mute, channel up/down.
- Setup controls: in the battery compartment, microphone sensitivity, NiMH/alkaline battery, SQ enable/disable.
- Programming: channel lockout, channel lock.

**Indicators**
- LED red: illuminated when unit is on, flashes when batteries are low, or to indicate charging. Flashes two times when muted.
- Display: channel designation, lock status, signal strength indication, battery life, RF power.

**Power**
- Battery type: 2 AA batteries, Alkaline or NiMH.
- Battery life: alkaline –10 h, NiMH rechargeable.
- Battery charging: (NiMH only), fully automatic, 13 h.
- Power supply compliance: RoHS, WEEE, UL, PSE, CE, CUL, TUV, CB compliant.

**Physical**
- Dimensions: (H × W × D) 5.0 inches × 3.0 inches × 1.0 in (13.0 cm × 7.6 cm × 2.5 cm).
- Color: dark gray with white silk screening.
- Unit weight: 3.9 oz (111 g).
- Unit weight with batteries: 5.8 oz (164 g).

**Environmental**
- Temperature—operation: 14 to 104°F.
- Temperature—storage: –4 to 122°F.
- Humidity: 0 to 95% relative humidity, noncondensing.

Figure 41-11. Typical high-quality FM transmitter, the Listen LT-700-863. Courtesy Listen Technologies Corporation.
41.4.2. FM Receiver

A typical FM receiver is shown in Fig. 41-12. The specifications for this FM receiver are:

**General**
- Number of channels: 19 wide band, 38 narrow band.
- SNR: 70 dB or greater.
- Programmable to electronically lock out unneeded channels.
- Can seek channels and can be locked on a single channel.
- Adjustable squelch.
- Audio frequency response: 50 Hz–15 KHz ±3 dB.
- Includes: a stereo headset jack for either a mono or stereo headset.
- Includes: an LCD display that indicates channel, battery level, low battery, battery charging, and RF signal strength.
- Functions in both DX and Local mode.
- Operates on two AA batteries.
- Includes: an automatic battery charging circuitry for recharging of NiMH batteries.

**Radio Frequency**
- RF frequency range: 216.0125–216.9875 MHz.
- Number of channels: 19 wide band, 38 narrow band.
- Sensitivity: 0.6 uV typical, 1 uV maximum for 12 dB sinad.
- Frequency accuracy: ±0.005 stability, 32 to 122°F.
- Antenna: uses earphone cable.
- Squelch: programmable in twenty steps, automatic on loss of RF signal.

**Audio**
- Frequency response: 50 Hz–10 kHz ±3 dB 216 MHz.
- SNR (A-weighted): SQ enabled: 80 dB; SQ disabled 60 dB.
- System distortion: <2% total harmonic distortion (THD) at 80% deviation.
- Output: unbalanced, 0 dBu nominal output level, 16 mW maximum, impedance 32 Ω.

**Controls**
- User controls: channel up/down, seek, volume.
- Set up controls (battery compartment): alkaline/NiMH batteries, SQ enable/disable.
- Programming: channel lock, squelch, channel lock-out.

**Indicators**
- Red LED: illuminated when unit is on. Flashes when batteries are low, or to indicate charging. Flashes when locked and seek is pushed.
- Display: channel designation, lock status, signal strength indication, programming.

**Power**
- Battery type: two AA batteries, alkaline or NiMH.
- Battery life: alkaline–15 h NiMH rechargeable.
- Battery charging (NiMH only): fully automatic, 14 h.
- Power supply: Input—120 Vac, Output—7.5 Vdc 250 mA.

**Physical**
- Dimensions (H × W × D) 5.0 × 3.0 × 1.0 inches (13.0 × 7.6 × 2.5 cm).
- Color: dark gray with white silk screening.
- Unit weight: 3.9 oz (111 g).
- Unit weight with batteries: 5.8 oz (164 g).

The above specifications are fairly common for high-quality receivers.

Figure 41-12. Typical high-quality FM receiver, the Listen LR-500-863. Courtesy Listen Technologies Corporation.

41.4.3. All-in-One System

An all-in-one system or self-contained system for use in multiple venues is Listen Technologies’ Soundfield FM,
Fig. 41-13. Soundfield FM applications can be in a classroom, meeting room, training center, or theater. Studies have shown that boosting the audio levels of normal voices increases retention by as much as 30% for the listeners, and can reduce potential for voice strain and fatigue for the presenter.

Wherever a large PA system is impractical, a Soundfield FM-type solution is a possible answer. A Listen Soundfield FM system is an easy way to deliver interference-free sound to groups of all sizes insuring that all participants hear the message clearly.

The LR-100 Stationary Receiver/Power Amplifier, when used with a Listen transmitter, delivers audio for use in a variety of locations and applications—most commonly soundfields. The unit has an LCD display showing channel, lock, and battery level. A security cover protects auxiliary and receiver volume and trim controls. It has an adjustable squelch control, balanced or unbalanced loudspeaker wire output options, and multiple input options for flexibility. The system is powered by a 16 Vac/1000 mA power input or a 12 Vdc battery. An antenna can be added for longer range applications.

The LR-600 is a wireless receiver, two-channel 10 W power amplifier and loudspeaker. The unit is powered by alkaline or NiMH rechargeable AA batteries, or a 15 Vac power supply or 12 Vdc, for 15–10 W continuous power output. It has unbalanced auxiliary input and output ports. The LCD display shows channel, lock, and battery level.

42.1 Nature of the Problem

There are millions of people in the world (20 million in America alone) with hearing impairments for whom the acoustical and electronic systems described elsewhere in this book are inadequate. It is surprising that the special hearing needs of so large a group have been largely ignored for so long, especially when each of us faces the very real probability of joining that group through disease, trauma, or just by growing old.

According to the National Association of the Deaf, NAD, assistive listening systems (ALSs), sometimes called assistive listening devices (ALDs), are amplifiers that bring sound directly into the ear. They improve the speech-to-noise ratio by separating the sounds, particularly speech, that a person wants to hear from background noise.

Research indicates that people who are hard of hearing require a signal-to-noise ratio increase of about 15–25 dB in order to achieve the same level of understanding as people with normal hearing. An ALS allows them to achieve this gain for themselves without making it too loud for everyone else.

ALSs are used by people with various degrees of hearing loss, from mild to profound, including hearing aid users and those with cochlear implants, as well as those who use neither. ALSs are sometimes described as “binoculars for the ears” because they stretch hearing aids and cochlear implants, thus extending their reach and increasing their effectiveness.

ALSs address listening challenges by minimizing background noise, reducing the effect of distance between the sound source and person with hearing loss, and overriding poor acoustics such as echo. ALSs are used in places of entertainment, employment, education, and home/personal use.

The hearing impaired are not just the people who wear aids. In fact, only about 20% of the hearing impaired wear aids. Many people with hearing losses are able to function in close or face-to-face situations but are lost in noisy or reverberant settings. Even people who wear hearing aids have problems in reverberant rooms or where there is a high background noise level. Our standards for speech intelligibility are based on listening tests with normal-hearing subjects and are not directly applicable to the hearing impaired, see Chapters 2 and 40. Noise and reverberation degrade intelligibility far more rapidly for the hearing-impaired individuals whether they are fitted with hearing aids or not. Often the very highly prized acoustical qualities of theaters and concert halls operate against the needs of the hearing impaired, and the acoustical design of most classrooms and lecture halls are inadequate for the hearing-impaired student.

For years the only special assistance offered to the hearing impaired was headphones in a couple of pews in the front of the church sanctuary. In recent years new wireless technologies have been developed or adapted to meet the special needs of the hearing impaired in public assembly spaces. No longer is the user restricted to a specially wired seat; now every seat is available; no special ticketing is required. The user is free to sit with family and friends.

Wide area ALSs are covered under Title III of the ADA (Americans with Disabilities Act of 1990). This title stipulates that ALSs be provided in public places unless a provider can prove that it is an undue burden. Examples of such venues include movie cinemas, live performance theaters, and public classes. The ADA specifies that ALS receivers be provided at no cost and specifies the number of receivers that must be provided depending on the number of seats (4% rule). Revised ADA Guidelines to be released in the future are expected to increase standards for performance of ALS and address related issues.

ALSs may also be indicated under ADA Title I (employment accommodations) as well as Title II (accommodations provided by state and local governments). Other public policies that may require use of ALSs include Section 504 of the Rehabilitation Act (affecting federally funded agencies) and Individuals with Disabilities Education Act.

42.2 Types of Assistive Listening Systems

There are four basic types of wireless systems: magnetic induction, FM broadcast, AM broadcast, and infrared light. Each type has its own set of advantages, problems, and limitations. There is no single best system for every application; each system is simple to operate and to install.

The system, no matter what type, must pick up the program sound. In a fully mic’ed event, this pickup could be a feed from the reinforcement control console. Where the event is not mic’ed, there must be a special microphone or microphones to feed the hearing-impaired system. It is very important that the feed to the system be of the highest quality possible with a minimum of reverberation pickup and extraneous noises. A pressure zone-type microphone, see Chapter 16, on the forestage floor or mounted on an acoustical reflector panel over the forestage would be good for many shows. An even better system, which would reduce room effects, would be to individually or close-
mic the actors, talkers, or singers. A sound pickup that does not reject the reverberant field and extraneous noise, and/or has distorted sound will not be useful for a system for the hearing impaired.

### 42.2.1 Magnetic Induction Loops

*Magnetic induction,* sometimes called a *loop system,* is one of the oldest but still useful systems. The principal advantage of this system is that it can operate directly into the user’s hearing aid without the need for a portable receiver as required by all other systems. A loop of wire is wrapped around the seating area, usually under the carpet, and connected to an amplifier. The electrical current flowing through the loop will create a magnetic field (as the primary of a transformer) that can be picked up by a hearing aid equipped with a *T-coil* (T as in telephone). About 60% of the hearing aids in the United States have T-coils for magnetic coupling with the earpiece of a telephone. Portable receivers are available for use by patrons who do not have an aid with a T-coil.

There are, however, several problems with the loop system. Most buildings have other magnetic fields that will be picked up by the T-coil. Ordinary electrical wiring will radiate a large 60 Hz field throughout the room, so the T-coil and the portable receivers are designed to have no response in the low-bass region in order to avoid the 60 Hz hum. There are other power-line-related noises that cannot be filtered out—motors, dimmers, and fluorescent lamps being the most common. The size and shape of the loop and the amount of nearby steel in the building or in the seats will affect the strength and uniformity of the magnetic field. Simultaneous use of loops in adjoining rooms is often a problem because of crosstalk between the systems. Quality of reception is also dependent upon the quality of construction of the T-coil in the hearing aid. All these factors combine to provide reception that sometimes has poor sound quality, is noisy, and varies in volume depending on the location of the listeners and how they turn their heads.

The limited statistics available indicate that of the people needing hearing assistance, only about 20% are actually wearing aids, and only 60% of those aids are equipped with T-coils, which suggests that only 12% of those needing help are able to make use of a magnetic loop through their hearing aids. It has been argued that the majority of those without T-coils actually are young children and the very old; active adults are most likely to have T-coils. Despite the comparatively limited availability of T-coils and the several substantial limitations of the magnetic loop system, it remains popular and enjoys the vocal support of many of those 2.5 million people who have T-coils.

The cost of a magnetic induction loop system is largely the cost of the amplifier and the labor of installing the wire loop. The receivers are inexpensive. Until recently, the magnetic loop was the least costly system. However, advances in solid state electronics have made the AM and FM broadcast systems very competitive in price. Where large areas are to be covered, the magnetic loop is probably not as cost effective as a broadcast system.

#### 42.2.1.1 Loop Design Criteria

The international standard for the magnetic field strength of a loop system with an input signal of normal speech level is 0.1 A/m. Magnetic field strength $H = 0.1 \text{ A/m}$ in SI units or 0.125 Oe in cgs units. This field strength produces an audio voltage in the T-coil about equal to the output of the hearing aid’s microphone at normal speech levels, Fig. 42-1. This eliminates the user having to make volume control adjustments when switching between microphone and T-coil. Also, this field is strong enough that noise and interference problems are minimized, yet it is not so strong as to overload the hearing aid amplifier.

![Figure 42-1](https://via.placeholder.com/150)

*Figure 42-1. Typical hearing aid response. (From Reference 1.)*

The field strength should be as uniform as possible over the coverage area. An achievable criterion for uniformity is a maximum variation of $\pm 3 \text{ dB}$ in the audio output signal.

System design is based on the vertical component of the magnetic field, ignoring the horizontal field components for three reasons:
• The vertical field strength predominates over most of the loop area, Fig. 42-2.

• The T-coils in hearing aids are typically positioned to be most sensitive to the vertical field.

• Rotating the hearing aid about the vertical axis (as in turning the head) results in no change in the pickup of the vertical component, whereas the pickup of the horizontal component changes from zero to maximum to zero with such rotation.

42.2.2 Loop Location and Size

The field strength produced by the loop will vary in intensity from the edge of the loop to the center, Fig. 42-3. The range of variation is dependent on the area and shape of the loop and the listening height, which is the vertical distance between the plane of the loop and the receiver. This interrelationship is expressed as the relative listening height and is determined by

\[ h_r = \frac{h}{\sqrt{0.5A}} \]  

(42-1)

where,

- \( h_r \) is the relative listening height,
- \( h \) is the listening height,
- \( A \) is the area covered.

The normalized field strength along the diagonal of loops of various shapes and the corresponding range of acceptable values for \( h_r \) are shown in Fig. 42-4.

By application of Eq. 42-1 and the \( h_r \) values found in Fig. 42-4, it is possible to design a loop of acceptable shape, area, and listening height. The penalty for an inequality in Eq. 42-1 is degraded uniformity of field strength, as can be seen in Fig. 42-4.

If the loop is to be placed at floor level (\( h = 48 \) inches for seated listeners), square loops falling within the acceptable \( h_r \) range will vary from \( 28 \text{ ft} \times 28 \text{ ft} \) to \( 38 \text{ ft} \times 38 \text{ ft} \). A rectangular 1:4 loop may range in size from \( 24 \text{ ft} \times 96 \text{ ft} \) up to \( 32 \text{ ft} \times 126 \text{ ft} \). Smaller loop dimensions will require a smaller \( h \); larger areas need a larger \( h \).

As \( h \) grows larger, the field-distorting effect of steel in the building structure and in the audience chairs...
becomes more pronounced. This field distortion is manifest by dead spots within the loop. At its worst, the entire system may be rendered useless.

The great listening height required of large loops also presents architectural problems. Often the only practical place to locate a loop is at floor level, either below the floor or under the carpet. Where it is not feasible to locate the loop far above (or far below) floor level, the single, large loop can be broken up into a number of smaller loops that can be sized to locate at floor level. Because the vertical field strength rapidly falls to a minimum above the conductors, it is important to locate the loop wires in aisles or other areas that do not require coverage. For multiple loops, the current in parallel conductors of adjacent loops must flow in the same direction, Fig. 42-5.

![Multiple-loop current flow diagram.](image)

Unfortunately, multiple loops will almost always have poorer uniformity than a single loop of the same size as one of the multiples. There is a special design technique for achieving a more nearly constant vertical field strength when using multiple loops. It involves the use of two sets of overlapping loops that are driven with electrical signals 90 degrees out of phase. This complex procedure is described by Bosman and Joosten.3

42.2.2.1 Loop Current

Once the size and location of the loop are fixed, the required current in the loop can be calculated. The strength of the magnetic field is directly dependent on the current in the loop. The required current, $I$, in a single-turn loop is

$$I = \frac{0.1 A/m \cdot \pi A}{2D} \times \left(1 + 2h_r^2\right) \sqrt{\frac{1 + h_r^2}{1 + h^2}}$$  \hspace{1cm} (42-2)

where,  
0.1 A/m is the field strength criterion,  
$A$ is the loop area in square meters or square feet,  
$D$ is the loop diagonal in meters or feet.

The terms containing $h_r$ are a correction for the distance of the listener from the plane of the loop and are obtained from Fig. 42-6 by going vertically from $h$ to the line and horizontally to the correction distance.

![Graph for obtaining distance correction.](image)

If a multiturn loop is used, the required current in the loop is

$$I_M = \frac{I}{n}$$  \hspace{1cm} (42-3)

where,  
$I$ is the current from Eq. 42-2,  
$n$ is the number of turns.

42.2.2.2 Loop Impedance

Wire size and number of turns in the loop must be selected to handle the required current safely and to control the range of variation of impedance across the audio band. A loop can be designed to provide the required magnetic field strength by using a relatively small wire with one turn or by using a larger wire with several turns. In the first case the loop impedance would be mainly resistive; in the second, it would be heavily inductive.

The impedance increases with frequency because of the inductive reactance of the loop. This increase is limited by adjusting wire size and the number of turns so the impedance at 1000 Hz is no more than three times the impedance at 100 Hz. This moderately rising
impedance characteristic and falling loop current will complement the rising sensitivity characteristic of the T-coil, Fig. 33-7. Too high an impedance at high frequencies will result in too low current, producing poor response and degraded SNR.

![Figure 42-7. Sensitivity of typical inductive coil. (From Reference 1.)](image)

A wire size that can handle the required current with an acceptable heat rise is selected from Table 42-1. The impedance is then calculated at several frequencies such as 100 Hz, 1 kHz, and 10 kHz. The following equations are useful:

\[ L = \frac{r n^2}{13.5} \log \frac{2.8 r}{d} \]  
\[ (42-4) \]

where,
- \( L \) is the inductance in henrys,
- \( r \) is the radius of the loop in inches,
- \( n \) is the number of turns,
- \( d \) is the diameter of the conductor in inches (this is a simplification of Wheeler’s equation);

and

\[ Z = \sqrt{R^2 + \left(2\pi fL \times 10^{-6}\right)^2} \]  
\[ (42-5) \]

where,
- \( Z \) is the loop impedance,
- \( R \) is the dc resistance of the length of the coil,
- \( f \) is the frequency of interest,
- \( L \) is the inductance of the loop from Eq. 42-4.

An example of the calculations required to determine the impedance of a one turn 20 ft × 20 ft loop of AWG #20 wire at 1 kHz is

\[ L = \frac{(10 \text{ ft} \times 12 \text{ ft}) \times 1^2}{13.5} \log \left[ \frac{2.8(10 \text{ ft} \times 12 \text{ inches})}{0.03196} \right] \]

\[ = 143 \, \Omega \]

If this is connected to a 1:4 autotransformer, the amplifier will see 4.84 \( \Omega \).

Throughout this design procedure there is a certain amount of approximation involved; for instance, Eq. 42-4 applies to round loops. Error is introduced in calculating the inductance of a square or rectangular loop, however, this error is not great enough to seriously affect the results.

42.2.2.3 Electronic System

The power amplifier is selected that can supply the required current to the loop. The power required is determined with the basic equation

\[ P = I^2 Z \]  
\[ (42-6) \]

The adjustment of the output current is determined by the equation

\[ I = \frac{E}{Z} \]  
\[ (42-7) \]

An autotransformer or other suitable impedance matching device is used to match the amplifier to the loop. In the absence of an impedance meter, the loop dc resistance may be used for matching to the amplifier because at the minimum impedance point (low frequencies), the impedance is largely resistive.

A typical loop system diagram is shown in Fig. 42-8. In very large halls, a delay unit may be required in the more distant loops in order to avoid excessive time delays between the loop signal and the acoustic signal. Equalization is desirable to compensate for any frequency response irregularities. The equalizer is adjusted to provide a natural sound quality with a typical receiver and to insure that power is not transmitted outside the power bandwidth of the receiver.

A compressor is needed to insure that the system does not produce excessive distortion at high signal levels, either from clipping the amplifier or from overloading the hearing aid T-coil. The compressor should
be adjusted according to the nature of the principal program material. If the system is used mostly for music, a compression ratio of about 4:1 will result in minimal harm to the music. If speech is the principal program, compression ratios up to 20:1 can be used to improve both intelligibility and SNR.

42.2.2.4 Installation

If the loop is installed in conduit, it must be nonmetallic conduit such as PVC and should be placed so that there is little (or no) steel between the loop and the listener. Often the conduit is run in the top of a concrete slab or below a wood-framed floor; but it can also be run in walls or even the ceiling of a room. When installing a loop in an existing room, it is often easiest to run the loop wire under the carpet, using conduit only for the run to the amplifier.

42.2.3 FM Broadcast

FM broadcast systems have replaced many magnetic loops in classrooms where hearing-impaired children are taught because the FM signal is normally free from noise and provides a more uniform and reliable signal. Several channels are available so systems can be used in adjacent rooms. The sound quality is excellent. The useful receiving range will vary from 30–90 m (100–300 ft) depending on the amount of steel in the building. Transmitters are available for operation from the powerline for permanent installations or by battery for portable applications.

The Federal Communications Commission (FCC) has set aside a band of frequencies, 72.025–75.975 MHz, for FM broadcasting to the hearing impaired under FCC Rules Part 15. These frequencies cannot be used for any other purpose, such as language translation systems or communications applications. No license is required, although the manufacturer of the transmitter is required to have FCC approval of the transmitter design. The FCC restricts radiation to a maximum field strength of 8000 μV/m at 30 m. The FCC rules require a special antenna connector on the hearing assistance transmitters to prevent the use of illegal gain antennas that could result in a higher transmitted field strength than dictated by the FCC. The system requires no special knowledge to install; sufficient instructions are provided by the manufacturers.

The FCC has opened the 216–217 MHz band for assistive listening devices. This band falls under the low power radio services (LPRS) of the FCC, which limits the power output to 100 mW. While the 72 MHz band could transmit 500–1500 ft, the 216 MHz band can transmit 1000–3000 ft.

The systems can be either wide-band or narrow-band. Wide-band systems have the following characteristics:

- High fidelity for all applications.
- Low cost.
- Good rejection of unwanted or external radio signals.
- Limited to six simultaneous channels.

Narrow-band systems have:

![Figure 42-8. Induction loop system block diagram.](image-url)
• High immunity to unwanted or external radio signals.
• More than ten simultaneous channels.
• Good fidelity for voice applications.

FM broadcast is much like wireless microphones; more information can be found in Chapter 16.

An FM assistive listening system by Listen Technologies LS-04 Installed System includes programmable receivers, and a charging case and rechargeable batteries, Fig. 42-9. The LR-500 receiver can be programmed to receive only the channels available at the venue. This system helps public venues to meet Americans with Disabilities Act (ADA) guidelines. It is easy to add receivers and a wireless speaker/receiver.

The system has an SNR of 80 dB and is available for 72 MHz, 216 MHz, or 863 MHz band. The system includes one LT-800 stationary transmitter, an antenna kit, rack mount kit, and four LR-500 programmable display receivers with ear speakers.

The Personal System by Listen Technologies includes a portable transmitter and receiver in a soft-sided carrying case. The Personal System’s LT-700 portable transmitter, lapel mic, LR-400 display receiver, and ear speaker all fit in a soft case so they can be taken to school, house of worship, or theater. The listener gives the transmitter with its microphone to the presenter and the listener uses the receiver with an LA-166 neckloop or LA-164 earphone. The neckloop generates a magnetic field that is picked up by hearing aids that are equipped with a T-coil, Fig. 42-10.

The Sennheiser Mikroport 2015 is suited for classroom use and allows a hearing impaired student to have an improved learning experience via wireless audio connection to the teacher. The system includes a wireless transmitter with a lavalier microphone worn by the teacher and a body worn wireless receiver for the student. Direct audio input cables are available for use with cochlear implants and hearing aids and induction neck loops for use with T-coil hearing aids. The systems can also be used with standard headphones or ear buds. Multiple receivers can be used with a single transmitter and, because there are hundreds of discrete frequencies available, systems can be used in adjoining classrooms without crosstalk or interference, Fig. 42-11.

42.2.4 AM Broadcast

AM broadcast systems are largely unregulated by the FCC in the United States. The International Standard IEC118 Parts 1 and 4 define the performance, field strength, frequency response, and spurious levels for induction loop and hearing aids. The European Standard EN 60118 is also applicable in Europe. The basic rules (from FCC Bulletin OEC 12 dated July 1977) are:

• The system must not cause any interference to an existing licensed service.
• The operating frequency must be in the AM broadcast band or below (10 Hz–490 kHz and 510–1600 kHz).
• An open-wire antenna may be used in the 510–1600 kHz band providing it does not exceed 10 ft in length and providing the transmitter is restricted to an input power of 100 mW. Any type of antenna and transmitter power may be used provided the field strength does not exceed:
  • \((2400/F) \mu V/m\) at 300 m in the 10–490 kHz band.
  • \((24,000/F) \mu V/m\) at 30 m in the 510–1600 kHz band

  where \(F\) is the carrier frequency in kHz.
Carrier current system radiation limits are set differently. The radiation from the electrical system must not exceed $15 \mu V/m$ at a distance of $157,000/F$ ft, where $F$ is the frequency in kHz.

An examination of these radiation restrictions indicates that the lowest operating frequency results in the greatest coverage area. AM systems typically operate on carrier frequencies below 700 kHz. The sound quality and noise level of an AM broadcast signal are better than from a magnetic induction loop but inferior to an FM system. In general, if a pocket AM radio receives a local station well in the space, the low-power broadcasting system will work as well. Systems operating in the commercial broadcasting band (540–1600 kHz) may be picked up on any AM receiver. Systems operating below the standard broadcast band are available with fixed-frequency, nontunable receivers.

Open-wire antenna systems, with their restricted power and antenna length, usually achieve coverage ranging from 15–45 m (50–150 ft) depending on the amount of steel in the building. Fixed-frequency, below-the-broadcast-band systems usually employ an open-wire antenna. These systems are used by many churches.

Lossy coaxial cable systems employ a special type of coaxial cable that has a very loose or open shield, allowing a little radiation to occur all along the cable. The usable reception range is 15–23 m (50–75 ft) from the cable. The length of the cable may be quite long. The lossy coaxial technique is found in drive-in cinemas, stadiums, and arenas and can be used for broadcasting flight arrival and departure information along the highway approaches to airports.

The most common type of AM system is carrier current. In this system the output of the transmitter is capacitive coupled into the main power distribution wiring of the building. The radio signal travels throughout the building on the electrical wiring. This system is widely used on college campuses for limited-coverage, student-operated radio stations. Carrier current is an inexpensive way to provide program monitoring throughout a building.

The costs of the low-frequency, open-wire transmitter and fixed-frequency receivers are about the same as FM systems. The lossy coaxial and carrier-current systems may cost more, depending on the power required and the length of the coaxial cable. Any of these systems can be installed easily by following the instructions from the manufacturer. Both the lossy coaxial and carrier-current systems should be planned through consultation with the manufacturer of the transmitter.

### 42.2.5 Infrared

Infrared light can be used to broadcast a very high-quality signal. Presently available systems can broadcast up to twelve different programs on the same emitter, making infrared very useful for large-scale language translation systems. Infrared systems are also used in museums and for lecturing and teaching on auscultation, the listening of heart beats. Systems are also produced for home listening, for both stereo and for video (TV). It is the only system for the hearing impaired that can transmit in stereo. Also unlike the other systems, infrared broadcasts are completely contained within the room because infrared behaves like visible light; it cannot go through a wall; even a heavy cloth is an opaque barrier. This control of the broadcast range is a significant factor where confidentiality is

---

**Figure 42-11.** Personal system including FM transmitter, receiver, and battery charger. Courtesy Sennheiser Electronic Corporation.
important, as in corporate meeting rooms. For this reason and because of its outstanding sound quality, infrared is the system of choice for professional theaters and concert halls.

42.2.5.1 Components of an Infrared System

The basic components of an infrared system are:

- The control transmitter (which is connected to the audio source)
- Slave emitters, daisy-chained together (if needed).
- The receivers.

42.2.5.2 Categories

Any installation generally falls into four categories:

1. Personal listening systems (PLS) for living rooms, bedrooms, offices, etc.
2. Medium area systems (MAS) for lounges, meeting rooms, courtrooms, classrooms, small theater, churches, etc.
3. Large area systems (LAS) for auditoriums, large theaters, churches, arenas, etc.
4. Large area multichannel Systems (up to 32 channels) for simultaneous interpretation and other applications.

42.2.5.3 Coverage

Transmitter and emitter panels with present state-of-the-art design and components allow over 70 ft² of coverage per IR light emitting diode in single channel IR systems. The shape of the polar pattern of a panel is nearly identical to the pattern of a single diode. The half-power angle of luminosity for the presently used LEDs is approximately ±25 degrees. More LEDs increase the IR intensity, and the area of coverage multiplies by the number of diodes in the panel. The radiation pattern can be considered the same for horizontal and vertical orientations, and is scarcely influenced by the arrangement of diodes or the housing of the array.

Since there is a physical limit to the light output power of any LED, the total output has to be shared between channels in a multichannel system and the available coverage area per radiator has to be divided by the number of channels in the system. Conversely, for the same required coverage, the number of radiators should be multiplied by the number of channels in the system, or twice the amount of emitters in a stereo system as would be required in a single channel installation in the same venue.

Reflection and scatter off walls, ceilings, floors and furnishings broaden the coverage and make it largely nondirectional. Infrared light behaves a lot like visible light as it reflects best off bright and smooth surfaces like white walls, and is absorbed by dark and rough materials like black velvet curtains.

Emitters should be placed in a manner to provide even illumination throughout the room. The are usually mounted 10–40 ft above the floor and pointed down toward the audience. When emitters are placed on both sides of the stage, they should be cross-fired into the audience. Any number of receivers can be used in the system as they will not effect the signal source.

LEDs have degradation of light output over time, however, by using good electronic circuit design, a projected continuous operating life under standard conditions of more than 100,000 h, before the light output diminishes to 70% of its original value, can be obtained.

42.2.5.4 Ambient Light

Infrared systems work in virtually any environment except for direct sunlight. Systems can even be installed in shaded outdoor areas. Rooms with very high ambient light levels or poorly filtered fluorescent ballasts may require additional emitters for a sufficient SNR.

42.2.5.5 The infrared Link

Infrared systems can be either narrow band or wide band, depending on your requirements. Table 42-2 gives the technical specifications for infrared systems.

The infrared link uses a specially doped gallium arsenide light emitting diode (LED) to transmit the signal. Each diode emits about 10 mW total radiant power, requiring up to 143 LEDs in each array to produce adequate power. The wavelength of the emitted light is 930 nm and is neither monochromatic nor coherent, so any number of diodes can be used together without interference between them. The useful coverage pattern of the emitter varies with distance and the number of channels being transmitted, Fig. 42-12. The number of emitters required depends upon the size and shape of the area to be covered and the number of channels in use. Emitters are usually employed in pairs, located at each front side of the audience and cross-fired across the seating area so that each person receives an infrared beam from each side. This cross-firing helps to eliminate shadowing from other people in the audience.
The receiving end of the infrared link is a silicon photo diode that is reversed biased and produces current when struck by photons. The light gathering area is small, 7 mm², but is effectively increased by mounting it in a collecting lens, Fig. 42-13.

The silicon PIN receiving diode has a maximum sensitivity at a wavelength of 850 nm. Fig. 42-14 shows the spectral sensitivity of the eye, IR LED transmitting diode, IR filter, and receiving diode.

Infrared light behaves much like visible light; it reflects off of light-colored walls, ceilings, and other surfaces so a receiver can “see” the signal even without direct line-of-sight to the emitter. Also, the receiver’s ultrawide-angle fisheye lens captures direct or reflected signals from almost any direction.

There is a unique limitation to the use of infrared: it cannot be used in bright daylight. The infrared light occurring as a natural part of daylight will override the lower power-modulated light from the system. The system can also receive interference from very high-level incandescent lamps. Partially dimmed incandescent lamps can also be a problem in some situations because the reduced voltage to the lamps causes a shift toward red that greatly increases the infrared output of the lamp. This increase in infrared interference can, on rare occasions, be a problem where audience down lights are left at a dimmed setting and the infrared beam from the system is weak. Deep under a balcony is a likely trouble spot. When this problem occurs, it is necessary to dim the lights more or add more emitters to the infrared system to cover under the balcony.

An infrared system comprises three sections: the transmitter, the emitter (sometimes both combined in one unit), and the receiver. The transmitter imparts the

audio signal onto a subcarrier signal which the emitter converts into infrared light. The receiver decodes the infrared signal to retrieve the original audio.

To achieve a usable radiated power level, the IR LEDs are used in multiple arrays. Their light output is amplitude-modulated by one or more frequency-modulated subcarriers (typically 95 kHz for single-channel wideband systems; 95 kHz and 250 kHz for two-channel systems). Each channel’s audio signal frequency-modulates its particular subcarrier, Fig. 42-15.

Two transmission modes are available: wideband, for one or two channels of high-fidelity audio; or narrowband, for up to twelve channels with a 70–7000 Hz response suitable for communications, Fig. 42-16.

Since the transmission medium is a modulated carrier of harmless invisible light, Fig. 42-17, instead of radio or audio signals, it is immune to outside interference and also causes none itself. No operator licensing is required for use of infrared systems.

Manufacturers provide detailed instructions for planning and installing the system. Typical installations are shown in Fig. 42-18. The rear emitters must cover both under the balcony plus the balcony. For this reason, separate emitters may be required to cover both areas. The advantages of infrared systems are fully realized in applications where different audio programs are required in adjacent rooms, such as a multicinema complex. Each room can be equipped with the same system without interference among them. No frequency coordination is required as with radio frequency systems. The same receiver can be used in any theater.

A useful tool in aiming the emitters is a low-cost, black-and-white television camera and monitor. Most monochrome television cameras have useful sensitivity in the infrared region. With the room lights off, observe on the television monitor the part of the room illuminated by the infrared beam. The well-illuminated area will be the area of good reception. A corollary to this procedure is that the infrared television viewing system can be used to view a darkened stage—for instance, for coordination of rigging and prop moves in a fast, complicated change in the dark.

42.3 Receivers

Receivers are required with all systems, though fewer are needed with an induction loop because many patrons will have aids equipped with T-coils. Most manufacturers of systems for the hearing impaired offer several types of earphones with their receivers. Typically these include a single earpiece, a stethoscope-type dual earpiece, Fig. 42-19, and an induction loop for use
with the patron’s T-coil. Most users report a strong preference for the dual earpiece instruments and also report a strong dislike for an over-the-head-type headphone because they are uncomfortable for long periods of use and destructive to hair styles. Two types of induction loops are available. One is a small coil that hooks over the ear close by the hearing aid; this type is often hard for elderly people to use properly. The more popular loop is a lanyard type that hangs around the neck and may be used to support the receiver.

Many theaters and churches that have installed a system for the hearing impaired have found normal-hearing patrons using the system to enhance their listening comfort, which is especially true in larger houses with seats in areas of poor natural acoustics. These normal-hearing patrons universally prefer the dual earpiece both because it sounds more natural and because a single earpiece leaves one ear open to receive the live sound from the stage with a signal-delay annoyance. Depending upon the distance from the stage, this
delay can be very distracting to those with less than profound hearing impairments.

Battery replacement and earpiece sanitizing are the principal maintenance problems with all systems for the assisted listening devices. Batteries may last up to one year, although that seems an uncommonly long life if the receivers are being used often. The infrared receivers have rechargeable batteries, which should be recharged after each use. Earpieces are most commonly sanitized by replacing the plastic ear tips or by using replaceable foam balls.

Most theaters and concert halls provide receivers to their patrons for no charge or for a small fee to cover the cost of handling, batteries, and sanitizing. Some organizations have been successful in selling receivers to regular patrons, especially in communities where several theaters and churches use the same technology.

Intercoms, short for intercommunication systems, are often more sophisticated than sound reinforcement systems because sound systems are unidirectional while intercoms are bidirectional. Sophistication varies from the simple home intercom to hotel and apartment intercoms, to hospital nurse call and emergency systems, to party line systems, to the multiprocessor controlled, multimemory, analog and digital intercommunication systems.

### 43.1 General Purpose Intercoms

Intercom systems fall into three categories: point-to-point, party line, and matrix, Fig. 43-1. The point-to-point or dedicated line is a private line between two stations. Normally, no other stations can hear your conversation.

The party line, conference line, or distributed line is a shared line where a number of people, usually sharing a common task, are all talking to each other. This is like being at a conference table where everyone can talk and listen to one another at the same time and there is no privacy capability. By having multiple circuits and multiple wires, this system can communicate to different parties at the same time. Most often this type is found in broadcast intercoms.

Most major intercom manufacturing companies are offering digital matrix systems. These systems are multi-processor controlled, multimemory, and have analog and digital audio and can combine the point-to-point and party line communications together. All have advantages and disadvantages and they can be either hard-wired or wireless or a combination of the two.

Intercom systems can be simple, a two unit system with only a call button and a microphone/loudspeaker combination in each unit, to a complicated multichannel multistation system with a separate microphone and loudspeaker, display window, keypad, TV entrance monitor, auxiliary inputs, can be programmable, plus have a multitude of special features.

#### 43.1.1 Point-to-Point Systems

Point-to-point systems are the simplest type of intercom and are mostly used in residential and office applications, schools, apartments, and nurse call and emergency call systems. With point-to-point, a caller or originator makes contact with the desired receiver or receivers and communicates only with them, Fig. 43-1. All other stations are isolated so they cannot be part of the one- or two-way conversation. This is like the telephone system, you dial a party or parties through a conference call, and the conversation can only be heard by those parties that were called up even though the telephone system has hundreds of thousands of other phones on the system.

Systems are normally made up of master stations, slave stations, door monitoring and opening stations, and input devices such as AM/FM receivers.

These systems have a variety of features and are used for intercommunications between rooms or desks, intercommunications between an indoor station and an outside door including door release, and provide some form of playback signal at all or selected stations in the system. The system can be one master to one or more slaves, all master, or a combination of the two. Masters have the ability to originate calls to any or all stations while slaves can only call the master station they are connected to, Fig. 43-2. Stations can be in-the-wall units or self-contained desktop units, wired or wireless. Normally hardwired systems are the best for point-to-point systems as they are less expensive and less likely to have interference. The disadvantage is they are more difficult to move or reposition.

The Bogen Model PI35A, Fig. 43-3 is a twenty five-station intercom. It provides facilities with two-way communication, emergency paging, time tones, and
background music or other audio program material to speaker-equipped locations. The Bogen P135A is designed to meet highpower paging and intercom requirements with features suitable for applications with mixed noise environments (construction, retail stores, small factories, parking garages, etc.). A 20 W intercom amplifier features a voice-shaped frequency response for intelligibility. A 35 W program amplifier is used for program material and/or emergency announcements.

Figure 43-2. Master/slave, master/master, and intermixed intercoms.

Program material from microphones, a CD player, or other background music source can be used. Distribution is accomplished by simple push-button selection. Emergency announcements take precedence over program distribution and are accomplished with a single push-button selection. A time signal can also be sent to all stations. Optional paging facilities permit emergency all-call paging from a remote telephone, or interphone or microphone. Telephone paging captures system priority and overrides all system functions except the emergency page feature.

A room selector panel is provided to select intercom and program functions for each station. Calls from stations are initiated through call-in switches in the various rooms and are announced at the control center by light and tone annunciation. The system provides a 25 V balanced output and operates from a 120 Vac, 60 Hz source. The system consists of a master control panel and a twenty five-station room selector pane. A number of options are available including room call-in switches, call-in adapter modules for existing older call-in switches, two-wire call-in adapters, and various styles of transformer-coupled loudspeakers.

43.1.2 Matrix Systems

Not too many years ago, all intercoms used a mechanical switching matrix to call and to route the voice signal. Systems were simple, wires came from a central system and went out to the individual masters and submasters. Switches were multipole and carried signal and voice. Often the voice line was shielded to eliminate hum and stray noise pickup, however, on inexpensive systems unshielded lines were used and the frequency response of the receiver was limited to 200 Hz–4 kHz to eliminate noise and hum.

While these systems are still used today, many have been replaced with digital matrixes and electronic switching. These systems use low voltage/low power
and because the signal is digital, seldom require shielded lines.

Matrix systems can control upwards of 256 station units and can have as many as 7170 stations by tying more than one exchange together.

Because they are digital, it is easy to set them up with quick dial single or double digit dialing of often used numbers, connect them with outside C/O or PBX lines, and record a customized outgoing message for callers and record their response, retrievable at any master. Because they are telephone system compatible, they are capable of supporting a DTMF generating, single line telephone instrument (telephone, autodialer, fax machine, etc.). Interconnections are through twisted pairs of copper wire or through fiber-optic cable.

Many of these systems are programmed with a computer. Through simple programming, only selected stations can be given access to special functions—i.e., paging, telephone calls, priority calls, external sources, etc. Compression circuits and/or automatic leveling circuits can be adjusted for individual units as well as their overall level.

43.1.3 Apartment Security/Intercom Systems

Apartment systems are usually point-to-point and are used for the visitor to contact the apartment owner for access into the building and then into the apartment. This system consists of a master panel outside the main access door to the building and slaves in each apartment, Fig. 43-4.

![Figure 43-4. Audio/video entry security system. Courtesy Aiphone Communications.](image)

The outside master panel must be waterproof and vandal proof so the outside unit panels and buttons must be made of strong material such as aluminum, stainless steel, or LEXAN®. The microphone/loudspeaker grill must be indestructible and shed water, preferably a continuous part of the panel and the loudspeaker must be waterproof. The panel must be fastened to the wall with vandal-free mounting hardware. The outside master panel consists of a microphone/loudspeaker and a means of contacting the person of choice. This can be accomplished by a series of push buttons that connect the visitor to the desired apartment or it may be a twelve button telephone panel that connects the caller to the suite through digital circuitry.

A power supply and amplifier is mounted inside where it is out of the elements. Only one amplifier and power supply is normally used for a system because only one conversation goes on at the same time. The door opener usually operates on 3–6 Vdc or 8–16 Vac.

The apartment loudspeaker station consists of a microphone/loudspeaker unit, a talk button, a listen button, and a door release button.

The more sophisticated security systems include a video monitor for improved safety. The outside door panel includes a camera and the indoor units include a 4 inch flat screen monitor. A pan and tilt capability improves security as it can scan a large area. Because the camera is behind a glass, the visitor cannot see where it is aimed so the visitor cannot hide from it. With today’s technology, wide angle cameras are possible, eliminating the need for the more expensive and complicated pan and tilt. The cameras require very good low light level operation as most access is in the evening or at night. One lux sensitivity is normal. Most systems do not require coaxial cable between the cameras and the monitors.

Self-contained video door answering systems are rapidly becoming today’s replacement for the common doorbell. They are a simple-to-install answer to the growing need for entry security in both small businesses and homes. Some use the same two wires as a doorbell, often using existing wiring in older buildings, and simplifying installation in new construction.

An example is a system where one pair carries an FM modulated signal with both audio and video, and a second pair operates the door releases shown in Fig. 43-4. In this system the door unit incorporates a high resolution infrared CCD (charge-coupled device) camera with 250,000 pixels, providing a clear, sharp picture down to one lux of light.

By using a wide angle lens, an overall viewing area of 39 inches × 27 inches at 20 inches away can be attained, Fig. 43-5. For more coverage, a PanTilt door station can be used, Fig. 43-5. This allows for a coverage of 72 inches × 36 inches at 20 inches. Like any transmission system, cabling is important. The system was designed to operate with two wires such as typical bell wire. Coaxial cable or two separate wires or multicable will affect picture quality. If the cable has more than one pair, the other pairs should be terminated...
at each end with a 120 Ω resistor. This keeps a proper impedance of the line.

Any door entry system camera should be mounted so the unit is not exposed to environmental extremes. Sudden temperature drops, for instance, can cause the camera to fog up and raindrops can distort the picture. Lighting should be on the front of the person. Strong backlight—i.e., sunlight or street lights—can cause a silhouette image on the monitor, and fluorescent lights can cause flickering. Taking these into account will give a good picture under most conditions.

It is important that the door release button has normally open contacts to activate an optional electric door strike. The normally open contact assures that the door will not open during a power failure.

### 43.1.4 Residential Intercom Systems

Residential intercom systems are used to talk between rooms, or between a master unit and all other rooms, as a door security system and for programming external sources such as AM/FM or CDs to any or all rooms. Because of the limitations of intercom systems, the music is usually not in stereo and not of the quality of a dedicated stereo system, but is quite adequate for background music. They also have the advantage that the same source is heard as a person walks between rooms. Normally residential intercoms are wall mounted, incorporate hands-free answering and include a privacy switch. The systems can be master/slave, master/master, or all master.

### 43.1.5 Commercial Security Systems

A building security system assists security personnel in the protection of the lives and property of all tenants, employees, and visitors. People in parking areas, ramps, tunnels, stairwells, and elevators should have access to conveniently located, easily operated hands-free emergency call-in stations.

#### 43.1.5.1 Zone Paging

High-rise buildings and multibuilding complexes have special needs for zoned public address announcements. Buildings with controlled access need audio voice confirmation and integration with CCTV cameras. Elevators require intercommunication to security and the lobby and communication to the elevator machine room for maintenance, Fig. 43-6.

Variations of this type of intercom can be used for campus security where there are multiple buildings, parking lots, dorms, and walkways.

#### 43.1.5.2 Security Audio Monitoring

Unfortunately, all too often crisis situations do develop in the shadows of darkened areas or dimly lit passageways. These are the areas where criminals tend to stalk. These are also the places where a building’s highly volatile power transformers, generators, and steam lines are neatly tucked away. Security and maintenance personnel can’t be everywhere. Even with the assistance of video surveillance there are limits to the number of cameras used and manpower to monitor them. Even in the best of situations video cameras can’t see around corners, through closed doors, or behind parked cars or trucks.

To eliminate problems with video only monitoring, security system manufacturers have developed listening devices and loud-noise triggering alarms. Although these products seem to be moving security systems in the right direction, they still have substantial limitations.

Listening devices are a great idea because they allow security personnel to interpret and discriminate the sounds they hear. Unfortunately, like video cameras, they must continually be monitored to be truly effective. There is also the question of open microphones being construed as invading individual privacy.

Loud-noise triggering alarms have the problem of discerning sounds, for instance, screams from laughter, or the loud noise of a car engine starting up. Without the ability to discern specific sounds and discard normal background sounds, false alarms would render the system useless.
Today there are smart security devices that incorporate the best features of both a listening device and a noise trigger without many of the drawbacks.

One effective method is a sound sensing device that continually adjusts itself to background noise levels, while detecting and discerning the unique sound characteristics of specific sound patterns usually associated with crisis and emergency situations. When the system picks up one of the crisis sound patterns it fires and alerts security personnel of a probable emergency situation in a particular area. The system can also automatically turn on video cameras, sound alarms, or activate two-way intercoms, so that security personnel can instantaneously communicate with individuals involved at the scene.

Because this type of system continually adjusted itself to the continuous changes in levels and frequency response of background sounds, and has the ability to insert a time gate to further assist in doing away with false alarms, it is able to isolate the sound of a scream or the smashing of a pane of glass, Fig. 43-7.

This type of monitoring is useful in security applications including correctional facilities and mass transit subway authorities, parking lots, schools, large warehouses, and empty office building hallways after regular business hours.

Figure 43-6. Basic building communication system. Courtesy Ring Communications, Inc.
43.1.5.3 Emergency Crisis Communications

Methods of communications change, methods of transmission change, and methods of installation change. Manufacturers continue to upgrade their equipment to handle these changes.

At one time the basic accepted method of signal transmission was via copper conductors only, now there are multiple methods to accomplish this.

Voice communications is often overlooked in some areas, but an alert that is only a bell or horn or chime sounding only alerts people that there is a problem, it does not tell them what the problem is, where it is, or what response they should take to protect themselves. By adding voice communications to panic alarms, fire alarms, or crash alarms, the general public can be advised of what the nature of the alarm is, where it is, and what to do to avoid it.

Often huge geographical areas must be covered. To do this with copper alone is almost impossible. The Ring Master Intercommunications Crisis Alert System has the ability to tie equipment together to operate as one complete system, providing for line supervision over multiple methods of transmission, simultaneously solving any such problem.

Fig. 43-8 shows such a system that is in use today to cover the many and varied needs of an airport site.

The system provides communications for all aspects of airport communications requirements over one integrated supervised system. The system includes:

- Air traffic control.
- Security.
- Baggage handling.
- Staff location.
- Access to general over-head paging.
- De-icing.
- Flight operations and planning.
- ADA elevator communications.
- Door access and control.
- Emergency call boxes for the parking facilities.

When distances between buildings and operational sites are long, copper is not a viable solution. Fiber is better utilized to tie geographically distant areas together. In other areas the newest method of VOIP, over radio links, can be utilized to provide communications, for instance, to the people mover train system.

With this type of system, any station in the system, no matter where its geographical location on the airport site, can be programmed remotely, to call or be called by any other station in the system or to access any of the multiple functions and features of the communications system at any time.

When these connection capabilities are added to the commercial security intercom system there are virtually no restriction to fulfill the requirements for safe, secure communications.

43.1.6 Commercial/Industrial Systems

Commercial/industrial intercom systems are used in airports, car dealers, dormitories, factories, hospitals, nursing homes, department stores, and schools. Most of these systems are master/slave systems or subsystems.

The health care and hospital facilities systems must be designed for emergency hands-free operation from operating rooms, trauma rooms, delivery rooms, etc. The systems must also be capable of sterilization after each use. This can be accomplished with a Mylar covered face plate that is easy to sterilize because of lack of crevices, etc. The system can include a paging system for doctor, nurse, or security call and for calling patient’s in waiting rooms.

Operations of general commercial/industrial systems are very much like the door access or residential system but include many of the following special features:

**Absence Registration.** A unit can be programmed to display the station is unattended.

**All Call.** All call allows a master station to connect to every other station for an all-call message.

**Call Back.** Call back is initiated by the caller when the receiving line is busy. The caller can put the system on automatic call back which notifies him as soon as the
intended receiver is free so he can reinstate the call or the system can automatically recall the receiver.

**Call Forwarding.** Call forwarding allows all calls directed to a station to be forwarded to another station.

**Call Reply.** When the called person is absent, the caller may dial a call-back signal which indicates that he has been called.

**Call Transfer.** Particularly useful for transferring a call to or from a secretary.

**Camp On.** Camp-on is a feature which allows the caller to camp-on to the called person when that person is in communication with someone else. Once the called person hangs up, the caller is automatically connected to him. Normally, camp-on only holds on for 10–20 s before dropping out, or may remain in service until the next call is initiated.

**Central Answering Service.** Units can be set up to go through a central answering person with automatic queuing of incoming calls.

**Conference.** Conference calls can be held with more than one party. Normally three to four parties is the maximum limit, however some systems may be expanded to a 30 party conference.

**Display Features.** Today’s intercoms usually use an LCD type display system which gives the called or calling station number, in addition may display a series of preprogrammed messages, whether or not the called station is in privacy mode and time/date.

**Group Callback.** Many systems are setup so that various groups can be connected with one button so a person can call an entire group at one time.

**Hands Free.** In this condition, conversations are hands free from anywhere in the room as long as it is a duplex system. This can be changed to confidential at any time by a person picking up the handset and operating as a telephone system.

**Hurry Up.** If the conversation channel is busy, and the caller needs to make an emergency or an important call,
she can transmit a special signal on the conversation channel which tells them there is an important message to be received.

**Last Number Redial.** Last number redial, as on telephone systems, allows the caller to redial his last called number again and again and again.

**Microphone Cutout.** Microphone cutout is used to disconnect the microphone during a conversation so that the receiver cannot hear communications between the talker and another person in the same room.

**Paging.** Master stations can page to other master stations, substations, and to remote loudspeakers through an external amplifier.

**PBX Station Intercommunications.** Many intercoms can be connected to the PBX or an outside C/O line for communications to the outside world.

**Pocket Page Access.** Any master station can place calls to the desired pocket pager receiver, up to 10,000 units.

**Priority.** If a priority station dials a number while the conversation channel is busy, she has the option to override the busy link and be connected directly through to the called party. This is normally used for emergency systems.

**Privacy.** Privacy is initiated by a person so that a caller, when calling that person, hears a signal which tells him the receiving person does not want to be disturbed.

**Program Distribution Channels.** Music or special messages can be setup to be used as background music.

**Scan Monitoring.** Scan monitoring allows a control station to arbitrarily scan a group of slaves or substations for auditory monitoring. Scanning can be performed either manually or automatically.

**Time/Date.** Some intercoms have the capability of displaying the time and the date.

**Nurse Call Systems.** Nurse call systems must be fast, reliable, and of most all easy to use. Patients must not have to figure out how to use a system to call for help. The system must not interfere with the complicated patient monitoring systems and must not produce ground loops between it and other equipment.

The simplest and probably best method for a patient to call a nurse is with a pull chain. This chain, actually cord, electrically isolates the system from the patient and only requires a gentle pull by the patient to operate. The cord can be draped on the rail of the bed for easy access by the patient. A monitoring system is located at the nurse’s station with lights corresponding to room numbers or it could be a CRT with various messages. An indicator light outside the patient’s room is also energized, allowing a nurse in the hallway to answer a call without going back to the nurse’s station. The call remains energized until the nurse turns it off from the patient’s station. Because the nurse call systems only tell the nurse which room is calling, dual-bed rooms have one call station with two call cords.

Nurse call systems can also include master/slave two-way communications, eliminating a nurse’s extra steps. It also allows a nurse station to monitor a room. Some areas require an emergency button. This could be a pull chain, a large red mushroom button, or in the case of a psychiatric station, it could be key operated.

**Equipment Locator.** An equipment tracer system such as the Rauland Borg Tracer system saves hospitals time, money, and frustration by locating their key people and equipment quickly and quietly.

Using a Responder III Plus Nurse Console, staff can instantly locate and communicate with key staff or locate equipment. Equipment and staff locations can be displayed in real time on networked PCs throughout the facility.

Tracer works in the following manner. Three elements comprise the system: tracer tags, in-ceiling network, and software elements. The Windows-based software gives a graphic, easy-to-understand location depiction or a synthetic voice can give location over any telephone.

Special light-weight transmitter tags can be attached to a facility’s important equipment (IV pumps, wheelchairs, carts) and worn by key personnel. These tags continuously relay their position to room and hallway sensors, Fig. 43-9.

The tag is microprocessor based and emits an 880 nm infrared hemisphere of one of 30,000 unique ID digitally encoded packets for a broadcast range of about 20 ft.

Ceiling or wall-mounted sensors receive the packets and convert them to electrical signals. The packets are relayed to the collector box, which has star inputs for twenty four sensors.

The collector assembles the sensor packets into larger packets and prepares them to be sent to the concentrator.

Each sensor, or combination of sensors, is defined as a zone. Offices, hallways, or areas can be declared as zones.

Data from the network (tag, location) is combined with the time of day and written to binary history files, called *Logger*. The database and history files can be
Intercoms retrieved from the foundation of tracer software. The multitasking Microsoft Windows operating system is used, which creates an open system.

Three presentation methods are available. Tracer-LIST handles multiple floors and hundreds of tags. Features include a living directory presentation, fast alphabetic search, usual location and extension, current location, occupants currently in the room, and system condition heartbeat.

Tracer VR (voice response) uses a voice response card and allows users to dial into the system to audibly learn location. Tracer VR extends the tracer capability to before and after-hours callers, and personnel without workstations.

TracerMap is a living floor plan that gives a graphical location of Tags within an area.

### 43.1.7 Wireless Intercoms

When areas are constantly being reorganized, a wireless intercom may be useful. A wireless intercom may use RF for transmitting the signal or it may be transmitted through the 120 Vac lines. When the transmitting system is RF, two frequencies are required per unit, one for talking and one for listening unless the system operates like walkie talkies where simultaneous two-way communication is not possible. If each unit must have its own private communication, then each unit would require a different transmit and receive frequency or use a system of subaudio modulation to key the appropriate unit. The subaudio modulation system can have only one conversation at a time. The biggest drawbacks of wireless intercoms is their ability to pick up noise and stray signals and fewer bells and whistles are available. However, if the area is confined and relatively free from electrical noise, wireless intercoms can greatly reduce installation costs.

When the ac power lines are used to connect the audio between units, the frequency response must be limited to reduce noise and hum. If the two units are on different legs of the two phase 220/110 Vac transformer, communications may not be possible without some means to transfer the audio signal between the legs.

### 43.2 Broadcast Intercoms

The need for rapid, reliable, and flexible communications is required in broadcast intercoms. Fortunately, intercom equipment is capable of meeting almost any need that might arise.

Telephones are usually used for less than 20 minutes per call. Intercoms are often used for many hours at a time. The people involved in teleproduction work often can’t take a break or remove their headsets. If the system has limited frequency response, then the system’s filter effects create distortion. This unnatural sound can cause fatigue, which can be eliminated with a full-frequency intercom.

Broadcast intercoms can be point-to-point, party line, or matrix. The audio line can be balanced or unbalanced. Balanced line operation provides maximum protection from electromagnetic interference generated from sources such as fluorescent lights, patch panels, or light dimmers. The 24 Vdc phantom power is fed down the audio line with the minus voltage on the shield and the positive voltage bridged between the two shielded lines. The bridging is accomplished by connecting two resistors in series and across the balanced line and connecting the positive voltage to the junction between the resistors. It is important that the resistors be at least 1% tolerance or better. A balanced system can run as much as 5000 ft with standard two-conductor shielded microphone cable.

An unbalanced line, sometimes called a three-wire system, is easier to switch and operate special circuits as the audio and signal are on different lines, only using the ground (shield) as a common line. A second method provides two channels of unbalanced audio, one channel between each conductor and shield, and combining the dc operating power with one of the audio channels.
Many intercoms are engineered to receive phantom power from the 24 Vdc system power supply. Stationary or permanent user stations usually operate in a dry mode as they are supplied with power from a local power line. The term dry refers to an intercom channel that has audio but not the usual 24 Vdc phantom power on the channel. Dry operation has several advantages over wet operation as it is generally quieter, reduces the need and cost of large system power supplies, and takes up less master rack space. System configurations can include a mix of wet and dry channels, depending on the station equipment assigned to the particular channel. Generally, most wired belt-pack and loudspeaker stations require a wet channel and thus need a system power supply.

43.2.1 Broadcast Point-to-Point Systems

The point-to-point system consists of a centralized rack (or racks) of amplifiers and signal routing circuitry controlled from remote stations. The audio signal paths are analog and simplex or digital.

The system allows a station to route its voice or other signal to one or more other stations. The originating talker determines who hears the communication and the listener normally has no control over who is received at the individual stations. Normally, point-to-point systems require direct or home run cabling from each station to the central control.

Each station in a point-to-point analog system requires a minimum of one audio transmit pair, one receive pair, many control or station selection conductors, and a power pair or local power supply. It is essentially a switch-selected, multiple station, one-way paging system. A point-to-point digital system has the same functions plus many more and operates on a single pair of unshielded wires.

43.2.2 Broadcast Party Line System

In the party line system, each station is equipped with all of the required electronics for receiving and transmitting audio and for signal routing. Party line systems require minimal centralized rack equipment, which usually consists of the system power supplies and passive assignment switching in multichannel systems.

Party line systems allow groups of stations to communicate in real-time, full duplex fashion. In fact as it is a party line, all units on the line hear and are part of all conversations. Multichannel party line systems allow users access to several different channels, allowing them to determine which line they talk and listen to. Normally there are no private communications such as point-to-point systems provide.

Two-channel, dual-listen, with monaural output intercoms with programmable switching let the user listen to both channels simultaneously and select which channel to talk on. They include an individual volume control for each channel, microphone on/off control, a call signal button and indicators, and sidetone. These stations are ideal for ENG and EFP mobile production vans, production studio consoles, and TV facilities.

Straight two-channel units allows simultaneous listening and talking on two intercom channels. The headphone output operates in a split-feed stereo mode, feeding each channel into a separate ear of a double-muff headset with an individual volume control for each channel. The operator can talk or listen on either channel, combine them, or access them separately without tying both channels together. Often a stage announce output can be supplied with relay control for external paging. Microphone or line-level program inputs may be assigned to either or both channels. The systems capabilities can include a selectable program interrupt function, remote mic-kill function, dual-action, electronic momentary/latching talk buttons, and a no-fail power supply with automatic reset and short-circuit protection.

A typical two-channel party-line system by Clear-Com consists of a main station, which includes a power supply. Each channel is full duplex allowing everyone on the channel to choose to both listen and talk to everyone else. Although the min station provides two channels, single- and two-channel belt packs can be mixed within the same system. This reduces cost and allows one to control exactly who is assigned to what channel. All cabling is standard low capacitance shielded microphone audio wiring, Fig. 43-10. A party line belt pack is shown in Fig. 43-11.

Some multichannel systems have extensive programming capabilities, which allows individual stations to be customized by storing the button setups in nonvolatile memory. Many programmed setups can be stored, thus allowing quick and easy switching between setups for rehearsal and performance or shows and events. Individual button assignments can be stored in presets for instantaneous recall. When programming this equipment, messages prompt the operator through the programming sequence, simplifying station setup.

A four-channel, two-wire party line system is similar to the two-channel party line except with two additional channels. In Fig. 43-12, Channel A is for the floor crew, Channel B is lighting, Channel C serves audio with Channel D calling the talent dressing rooms and
box office. The producer and director have access to all four channels. The lighting director is limited to the floor and light crew. The audio engineer can access the floor crew and channel D audio. Note the majority of the belt packs is single channel. There is no reason for the lighting crew to talk to the dressing rooms, which keeps conversations specific to their assigned channels.

All cabling is standard low capacitance shielded microphone audio wiring.

### 43.2.3 Broadcast Matrix Systems

Matrix systems are a powerful and cost-effective communications tool. Expansion is easy and installation is inexpensive as only a single pair of wires is required for audio, signaling, and external inputs. System size ranges from $2 \times 2$ to over $784 \times 784$.

There are two basic methods of interconnection between matrix intercom stations and the central frame: analog audio and fully digital.

The two-wire party line matrix system is a very flexible multi-channel party line where numerous sources, or drops, are connected to an 8ft × 24ft assignment panel. The drops can be mixed. The example of Fig. 43-13 reflects twenty four drops across eight PL channels. The configuration permits the user to program any one of the twenty four locations to a specific PL channel. For example, one day you might need a camera position at stage left and tomorrow the lighting crew might use that location. You may also route wireless intercom, two-way radios, and fiber remote links to any
of the eight traditional party line channels. Fourteen pre-programmed configurations may be stored and recalled on the fly. All cabling is standard low capacitance shielded microphone audio wiring.

The standard analog wiring format provides wide audio bandwidth and easy connection over standard four-wire audio and data circuits. It allows station-to-matrix communication through repeaters and over satellite links, ISDN circuits, and fiber optic systems.

The fully digital format uses only a single pair of wires that carry data plus digitized audio, simplifying installation. Additionally, digital audio cannot be tapped by unauthorized persons, it offers total noise immunity from external sources. The wiring is easy, it permits standard punch-block connection techniques using existing unshielded multipair telco or CAT 5 wiring.

The digital matrix system differs from Party Line in several areas. In addition to party line conversations, one may also conduct private point-to-point conversations between the panels. Through intuitive programming, members of the groups may be changed at will. This system easily integrates telephones, two-way radios, line-level audio in/out, voice over IP, GPIs, and relays, which allows incoming and outgoing telephone calls to be routed to particular panels or groups. Matrix systems are well suited for dynamic broadcast environments where IBF audio feeds must change quickly. A wireless intercom is easily integrated and can be treated as another panel depending on the wireless version in use. The connections between the mainframe and control panels are standard nonshielded Cat 5 or 6 cables. A digital matrix system by Clear-Com is shown in Fig. 43-14.

Matrix systems use crosspoint and CPU circuitry. The mainframe serves as the central interconnection point for the control stations, interface modules, power supplies, the configuration computer, and external audio and control equipment. All signals, digital and analog, are processed in the mainframe and routed according to the current software configuration program.

The CPU operates the frames and control all of the system data communications. Crosspoint electronics contain microprocessors that communicate with the CPU and with the stations. The crosspoint circuitry supports individual ports that can connect to stations, interfaces, or to analog four-wire circuits and devices.

Interface circuitry couples the master system to external four-wire circuits providing the proper isola-
tion, impedance matching, and level sets between systems. Additionally, it supports external relay activation and call sense circuitry. Typical circuits include 4-wire telephone lines, camera intercoms, two-way radios and microwave links, four-wire intercoms, fiber optic lines, and satellite links. Other types of four-wire circuits include IFB systems, ISO systems, and program audio in/out.

Many matrix systems have the capability of linking to other matrix systems. This allows stations in one system to communicate with stations in other systems and anything that can be selected or controlled in one system can be selected and controlled from any other linked system. This allows independent systems in remote locations, even in different cities, to operate a single system.

The station-to-matrix wiring in matrix systems can operate in either a three-pair mode or a four-pair mode. Using the four-pair scheme, remote station operation is possible from any location that can provide a standard four-wire audio circuit plus a four-wire RS-422 data circuit back to the central matrix. This can include transmission links such as satellite and fiber optic circuits, T-1 channel banks, ISDN, and switched 56 terminal adapters.

Port input signals are usually routed through software controllable digital potentiometers. This enables remote control of input levels from a PC, or directly from the intercom control stations, allowing instant on the fly adjustment of audio signals that are too loud or too soft.

Because the audio is digital, noise pickup is nonexistent, frequency response is 100 Hz–15 kHz ±1 dB, distortion is less than 0.5%, and the SNR is greater than 60 dB.

### 43.2.4 Program Interrupt (IFB)

IFB is a television production trade acronym that stands for interrupted feed-back, interrupted fold-back, interrupted return-feed, and in some cases prompt-mute. IFB plays an important role in the behind-the-scenes activities that make a production, as it permits the director or
producer to talk to the talent during a voice-over commentary either on or off camera in a live or taped production. Sports broadcasts typically use many channels of IFB to communicate with announcers in various locations on the field and in booths. When recording live performances on stage or in a studio, musicians can hear direct queues from the conductor or producer as well as the individual music mix designated for them. For television broadcasting, IFB queues on-camera announcers and is used between on-scene reporters and the in-studio anchor and studio director. IFB is controlled by the talker or person in control while the listener has no control over IFB.

43.2.5 Wireless Broadcast Intercom System

There are two types of wireless intercom systems. The first type provides a one-way, listen-only feature for the remote stations. In this system, the intercom is wired to the master transmitter. All communications on the intercom line are relayed to all of the wireless receivers. A one-way intercom is typically used for people who need to know what is going on, but don’t need to talk back.

The second type of wireless intercom is a two-way system. In this configuration, the base unit and the field units can both talk and listen to each other in a full duplex mode. This requires two frequencies, a talk frequency and a listen frequency.

Wireless systems can stand alone, but when connected to a wired intercom system, the wireless link is virtually transparent to the user. The FCC has approved the 150–216 MHz band for broadcast use with over 1700 possible frequencies available. This band is relatively free from external radio and electrical interference. Transmitter output power is limited to 50 mW. Operating distances between units vary with the environment. If it is in open areas, it is possible to have good reception up to 2000 ft. However if the area includes walls, obstacles, and other radio transmitters, transmitting distances are more likely to be 150–300 ft. Battery life on belt packs should be over 20 h as these units are

Figure 43-14. Digital matrix system. Courtesy Clear-Com Communication Systems.
Intercoms

Intercoms are often used for extended periods. Long life is obtainable because the transmitters are only on when talking.

FM transmission has a characteristic that is called capture and is normally rated as capture ratio. It occurs when two or more transmitters are on the same frequency. The stronger of the two signals at the receiver captures the receiver, blanking out the other transmitters. If the transmitters are moving with respect to the receiver, the stronger transmitter would capture the receiver, so the communications could be bouncing between the various transmitters. For this reason all transmitters must be off when not in use and the new talker must monitor the channel before transmitting. If multiple transmitters and receivers are required, multiple frequencies are required.

43.2.6 Belt Packs

Belt packs are used in remote areas and when the person has to move around and/or the communications must not be heard by others such as during a theatrical performance, Fig. 43-15, or for football communications between spotters and coaches, Fig. 43-16. They may be wired or wireless and incorporate either single or dual headsets. Belt packs often utilize noiseless, digital electronic switching on audio circuits. A push-pull amplifier supplies high levels of audio in the headset and a microphone limiter compensates for user voice variance. The belt pack may also include a two position gain switch for normal and high-noise environments. The remote mic-kill function at the base station enables belt pack microphones to be shut off from another location to conveniently eliminate microphone pickup. This is done by sending a 20–24 kHz ultrasonic signal down the audio line, turning off the talk gate on each unit on the line. A visual call signal is provided by high-intensity LEDs on the belt pack to alert operators who have removed their headsets.

43.2.7 Telephone Interface

Broadcast intercoms are often connected to a telephone line. This is accomplished through a microprocessor-based telephone interface that provides communications between a wet dial-up phone line and an intercom system. The interface is ideal for the broadcast industry, and is specifically designed to connect a telephone line to ENG and EFP trucks, production studio consoles, and TV facilities. The device automatically answers incoming calls to the intercom system, and automatic forward-nulling circuitry adjusts internal hybrids on both sides of the line to achieve a null of up to 40 dB in less than 1/10 s. The devices also include automatic gain control to insure that the incoming telephone audio remains at a constant level. It is also capable of automatic dial-up IFB, enabling a field crew to directly access a preset IFB circuit to immediately communicate with the studio crew.

When the device is set up for automatic answering, an incoming call is automatically answered, and the ringing is indicated on the master station and can illuminate a light at all intercom stations. The interface can automatically hang up or release the line if it detects a dial tone, resulting from either an intentional hang-up or a disconnection due to a line problem. If an audio program becomes too loud or distracting, it can be momentarily or permanently interrupted by any local intercom user.

Because telephone-to-intercom interfaces are used with standard telephone lines, frequency response is limited to 250 Hz–3.4 kHz ±3 dB. Automatic volume control (AVC) is about 20 dB and the depth of the null is greater than 30 dB, 200 Hz–8 kHz.

Many of the digital matrix intercoms offer extensive direct dial-in access to the system from any touch-tone telephone in the world. They may include up to 50 two digit DTMF codes that can be used to select any station, group, program source, or IFB circuit in the system.

43.2.8 Headsets

Most headsets are designed to work with all major types of communication systems including party line and matrix intercoms. They are used in intercom and sportscaster/announcer applications where audio quality, reliability, comfort, and the ability to hear and talk in noisy environments are of prime importance.

Light weight and comfort as well as durability are of major importance. Many headsets are made of flexible composite materials, which will not be damaged if dropped, thrown, or stepped on.

![Figure 43-15. Football communication system. Courtesy Telex Communications, Inc.](image-url)
Attention must be paid to acoustical and electrical isolation between the microphone and earphone(s) to minimize the common problem of crosstalk in multiple channel intercom systems. Also by using dual chamber foam filled ear cushions, the acoustical isolation of earphones allows for comfort and low ear fatigue in high-noise environments.

Broadcast-quality microphones require noise rejecting abilities with wide-frequency response and good resistance to breath and wind noise as the microphone is usually very close to the lips. Boom microphones can be adjusted to any position, and located as a right or left hand headset with positive detent stops. In addition, the boom can be bent into any required position. Often swinging the boom up shunts off the microphone to eliminate feedback and unwanted noise.

The headset cable is specially designed to minimize crosstalk between the microphone and the earphone. The wire stranding is a special composition for flexibility and resistance to breakage.

Earphones have specially contoured wide-bandwidth frequency response and a sensitivity of 94 dB SPL with 1 mW of power. This reduces amplifier power, increasing battery life.

44.8.4.2 LCoS Operates in the Following Manner

44.8.5 Organic Light Emitting Diode

44.8.5.1 OLED Characteristics

1577
In this chapter we will explore the fundamentals of display technologies and how each technology does its work. We will begin by covering display specifications, video and computer signals, and finally the display technologies themselves providing the full context of how an image is produced on screen.

44.1 The Effect of Display Specification

In most audiovisual systems design, the display is the key focal point in the room. With this in mind, it is a requirement to match the display to the environment and the explicit needs set forth in the original sales proposal and system design. It is necessary to understand the specifications relating to display technologies, in order to properly design for individual applications. The key considerations are:

- Brightness.
- Contrast.
- Color.
- Resolution.
- Scaling.

Brightness is the element that we are most familiar with. It is the measurement of light falling on a surface, or light emitting from a source such as a plasma, LCD, or OLED flat panel display. It is most commonly stated in two units of measurement when relating to display technologies.

44.1.1 Lumens

A lumen is a measurement of light falling on a surface, such as a projector illuminating a screen. The measurement is taken using a light photometer pointed at the projector lens thus measuring the light output of the projector itself.

A lumen is equal to one foot-candle falling on one square foot of area.

Properly specified, it is referred to as an ANSI lumen, which infers adherence to the American National Standards Institute method of measurement utilizing a nine zone pattern of rectangles and averaging the light measurement from each of the nine zones.

Since there are no mandatory/standardized methods of verifying lumen specifications from a given display manufacturer, the actual light output may vary as much as 20% less than the published specifications. This necessitates testing each display for actual lumen light output prior to specifying a specific projector in each application.

While lumen light output is the common specification, it is really foot Lamberts or the light reflected from the screen surface to the viewer that is most important. This necessitates taking the screen surface gain and ambient light in the room into consideration when specifying a projector.

Lumen light output will range from 100 lumens in a tiny pico projector up to over 30,000 lumens in a large rental and staging or digital cinema projector.

44.1.2 Candelas per Meter Squared (cd/m²), or Nits

Candelas per meter squared, or cd/m², is a unit of measurement that may also be referred to as nits and is typically used in the measurement of light emitting from a flat panel display such as plasma, LCD, or OLED directly at the viewer.

Broken down, candela, abbreviated as cd, is a term that originated in the days when candles were used in theaters.

For our purposes, candela per meter squared measures the light properties radiating from a one-meter-square surface, providing a technical frame of reference for the performance of a display’s black level, peak brightness, grayscale, and gamma readings.

Candelas per meter squared are more accurate than lumen light output measurements and can be measured using the same nine zone ANSI pattern. Since the screen reflectivity or gain is taken out of the equation it is less complex than a projector and screen combination.

Typical candela per meter squared measurements vary from 300 cd/m² for a 19 inch desktop monitor to the latest LCD displays providing 1500 cd/m² in sizes up to 108 inches diagonal.

It is generally agreed that contrast is the element in a picture that provides the appearance of quality in an image. Poor contrast makes the image appear washed out while good contrast gives us excellent depth of field and much more detail in a picture. It also gives us the appearance of higher resolution while not actually providing more lines of resolution or more pixel density in the image.

44.1.3 Contrast

Contrast is the range of light and dark values in a picture.

- It is stated as the ratio between maximum and the minimum brightness values—e.g., 1000:1.
- Low contrast is shown mainly in shades of gray.
• High contrast is shown as blacks and whites with very little gray.
• In digital technologies, contrast is the difference between the luminance or brightness of an ON pixel and an OFF pixel.

Contrast is used as a marketing specification and is the most misstated of all specifications from manufacturers. The proper method to measure contrast is by using a sixteen zone black and white ANSI test pattern and comparing the average of the dark rectangles to the white rectangles to get the proper contrast ratio. As a point of reference, when measured in this manner, the most expensive digital cinema projectors in the world will produce approximately 500:1 contrast and a typical boardroom projector will produce less that 100:1 contrast in a typical lighting condition.

44.2 Display Color

Each display technology produces the color we see in a different manner but they all utilize the primary colors of red, green, and blue as well as the secondary colors of cyan, magenta, and yellow to create the full color spectrum we see onscreen.

Going back to our physics class in high school, we remember that white light, when viewed through a prism, produces a veritable rainbow of colors, known as the full color or electromagnetic spectrum. The easiest way to remember the visible color spectrum is the name ROY G BIV (red, orange, yellow, green, blue, indigo, and violet).

Infrared and ultraviolet light are not visible, and fall at the far extremes of the spectrum.

In the world of professional audiovisual, you may encounter what is known as the CIE chromaticity diagram (color chart). This chart illustrates the full color spectrum, including wavelengths of light measured in nanometers and color temperature, measured in degrees Kelvin. As a specific point of reference, you can see the overlap of red, green, and blue, producing white light.

In modern display technologies, color is created in a variety of ways, by the manipulation of white light:

• Color is produced from the light of a projector lamp shining through a color wheel, in the case of single chip DLP (digital light processing).
• Color is produced from the light of a projector lamp shining through a transmissive display device, or bouncing off a reflective display device, such as LCD, three chip DLP, or LCOS (liquid crystal on silicon).
• Color is produced from an emissive (light producing) display device, such as a CRT, plasma display, or OLED.
• Color is produced from the backlight of a transmissive display device, such as a flat panel LCD.

Color and color space can be calibrated in the majority of displays by using instruments known as colorimeters. These devices measure the visible color spectrum and permit the technician to calibrate for a specific color temperature depending on the application. Most displays are set for 6500 Kelvin, also known as D65, which replicates an image in a full daylight mode.

44.3 Display Resolution

The resolution of digital display technologies is fixed as in the reference to fixed matrix displays. Resolution relates directly to visual acuity and what the eye can see. Each display technology differs in the spaces between the pixels and this is called the fill factor. The displays with the highest fill factor appear to have less of what is known as the screen door effect thereby providing a look closer to that of an analog image of 35 mm color film or CRT displays. The higher the number of pixels, the more detail in an image.

• In digital displays, resolution is the number of pixels (picture elements or individual points of color) contained on a display, expressed in terms of the number of pixels on the horizontal axis and the number of pixels on the vertical axis—e.g., 1920 × 1080.
• The sharpness of the image on a display depends on the resolution and the size of the display. The same pixel resolution will be sharper on a smaller display and gradually lose sharpness on larger display because the same number of pixels is being spread out over a larger number of inches.
• In terms of fill factor, LCD has the most space between pixels, with DLP providing more fill factor, and LCoS providing the highest fill factor available today.

44.4 Display Scanning

Television signals and compatible displays are typically interlaced, and computer signals and compatible displays are typically progressive (noninterlaced). These two formats are incompatible with each other; one would need to be converted to the other before any common processing could be done.
Designed for analog NTSC television, interlaced scanning is where each picture, referred to as a frame, is made up of two separate subpictures, referred to as fields, so two fields make up a frame. An interlaced picture is drawn on the screen in two passes, by first scanning the horizontal lines of the first field and then retracing to the top of the screen and scanning the horizontal lines for the second field in between the first set. Field 1 consists of lines 1 through 262½, and field 2 consists of lines 262½ through 525. A television scans 60 fields every second (thirty odd and thirty even). These two sets of thirty fields are combined to create a full frame every 1/30th of a second, resulting in a display of thirty frames per second. Drawbacks to interlaced scanning compared to progressive scanning include lower resolution, flicker, aliasing, and image artifact quality issues.

Progressive scan differs from interlaced scan in that each line (or row of pixels) in the signal is drawn in a sequential order rather than an alternate order, as is done with interlaced scan. In short, with progressive scan, the image lines (or pixel rows) are scanned in numerical order (1, 2, 3) down the screen from top to bottom, instead of in an alternate order as done in interlaced scanning. By progressively scanning the image onto a screen every 60th of a second rather than “interlacing” alternate lines every 30th of a second, a smoother, more detailed, image can be produced on the screen. The benefit is the viewing fine details, such as text, and is also less susceptible to interlace flicker and basically eliminates aliasing on the edges of objects in a picture. The drawback to progressive scan is that it requires more bandwidth to display the images onscreen.

### 44.5 Aspect Ratios and Screen Formats

*Aspect ratio* refers to the shape of the images we see on screen, but just what comprises an aspect ratio? Aspect ratio is typically described as the ratio of screen width to screen height. There are two common aspect ratios. The first is that of a standard televisio, which has a 4:3 (referred to as 4 by 3) aspect ratio. Also note that the television aspect ratio is listed as 1.33:1. This is another way of listing aspect ratios—dividing the width by the height (e.g., 4/3 = 1.33). This is referred to as 1.33:1 or 1.33 to 1. A widescreen display, such as a plasma panel, will usually have a 16 by 9 aspect ratio (16:9). Since 16/9 = 1.78, the aspect ratio is also known as 1.78:1 or 1.78 to 1.

#### 44.5.1 Common Aspect Ratios

- **4 × 3 (1.33:1).** This is the standard television format used throughout the second half of the 20th century. This is both typical computer and NTSC broadcast video.

  Note: 1280 × 1024 is actually 5:4 aspect, not 4:3.

- **16 × 9 (1.78:1).** This is the common format for widescreen DVD movies, HDTV (720p and 1080i) and widescreen computer resolutions (1280 × 720, 1920 × 1080, etc.).

- **13 × 7 (1.85:1).** This is the standard aspect ratio for theatrical release film prints.

- **29 × 9 (Cinemascope–2.35:1).** A very wide screen format used for theatrical release movies, and some new DVDs.

### 44.6 Scaling

In the realm of digital display technologies, there is quite often a mismatch between the resolutions of the display itself and the signals or sources coming into the display. This mismatch necessitates the incorporation of a process known as scaling or scan conversion.

By definition, a digital display can also be referred to as a fixed matrix display, with a finite number of horizontal and vertical pixels—e.g., 1024 × 768.

In many instances the actual resolution of the input signals and the physical resolution of the display do not match. The mismatch requires what is known as scaling.

While a scaler can be an outboard device, in most instances today, it is built into the display device.

Scaling, which is sometimes called scan conversion, refers to a process of taking a higher-resolution signal, and modifying it to be displayed on a lower-resolution device, or a lower-resolution signal, and modifying it to be displayed on a higher-resolution device.

#### 44.6.1 Analog Image Display

In an analog display, such as a CRT, scan conversion is not required, because the output of the display is infinitely adjustable to match the input signal entering the display.

The pixels, more properly referred to as rare earth phosphor spots, are adjusted in width and position on the CRT to match the source image.
44.6.2 Digital Fixed Matrix Display Scan Conversion

In a digital or fixed matrix display, where the pixels are in a fixed size and position, the input signal may or may not match. Scan conversion is a necessary process to fit the analog source image across multiple pixels in the display. Depending on the display technology, 20–30% of image information may be lost.

For example, if we have a fixed matrix display at 1024 × 768 and want to input a signal that is 800 × 600, a mathematical algorithm is employed where the signal information in the lower-resolution signal is reduced to a mathematical equation and fit into the higher-resolution display. The same process takes place where a higher-resolution image is fit mathematically into a lower-resolution display.

In all instances where scaling and scan conversion take place there is lost information. The quality of the scaler or scan converter varies with each display and the most fidelity in an image takes place where the signal and the display resolutions match each other.

44.7 Video Signals

In order to further the understanding of displays and display technologies, it is necessary to gain a basic comprehension of what comprises the different types of video signals in use today. We will now examine the core components of all signals, and their transmission standards.

44.7.1 What Comprises a Video Signal?

Chrominance noted as (C) is the hue or color with saturation in the red, green, and blue channels of a signal.

Luminance noted as (Y) is the amount of light in each red, green, and blue channel.

Without the chrominance in a signal, the picture is black and white.

44.7.2 Composite (aka NTSC)

An analog composite video signal is used in most home applications. It combines the chrominance and luminance, along with a sync signal into one cable. This facilitates the broadcast of the NTSC television signal to our homes.

44.7.3 Y/C (aka S-Video)

This is still a composite signal, but one that nearly separates luminance and chrominance to provide a more precise color reproduction on the screen.

44.7.4 Component Video

Commonly known as RGB (RGB sync, RGB with H and V sync, RGB sync on green).

This type of signal totally separates red, green, blue, and sync to give clearer definition to each of the color channels.

Component is never used for broadcast due to its excessive bandwidth requirement in the green channel. Note that the sync signal can be H/V (horizontal and vertical) or sync on green.

One version of a component signal is commonly known as YPbPr. In the broadcast community, this is known as a color difference signal. Since a normal RGB signal requires too much bandwidth to broadcast the dominant green channel, YPbPr, as a component signal, extrapolates the green signal by subtracting from the luminance channel (Y) both the blue component (Pb) and the red component (Pr), leaving the green component.

This allows the economical broadcast of a component signal by reducing the bandwidth needed by eliminating the dedicated green signal.

44.7.5 VGA (Video Graphics Array)

VGA is the analog display standard for the PC. VGA uses an analog monitor, and PC display adapters to output analog signals. All PC CRTs and most flat panel monitors accept VGA signals, although newer flat panels may also have a DVI interface for display adapters that output digital signals.

VGA may refer to the physical 15-pin VGA socket on a PC in order to contrast it with a digital DVI socket for flat panels. Or, VGA may also refer only to the original VGA resolution of 640 × 480 and 16 colors.

44.7.6 DVI (Digital Video Interface)

DVI is a multipin connection used for passing standard-definition and high-definition digital video signals, found on HDTV tuners, a growing number of DVD players, HDTV-ready televisions, and some computer displays. DVI connections transfer video signals in pure digital form, which is especially beneficial if you’re using a fixed-pixel display (like a LCoS, plasma, LCD, or DLP TV). Signals are encrypted with HDCP (high-bandwidth digital content protection) to prevent content from being re-recorded and pirated.

There are different kinds of DVI connections. DVI-D, which is the type of DVI connection found on most home video gear, carries digital-only signals. DVI-I, used with some computer video cards, is capable
of passing both digital and analog video signals. Some TVs feature DVI-I inputs for greater hookup flexibility.

44.7.6.1 HDMI (High-Definition Multimedia Interface)

HDMI is the second generation digital interface that evolved out of the DVI standard.

HDMI is a multipin connection used for passing standard- and high-definition digital video signals, as well as multichannel digital audio, through a single cable. These connections are usually found on newer HDTV tuners, and a growing number of DVD players, HDTV-ready televisions, and home theater receivers. HDMI cable accommodates up to 5 Gbps bandwidth, so it can simultaneously transfer pure digital video and audio signals without compression (even HDTV video).

HDMI works especially well with a fixed-pixel display (like a LCoS, plasma, LCD, or DLP TV), and is backwards compatible with most DVI connections. Signals are encrypted with HDCP (high-bandwidth digital content protection) to prevent recording.

Although many first generation HDMI-equipped components only pass two-channel audio signals, HDMI can carry up to eight discrete audio channels, making it forward-compatible with 7.1 sound systems. That means you can pass digital video and multichannel audio signals between newer HDMI-equipped components along a single cable.

44.8 Digital Display Technologies

In the early days of the audiovisual industry, it was necessary to immerse oneself in the tiniest details of technology and how it operated. In today’s market, it is necessary to understand the basic function of various technologies, and more specifically, how the basic functions affect the final design, and the solutions presented to the client and for the specific project.

We will examine the characteristics and basic functions and operation of the following:

- PDP (plasma).
- DLP (digital light processing).
- LCD (liquid crystal display).
- LCOS (liquid crystal on silicon).
- OLED (organic light emitting diode).
- LED (light emitting diode).

44.8.1 Plasma Display Technology

Of all fixed matrix display technologies, plasma, or PDP displays most closely replicate the smooth image from a 35 mm film projector and a CRT. Plasma displays are emissive in nature, and utilize a similar rare earth phosphor to a CRT to provide color saturation for the display, Fig. 44-1.

![Figure 44-1. Plasma monitor.](image)

44.8.1.1 PDP Characteristics

- 3 to 4 inch thick displays (wall or base mount).
- 60 to 500 pounds.
- Panel sizes 37 inch, 40 inch, 42 inch, 43 inch, 46 inch, 50 inch, 55 inch, 60 inch, 61 inch, 63 inch, 71 inch, 103 inch, and 150 inch.
- 16:9 aspect ratio panels.
- PDP combines the pixel structure of LCD with the color generation of a CRT.
- No radiation or high voltage emissions.
- Fast response time.
- High contrast.
- Deep color saturation.

44.8.1.2 PDP Operates in the Following Manner

- The cells are filled with a xenon and neon gas mixture.
- A controlled current is passed through the gas.
- Ultraviolet rays are produced by the current energizing the gas, creating a plasma.
- Ultraviolet rays hit the red, green, and blue phosphors applied inside the cells.
- Visible light is produced by the ultraviolet rays exciting the rare earth phosphors.
- Voltage is applied to one of three terminals on a pixel. The voltage discharges through the pixel to a second electrode ionizing a rare gas (creating a plasma) in the process. The ionization creates UV light, which excites an R,G,B phosphor causing it to glow (like a CRT). Brightness variation is achieved by controlling the number of pulses of light that our eyes integrate to produce impression of dim or bright areas.
44.8.2 Liquid Crystal Displays

Liquid crystal displays have become ubiquitous. As the foundation for modern computer and cell phone displays, LCD technology is used for large flat panel displays as well as three chip LCD projectors. No matter the application, LCD technology and how it works is similar in the way it fundamentally operates.

44.8.2.1 LCD Characteristics

• 3 to 4 inch thick displays (wall or base mount).
• 60 to 400 pounds.
• Panel sizes ranging from under 8 to 108 inch panels.
• 4:3, 16:9, and 16:10 aspect ratio panels.
• No radiation or high-voltage emissions.
• Low power consumption.
• High resolution, up to 4 × HDTV.
• Ideal for computer display and digital signage.

44.8.2.2 LCD Operates in the Following Manner

There’s far more to building an LCD than simply creating a sheet of liquid crystals. The combination of four facts makes LCDs possible:

• Light can be polarized.
• Liquid crystal can transmit polarized light or change the plane of polarization.
• The structure of liquid crystals can be changed by electric field.
• There are transparent substances that can conduct electricity.

To create an LCD, you take two pieces of glass with polarizing films applied.

A polyimide film is applied to the liquid crystal side of the glass and then mechanically rubbed to produce microgrooves.

The two glass plates are assembled together with a carefully controlled gap dimension.

When LC material is introduced to this cell, the layers adjacent to the polyimide will align with the microgroove directions resulting in a helical structure of LC molecules between the two glass plates, Fig. 44-1.

Liquid crystal displays come in two basic configurations: flat panel displays and projection displays. Both variations utilize the same basic LCD principle, but differ in the way that they are illuminated.

In the flat panel, or desktop display, the illumination comes from bright cold cathode fluorescent lights behind the display.

In projection LCD displays, the illumination comes from a bright lamp reflecting off of the LCD and onto the screen.

LCD monitors make use of thin film transistors (TFT). TFTs are small switch transistors and capacitors that sit on a glass substrate in the LCD structure, Fig. 44-2.

![TFT-LCD technology.](image)

Each pixel is controlled by one up to four of these TFTs. To ignite a particular pixel, power is applied to the correct column and row (just like passive matrix).

Any pixels on the same row and column that are not targeted simply pass the current on. The transistor at the target pixel stops the current. The capacitor takes the current and stores it. It is then able to hold that charge until the next screen refresh.

Also, by adjusting the amount of voltage to each pixel, you can control the amount that the crystals will untwist, thereby allowing varying degrees of color.

For an LCD monitor to produce color, each pixel on the screen has to have three subpixels, each being a primary color (red, blue, and green). In this aspect, color LCDs work the same way as the color CRT. By taking each of the three colors, each having 256 possible shades, and blending it all together, the color active matrix LCD has a possible palette of 16.8 million colors. Each subpixel has a transistor/capacitor and with this design process, one can see that there are millions of transistors necessary to formulate a full TFT screen.

In an LCD monitor, the light source is behind the panel and illuminates the display from behind. Typically the lighting is a florescent type but the most recent development in illuminations is via side emitting LED display, which improve uniformity, durability, brightness, and the life of the backlight.

LCD projectors utilize three LCD panels or chips as the imaging devices but unlike LCD monitors, they differ in the way color and illumination are derived. By
looking at the LCD light path illustration, Figs. 44-3, we begin with a metal halide lamp for illumination. The lamp approximates pure white light from which the colors of the spectrum can be extrapolated. Color (RGB) is achieved by incorporating dichroic mirrors or filters into the light path. The dichroic mirrors filter out all of the unwanted color spectrum and pass on a narrow band of color coordinates of red, green, and blue, permitting each of those colors in a pure form to be transferred to the main optical prism or combiner just behind the projection lens.

LCD projectors come in various sizes, shapes, light outputs, and resolutions.

Typical native resolutions for commercial LCD projectors are 800 × 600, 1024 × 768, and 1280 × 1024.

In terms of weight, the brighter the projector, the bigger the lamp housing requirement and hence the heavier the projector.

Modern LCD projectors vary in size from 5 lbs to over 50 pounds for the high-brightness models.

Brightness has long been the holy grail of projectors and LCD with flat panel brightness reaching 1500 cd/m² and projector brightness achieving 15K lumens.

44.8.3 Digital Light Processing

Digital light processing was developed by Dr. Larry Hornbeck of Texas Instruments and brought to market in the mid-1990s. It is fundamentally a digital light switch that is used in projection applications as far reaching as tiny pico projectors to be inserted in cell phones all the way to digital cinema projectors replacing 35 mm film in movie theaters. Its compact size along with single chip and three chip variations make it unique in the world of display technologies, Fig. 44-4.

44.8.3.1 DLP Characteristics

- Projection technology, no fixed screen size.
- Single or three chip configurations.
- 16:9 and 16:10 aspect ratio panels.
- No radiation or high-voltage emissions.
- Low power consumption.
- High resolution, up to 2 K.
- High brightness and contrast.
- Does not require polarized light.

44.8.3.2 DLP Operates in the Following Manner

- DLPTM is based on an optical semiconductor called a digital micromirror device, or DMD.
- The DMD is an extremely precise light switch that enables light to be modulated digitally via millions of microscopic mirrors arranged in a rectangular array.
- Each mirror is spaced less than 1 micron apart.
- These mirrors are literally capable of switching on and off thousands of times per second and are used to direct light toward, and away from, a dedicated pixel space.
- When the display is off, all of the mirrors are flat.

Figure 44-3. LCD projection TV optical path.
When the display is turned on and the chip begins transmitting the signal, the mirrors flip back and forth thousands of times per second.

Mirrors in the on position reflect the light through a projection lens and onto the screen. The longer a mirror is in the on position, the lighter the pixel it creates. Mirrors that are off for longer periods create darker pixels, and mirrors that are always off create black pixels. By varying the length of time that the mirrors point toward the projection lens, the DMD creates up to 1024 shades of gray.

The gray pixels combine on the screen to create a progressive, fully digital monochrome image.

To add color to the picture, the single chip DLP system uses a color wheel, Fig.44-5.

The color wheel is a transparent, spinning wheel with red, green, and blue. The light passing through each section turns red, green, or blue.

The system’s processor synchronizes the spinning of the wheel with the action of the mirrors. Together, the DMD and the color wheel can create 256 shades of each primary color.

Each pixel of light on the screen is red, green, or blue at any given moment. The colors are then blended to create the desired colors of the image.

With DLP projectors, a small number of people might experience a rainbow effect when watching a DLP projection, especially when they change their focus from one part of the image to another, seeing the individual component colors.

This happens only in DLP systems that use a segmented color wheel, not in systems that use one DLP chip for each primary color.

A number of home theater systems use color wheels with additional segments, two segments of each color, or sequential color recapture (primary colors arranged in a spiral instead of in segments) in order to reduce the appearance of the rainbow effect.

New BrilliantColor™ color wheel technology reduces the appearance of the rainbow effect. In the newer DMD generations, a light-eating dark metal coat is applied to the interior of each chip, preventing stray light from traveling to the screen when mirrors are switched off. This improvement increases contrast ratios from 1200:1 to >2000:1 and higher.

Increased mirror tilt angle (from ±10 to ±12°), brings 20% more light to the screen for greater brightness.

Double data rate technology allows a DMD chip to tilt toward or away from its light source twice as fast, allowing more accurate grayscale reproduction.

**44.8.3.3 New DLP BrilliantColor™ Color Wheel Technology**

Historically, most display devices would render a scene using the three primary colors, red, green, and blue.

This limits available colors that can be displayed, making it difficult to display brilliant yellows, magentas, and cyans that are commonly found in natural scenes.

BrilliantColor™ technology adds yellow, cyan, and magenta colors to the color wheel, maintaining bright whites while providing deeper red, green, and blue colors.

BrilliantColor™ provides brightness increases in nonprimary colors and boosts overall color intensity.

BrilliantColor™ provides flexibility in color wheel design allowing for bright, large color gamuts and differentiation from OEMs.
44.8.4 Liquid Crystal on Silicon

Liquid crystal on silicon combines the best of both worlds of LCD and DLP. It is a reflective technology like DLP but uses liquid crystals instead of moving mirrors to control the light transmission levels of the individual pixels. The benefit of LCoS is that it has excellent color and contrast capabilities and has the highest fill factor of any current digital display. It is also capable of 4K resolution and is a competitor with DLP for digital cinema applications, Fig. 44-6.

44.8.4.1 LCoS Characteristics

- Projection technology, no fixed screen size.
- Three chip configuration.
- 16:1 aspect ratio panels.
- No radiation or high voltage emissions.
- Low power consumption.
- High resolution, up to 4K.
- High brightness and contrast.
- High fill factor.

44.8.4.2 LCoS Operates in the Following Manner

- LCoS technology is a reflective liquid crystal modulator where electronic signals are directly addressed to the device.
- The LCoS device has an X-Y matrix of pixels configured on a CMOS single crystal silicon substrate mounted behind the liquid crystal layer using a planar process that is standard in IC technology.
- The liquid crystal is placed on top of the CMOS substrate on an array of aluminum mirrors that define each pixel.
- A glass counter electrode covers the liquid crystal to complete the structure.
- A voltage is applied to a selected pixel of the matrix in accordance with the input signal, making the liquid crystal change birefringence, thus changing the polarization direction of the incident projection light.
- The nonactive area between the pixel mirrors is minimal, only serving to separate each pixel; the rest of the electrode is active as a reflective surface, thereby providing a high aperture ratio.
- Although having the highest overall performance of any current projector technology it is held back by manufacturing yield issues and cost of components that impede its progress.

44.8.5 Organic Light Emitting Diode

Organic light emitting diode (OLED) is the newest display technology and a direct competitor for other flat panel displays such as LCD and plasma. The most obvious benefit is the nearly paper thinness of the technology. Since it is an emissive technology that does not require separate lighting it can be manufactured to create a display the thickness of a credit card. It can be made transparent and even flexible. It also has advantages in the area of low power consumption and excellent picture performance dynamics. The big issues facing OLED are manufacturing costs, and panel life, both of which are in the process of being addressed.

44.8.5.1 OLED Characteristics

- Thinnest and lightest display technology.
- Fast response time.
- High brightness.
- Low power consumption.
- Can be made transparent or flexible.
44.8.5.2 OLED Works in the Following Manner

- The basic OLED cell structure consists of a stack of thin organic layers sandwiched between a transparent anode and a metallic cathode.
- The organic layers comprise a hole-injection layer, a hole-transport layer, an emissive layer, and an electron-transport layer.
- When an appropriate voltage (typically a few volts) is applied to the cell, the injected positive and negative charges recombine in the emissive layer to produce light (electroluminescence).
- The structure of the organic layers and the choice of anode and cathode are designed to maximize the recombination process in the emissive layer, thus maximizing the light output from the OLED device.

OLEDs are typically fabricated on a transparent substrate on which the first electrode (usually indium-tin-oxide which is both transparent and conductive) is first deposited.

Then one or more organic layers are coated by either thermal evaporation in the case of small organic dye molecules, or spin coating of polymers. In addition to the luminescent material itself, other organic layers may be used to enhance injection and transport of electrons and/or holes.

The total thickness of the organic layers is of order 100 nm.

Lastly, the metal cathode (such as magnesium-silver alloy, lithium-aluminum, or calcium) is evaporated on top.

The two electrodes add perhaps 200 nm more to the total thickness of the device. Therefore the overall thickness (and weight) of the structure is mostly due to the substrate itself.

OLEDs can be manufactured in several different types, classified by the size of molecule they use, and the type of substrate they are manufactured on. Some examples are:

- TOLED—Transparent OLED. This is manufactured on a clear substrate suitable for applications such as heads-up displays.
- FOLED—Flexible OLED. This type of OLED is manufactured into a sealed flexible substrate that can be curved, rolled, or bent.

44.8.6 Light Emitting Diode

Light emitting diodes are popping up everywhere due to their high light output and relatively low power consumption. They are finding uses in homes, automobiles, and of course high brightness outdoor displays. Their newest application is as backlight illumination for LCD flat panel displays and as a light source for small pico projectors utilizing DLP and LCoS chips.

44.8.6.1 LED Characteristics

- Extremely high brightness.
- Relatively low maintenance.
- Long life, >50,000 hours.
- Outdoor/indoor capability.
- Modular construction with scalable display sizes.
- 3 to 25 mm pixel pitches available.

44.8.6.2 LED Operates in the Following Manner

The phenomenon of electroluminescence was discovered in 1907 by Henry Joseph Round.

British experiments in the 1950s led to the first modern red LED, which appeared in the early 1960s.

By the mid-1970s LEDs could produce a pale green light. LEDs using dual chips (one in red and one in green) were able to emit yellow light.

The early 1980s brought the first generation of super bright LEDs, first in red, then yellow, and finally green, with orange-red, orange, yellow, and green appearing in the 1990s.

The first significant blue LEDs also appeared at the start of the 1990s, and high-intensity blue and green in the mid-1990s.

The ultra bright blue chips became the basis of white LEDs, in which the light emitting chip is coated with fluorescent phosphors.

This same technique has been used to produce virtually any color of visible light and today there are LEDs on the market, which can produce previously exotic colors, such as aqua and pink.

Light emitting diodes (LEDs) are source of continuous light with a high efficiency.

- At the heart of a light emitting diode is a semiconductor chip, containing several very thin layers of material that are sequentially deposited onto a supporting substrate.
- The first semiconductor material that is deposited onto the substrate is doped with atoms containing excess electrons, and a second doped material, containing atoms having too few electrons, is then deposited onto the first semiconductor to form the diode. The region created between the doped semiconductor materials is known as the active layer.
• When a voltage is applied to the diode, holes (positive charges) and electrons (negative charges) meet in the active layer to produce light.
• The wavelength of light emitted by the diode is dependent on the chemical composition and relative energy levels of the doped semiconductor materials, and can be varied to produce a wide range of wavelengths.
• After being fabricated, the chip is mounted in a reflector cup connected to a lead frame, and is bonded with wire to the anode and cathode terminals.
• The entire assembly is then encased in a solid epoxy dome lens that enables emitted light to be focused, controlled by embedding tiny glass particles into the lens that scatter light and spread the light beam, or angled, via changing the shape of the lens, or the reflector cup.

44.9 Resolution
What is resolution? A simple definition of resolution is the degree of sharpness and clarity of a displayed image. In LED displays, resolution is determined by the matrix area and pitch.

The area, also known as the pixel matrix, corresponds to the number of pixels that make up the display area. In our industry, we express the matrix area in the number of pixels vertically by number of pixels horizontally, such as $16 \times 64$.

The pitch is defined as the distance between two pixels. The distance is measured from the center of one pixel to the center of the next pixel.

Pitch can also influence the pixel matrix for a given area. For example, a 16 mm pitch will give you a $5 \times 7$ matrix area, while a 10 mm pitch will give you a $8 \times 11$ matrix area for the same area.

Pitch determines the amount of empty space between the pixels.

Therefore, the smaller the pitch and larger the matrix area, the greater the resolution.

44.10 Conclusion
The one thing we can be certain of is that display technologies are constantly evolving with advances taking place in months not years. We can look forward to plasma and LCD displays becoming thinner and lighter with significant power consumption reduction while producing brighter displays with longer panel life. Environmentally unfriendly CCFL backlights in LCD displays will be replaced with LED and laser illumination will gain acceptance for projectors and RPTVs. OLED is set to take on conventional LCD and plasma displays and will become larger and more economically priced in the next few years. The only constant is change in the world of display technologies and we all benefit in the end.

45.1 The Origin of Surround Sound

The first commercially successful multichannel sound formats were developed in the early 1950s for the cinema. At the time, stereophonic sound, as it was called, was heavily promoted along with new wide-screen formats by a film industry feeling threatened by the rapid growth of television. Unlike the two-channel format later adopted for home use because of limitations imposed by the phonograph record, film stereo sound started out with, and continues to use, a minimum of four channels.

With such film formats as four-track CinemaScope (35 mm) and six-track Todd-AO (70 mm), multiple sound channels were recorded magnetically on stripes of oxide material applied to each release print. To play these prints, projectors were fitted with magnetic playback heads like those on a tape recorder (only much larger), and cinemas were equipped with additional amplifiers and loudspeaker systems.

From the outset, multichannel film sound featured several channels across the front, plus at least one channel played over loudspeakers towards the rear of the cinema. At first the latter was known as the effects channel, and was reserved for the occasional dramatic effect—ethereal voices in religious epics, for example. Some formats even switched this channel off by means of trigger tones when it wasn’t needed because the magnetic track on the film was particularly narrow, and thus very hissy.

As time went on, sound mixers continued to experiment with the effects channel. In particular, because six-track 70 mm magnetic provided consistent signal-to-noise ratios on all channels, mixers began to use the effects channel to envelop the audience in continuous low-level ambient sounds. This expanded, more naturalistic application came to be known as surround sound, and the effects channel as the surround channel, Fig. 45-1.

45.2 Surround from Optical Soundtracks

Under the best conditions, the multichannel magnetic-stripe formats provided superb sound, way beyond anything the home listener could experience, and it was widely adopted in the 1950s. By the 1970s, however, the expense of magnetic release prints, their comparatively short life compared to those with traditional optical soundtracks, and the high cost of maintaining the playback equipment led to a massive reduction in the number of magnetic releases and cinemas capable of playing them. Magnetic sound came to be reserved for only a handful of first-run engagements of big releases each year.

As a result, by the mid-1970s, most films were being released with only low fidelity, mono-optical soundtracks, a technology that had hardly improved since the late 1930s. Then, in 1975, came a new breakthrough: the introduction by Dolby Laboratories of a highly practical 35 mm multichannel optical release print format originally identified as Dolby Stereo.

In the space allotted to the conventional mono-optical soundtrack are two soundtracks that not only carry left and right information as in home stereo sound, but are also matrix encoded with a third center-screen channel and—most notably—a fourth surround channel for ambient sound and special effects. The matrix process in essence “folds” four channels down to two tracks on the film, and “unfolds” them in the theater by means of a sound processor-decoder (a common industry term for the process is 4:2:4), Fig. 45-2.

This format not only enabled multichannel sound from optical soundtracks, but higher-quality sound as well, thanks to such techniques as noise reduction and loudspeaker equalization. The result was multichannel capability on easily manufactured, compatible 35 mm optical prints that rivaled that of four-track 35 mm magnetic, which soon became obsolete.

The multichannel optical format proved so practical that within a decade of its introduction, virtually all major releases could be heard in most local cinemas in four-channel surround sound. It was dramatically improved in 1987 by the application of spectral recording (SR), a new recording process developed by Dolby Laboratories that both lowered optical track noise still further and increased headroom, making it possible to record loud sounds with wider frequency response and lower distortion.

Today, virtually all 35 mm movie prints, including those with digital soundtracks, feature a matrix-encoded, four-channel SR analog optical soundtrack. The SR track makes it possible for the print to play in any theater in the world, and also acts as a backup on digital prints in case there are problems with the digital track(s).

45.3 Digital and 5.1 Surround

In the 1980s, as the success of the compact disc established with consumers the idea that digital sound meant better sound, the film industry began to investigate what it wanted by way of digital sound in the cinema. While not defining how it would be achieved, the industry agreed on several objectives, including fully discrete channels providing better channel separation than
Figure 45-1. 70 mm six-track magnetic was regarded by the film industry as the supreme audio format until the advent of multichannel digital in the early 1990s. Shown is the format as it evolved in the late 1970s, with tracks 2 and 4 carrying supplemental bass information.

A. 70 mm prints provided six channels recorded on four magnetic stripes.

B. Loudspeaker layout for 70 mm magnetic film.

Figure 45-2. Four-channel surround sound from optical soundtracks, first introduced in 1975, remains the standard analog format today, although much improved by the SR process.
matrixing, wider dynamic range, and what became known as the 5.1-channel configuration.

As shown in Fig. 45-3, the 5.1 configuration provides fully discrete left, center, right, left surround, and Right Surround channels. A sixth channel, intended for reproduction by subwoofers, carries low-frequency effects (LFE), and became known as a .1 channel because it covers only a tenth of the audible spectrum.

The first 5.1-channel digital format was cinema digital sound (CDS), introduced in 1990 by Optical Radiation Corp. and developed in conjunction with Kodak. The CDS format placed a digital optical soundtrack on 70 mm prints in lieu of analog magnetic tracks, and experiments with 35 mm prints were underway when the venture failed. Soon thereafter, beginning in 1992, came the three competing 35 mm digital film sound formats that have survived with varying degrees of success: Dolby Digital, Digital Theater Sound (DTS), and Sony Dynamic Digital Sound (SDDS).

The three digital formats differ more in how they deliver their respective digital soundtracks than in their actual performance. Both Dolby and SDDS use optical digital soundtracks on the print, the Dolby Digital track between the sprocket holes down one side, and redundant SDDS tracks down both outer edges. DTS supplies the digital soundtrack separately on a CD-ROM disk that plays in sync with the picture by means of an optical time-code track adjacent to the analog soundtrack on the film. To insure playback in any theater, many release prints provide for all three digital formats plus analog playback, giving rise to the nickname quad print, Fig. 45-4.

45.4 Variations on the 5.1 Theme

While the 5.1 configuration became the de facto standard for multichannel digital film sound in the cinema (and for the home as well, as will be seen), both Dolby and SDDS offered producers the option of using additional channels. With SDDS, it is possible to mix for a total of seven main channels, bringing back the full-range half-left and half-right screen channels of the original 70 mm magnetic format. Thus far relatively few films have been so mixed, and relatively few theaters are equipped with the extra full-range screen loudspeakers required.

The Dolby option, called Dolby Digital Surround EX, was co-developed with Lucasfilm THX, and has achieved some success since its introduction in May of 1999 with the release of Star Wars: Episode I–The Phantom Menace. Surround EX offers the option of a third surround channel intended for reproduction by rear-wall surround loudspeakers, while the left and right surround channels are reproduced by the side-wall surrounds.

Not a discrete track, which is why the format’s co-developers originally avoided the term 6.1, the extra surround information is matrix-encoded onto the left and right surround channels of otherwise standard 5.1 soundtracks. This insures print compatibility with
conventional 5.1 playback systems, while cinema owners wishing to take advantage of the extra channel can equip their theaters with an additional decoder unit and power amplifiers. No additional loudspeakers are usually required, only rewiring the existing banks of surround loudspeakers, Fig. 45-5.

### 45.5 Surround Sound Comes Home

In 1982, recognizing the increasing popularity of watching VHS videotapes of theatrical movies in the home—and that the extra, matrix-encoded channels on Dolby Stereo movies were being transferred intact to their stereo (two-track) VHS versions—Dolby introduced the concept of surround sound in the home. It was dubbed Dolby Surround to differentiate it from the film process then still known as Dolby Stereo, and the term is still used today to identify any program material with stereo (two-track) soundtracks matrix-encoded for four-channel surround playback at the viewer’s option.

Initially, Dolby developed a simple decoder circuit that passively derived just the surround channel from encoded VHS soundtracks, then licensed it to consumer electronics manufacturers. Later, in 1987, they introduced and began licensing a more sophisticated, true four-channel decoder, called Dolby Surround Pro Logic, with active steering and other features adapted from their professional cinema sound processors.

Pro Logic decoding, which began to be featured more and more in multichannel home playback products, heralded a new kind of home entertainment system, the home theater. During the late 1980s and well into the
next decade, home theater was the fastest growing category of consumer electronics products, and today is enjoyed by many millions of consumers worldwide.

The appetite for Dolby Surround encoded programming increased accordingly, not only for videos of Dolby encoded movies, but also regular TV series, specials, and sports events. Content providers rose to the occasion by mixing more and more program material in Dolby Surround, confident that the material would play properly on any system, mono, stereo, or surround. And the Dolby Surround format soon extended to include the soundtracks of video and PC games, Fig. 45-6.

The purpose of a home theater system is to provide a convincing facsimile of what is heard in the cinema. In order to do that, the speakers should be placed as shown in Fig. 45-6, with three speakers across the front of the viewing area at about ear level, with the left and right speakers subtending a 45–60 degrees angle with the center seating position. A surround speaker goes to either side of the prime seating area well above ear level. Their relatively high placement helps to provide a diffuse surround soundfield, like that in a cinema, that does not call attention to itself.

When home theater was in its infancy, some pundits were skeptical that home listeners would put up with five loudspeakers in their living rooms (just as their ancestors had predicted failure for home stereo because two speakers were required). However, enough enthusiasts invested in the original, bulky home theater equipment to prompt loudspeaker manufacturers to develop sleek satellite/subwoofer systems that both eliminated most of the objections and lowered costs. While many devotees still assemble home theater systems from elaborate tower loudspeakers and other models, the majority of home listeners today opt for single-brand sub/sat systems.

Satellite/subwoofer systems take advantage of the fact that the lowest bass frequencies are nondirectional, that is, the ear cannot readily detect where bass sounds are coming from. As a result, these systems channel the low bass to a dedicated bass loudspeaker called a subwoofer. The subwoofer can usually be tucked out of the way, because its placement is not critical to reproducing the directionality of the original sound.

Because they are not required to reproduce low bass, the satellite loudspeakers can be compact, making them less intrusive and easier to place. Many systems use identical satellites for the left, center, right, and surround channels. This means that all loudspeakers have the same timbre, or tonal characteristic, which is desirable in a home theater system. Other systems provide identical satellites for left, center, and right, and somewhat different units (usually with respect to their radiating characteristic) for the surrounds. The surround loudspeakers should still be timbre-matched to the front loudspeakers.

### 45.6 Digital 5.1 in the Home

Much like Dolby’s original analog film sound formats migrated into the home as Dolby Surround, Dolby Digital in the cinema provided a springboard for consumer formats with 5.1-channel digital surround. Beginning with laser discs in 1995, Dolby Digital 5.1 soon made its way to DVD, cable TV, DBS systems, digital TV broadcasting, and multimedia applications including video and PC games, Fig. 45-7. DTS also entered the home market, although program material with DTS encoded soundtracks is found on relatively few DVD titles, and is unavailable via digital broadcast formats.
That film sound has been the starting point for 5.1 digital surround in the home has enabled the accumulation of invaluable experience in mixing, recording, and distributing multichannel digital audio. What’s more, the widespread adoption of the Dolby Digital 5.1 format for consumer applications has resulted in the most direct link from program producer to home listener ever, giving the former unprecedented control over what the latter actually hears.

This is because the Dolby Digital bitstream carries not only the soundtrack as originally mixed, but also metadata, or data about the data, that can be used to control the home listener’s Dolby Digital decoder. For example, while the same unrestricted multichannel audio content is delivered to every system, the consumer decoder can be instructed by metadata precisely how to downmix a 5.1-channel soundtrack for stereo or Pro Logic surround playback, or even mono playback. Metadata also allows the original mixers to pass onto the home decoder instructions that will, when the listener wishes, create a compressed version of the soundtrack on the fly for late-night viewing, when unrestricted dynamic range could bother family or neighbors.

### 45.7 More Home Theater Channels from Existing Content

The success of the 5.1 format, followed by the introduction of EX in 1999, led to the consumer electronics industry offering home theater listeners more channels by means of advanced matrix decoders and additional amplifiers in equipment such as audio/video receivers (AVRs). The first step was to offer decoding of the extra surround channel on DVDs of EX films for 6.1 playback, with the extra surround channel reproduced by a third surround speaker placed behind the listening area. A further variation soon followed, using two back surround speakers in a mono configuration reproducing the EX channel.

This 7.1 format, Fig. 45-8, as it is now known by the CE industry, has taken on greater popularity with the introduction of matrix technologies such as Dolby Pro Logic IIx and Harman-Kardon’s Logic 7. These derive stereo back surround channels from regular 5.1, and even stereo, program sources, and today nearly all home theater AVRs in the $300 and up range are equipped for 7.1 playback.*

Deriving surround from stereo content became a practical and successful proposition with the introduction in 2000 of Dolby Pro Logic II, a 5.1 matrix-based decoding technology. Using a concept originally developed by audio pioneer Jim Fosgate, the decoder in essence seeks out surround cues occurring naturally in stereo content, such as ambience in music recordings. Pro Logic II can also be used to encode specific Left and right surround information up front onto stereo soundtracks, to achieve specific directional surround effects on playback with Pro Logic II decoding. This approach to delivering encoded surround content via stereo formats is replacing the older Dolby Surround technology for applications such as stereo broadcasting, and is used by some video game and console manufacturers as a practical and effective alternative to higher performance, but processing-power-hungry, digital 5.1 interactive audio.

* For home listeners not ready to commit to seven speakers in their living rooms, some 7.1 AVRs make it possible to use the extra two amplifier channels for stereo playback in another room, with the main system set up for standard 5.1 playback.
Surround Sound

Dolby later expanded Pro Logic II technology to derive 7.1 surround (Pro Logic IIx, above), while competing systems from DTS, SRS, and others along with Dolby’s have made surround sound from stereo content a standard feature in home theater systems and an increasing number of automobile sound systems. Many of these companies have also developed surround virtualizing technologies to provide a surround effect via just two stereo speakers. These technologies vary widely in their cost and effectiveness, but the best can provide quite startling results, albeit only in a limited listening “sweet spot,” while the less sophisticated can provide a pleasant broadening of the stereo image over the stereo speakers built into TV sets.

45.8 The Question of Playback Level

When Dolby introduced surround on optical movie soundtracks in the late 1970s, it also introduced the concept of a reference playback level for both cinemas and the dubbing theaters where soundtracks are mixed. By calibrating both to the same reference level, the moviegoer hears in the cinema the same level as the director and sound designers heard when mixing the soundtrack. The objective—further supported by the introduction by Lucasfilm of its rigorous THX standards for playback quality—was for the moviegoer to experience the filmmakers’ original intentions.

Over the past three decades, the standardization of playback level and other characteristics has rivaled surround itself as a significant improvement to the cinema experience. However, what about home playback of these same movie soundtracks via disc, tape, or broadcast?

Theoretically, to reproduce the cinema experience exactly, movies at home should be played at the same level as in the cinema. That level in the home, however, is both difficult to achieve and far too loud for most viewers. Most home movie viewers choose a level they find comfortable for dialogue intelligibility, which is substantially lower than cinema reference level. This results in a loss of impact compared to the cinema due to one of the peculiarities of human hearing: a loss of sensitivity to low and high frequencies that increases as playback level decreases. Indeed at lower playback levels, low-level detail, such as ambience in the surround channels, can disappear altogether.

So-called loudness controls that attempt to compensate for this effect have been incorporated in home playback equipment for many years. They boost low and high frequencies, usually based in some way on the famous equal loudness curves originally published by Fletcher and Munson in 1933 and updated over the years, Fig. 45-9. However, until recently, there has been no practical way to relate the actions of these controls to the actual playback level the listener has chosen. For the most part, therefore, they have been largely ineffective.
What has been needed is a way to establish a playback reference level based on the actual measured acoustic output of the listener’s playback system. The scientifically correct compensation could then be applied based on the listener’s preferred listening level relative to the reference level. The lower the level, the more compensation would be applied.

Measuring the acoustic output of a home system was once beyond the realm of practicality. Today, however, it happens all the time in home theater systems featuring audio-video receivers (AVR) equipped with automatic loudspeaker balancing. The majority of mid- to high-end AVRs has built-in noise generators and provides a microphone making it possible to measure the loudness of each loudspeaker from the listening position and automatically adjust it to match the others. Taking advantage of this built-in feature, several technologies, including Dolby Volume, THX Spectral Balancing, and Audyssey Dynamic EQ, have been recently introduced that make it possible to establish a reference playback level in the home, and apply appropriate loudness compensation at lower levels. It is now possible to automatically achieve at any level the same balance of low, middle, and high frequencies, and of main to surround channels, as at reference level, bringing home reproduction that much closer to what sound mixers achieve in the dubbing theater or music studio.

45.9 What’s Next for Surround Sound?

5.1 remains the standard for film-based cinema, with EX used with some regularity for big epic and sci-fi films. This is in part because of cost and complexity issues, in part because the movie industry is pouring its resources into converting to digital cinema, and in part because of the industry’s overall industry satisfaction with 5.1 both artistically and with respect to cost-effectiveness. After all, as stereo pioneer Harvey Fletcher put it way back in the 1940s,

Stereophonic systems do not consist of two, three, or any other fixed number of channels. There [only] must be sufficient of these to give a good illusion of an infinite number.

On the other hand, digital cinema content is capable of delivering twenty or more channels of uncompressed PCM audio. Even with the increasing number of digital cinema installations, however, 5.1 remains the standard for digital releases. Not only is equipping cinemas with more playback channels expensive, but so is mixing soundtracks with more channels, particularly since mixing is one of the final postproduction steps when time may be running out. Moreover, whether to use the additional channels—and if so, which ones—is wide open. As the SMPTE puts it in its standard for digital cinema channel mapping (428-3-2006), “This standard is not intended to define the suitability of these channels to a particular track, nor to specify that all the channels described herein will be used,” Table 45-1.

Because the movie industry has not yet ventured into the realm of more than 5.1 discrete channels, it continues to deliver 5.1 content for broadcast and video disc release. But that isn’t stopping the consumer electronics industry from experimenting with 7.1 discrete audio content, just pioneered matrix 7.1 playback. Both Blu-ray Disc and HD DVD have ample storage capability for more channels, whether uncompressed PCM, or using lossless or lossy coding technologies offered by both Dolby and DTS. A few hardy pioneers are going back to movie soundtrack stems and remixing titles in discrete 7.1 for high-definition disc release, with the blessing and supervision of the film’s producers.

Playback in 7.1 discrete depends on home theater AVRs equipped with appropriate decoders, and both players and AVRs equipped with HDMI 1.3 connectivity, which is far from universal. It’s impossible to predict just what will happen, but it’s conceivable that the consumer electronics industry, whose surround sound technology so far has mostly migrated from the movie industry, may wind up ahead in the multichannel race—assuming consumers buy into it, of course.

Perhaps more significant than the potential for more channels, however, are the rapidly expanding opportunities for delivering 5.1 content. New broadcast standards developed to take advantage of new, more efficient video and audio codecs alike all feature 5.1 capability. These new codecs are fostering new delivery methods, such as IPTV, for 5.1 audio. And the future is likely to offer 5.1 download opportunities, such as Apple’s pioneering effort enabling the purchase and rentals of downloaded high-definition movies with Dolby Digital 5.1 audio. Indeed, there are those predicting that in the foreseeable future the Internet will overtake discs as the prime conduit for movies and other surround content into the home.

Regardless of what the future brings, however, surround sound has come a very long way already, from rarefied and costly magnetic sound in cinemas 50 years ago, to home theater audio systems costing as little as a few hundred dollars today. Involving the viewer is what surround is all about, and there’s no doubt that moviegoers and home viewers alike prefer—even
Surround Sound

demand—the surround experience in ever-increasing numbers, for every possible entertainment medium.

Table 45-1. Channel Definitions for Digital Cinema (SMPTE Standard 428-3-2006). So Far, However, 5.1 Remains the Norm for Digital as Well as Film-Based

<table>

Part 7

Measurements
This page intentionally left blank
46.1 Test and Measurement

Technological advancements in the last two decades have given us a variety of useful measurement tools, and most manufacturers of these instruments provide specialized training on their use. This chapter will examine some principles of test and measurement that are common to virtually all measurement systems. If the measurer understands the principles of measurement, then most any of the mainstream measurement tools will suffice for the collection and evaluation of data. The most important prerequisite to performing meaningful sound system measurements is that the measurer has a solid understanding of the basics of audio and acoustics. The question “How do I perform a measurement?” can be answered much more easily than “What should I measure?” This chapter will touch on both, but readers will find their measurements skills will relate directly to their understanding of the basic physics of sound and the factors that produce good sound quality. The whole of this book will provide much of the required information.

46.1.1 Why Test?

Sound systems must be tested to assure that all components are functioning properly. The test and measurement process can be subdivided into two major categories—electrical tests and acoustical tests. Electrical testing mainly involves voltage and impedance measurements made at component interfaces. Current can also be measured, but since the setup is inherently more complex it is usually calculated from knowledge of the voltage and impedance using Ohm’s Law. Acoustical tests are more complex by nature, but share the same fundamentals as electrical tests in that some time varying quantity (usually pressure) is being measured. The main difference between electrical and acoustical testing is that the interpretation of the latter must deal with the complexities of 3D space, not just amplitude versus time at one point in a circuit. In this chapter we will define a loudspeaker system as a number of components intentionally combined to produce a system that may then be referred to as a loudspeaker. For example, a woofer, dome tweeter, and crossover network are individual components, but can be combined to form a loudspeaker system. Testing usually involves the measurement of systems, although a system might have to be dissected to fully characterize the response of each component.

46.2 Electrical Testing

There are numerous electrical tests that can be performed on sound system components in the laboratory. The measurement system must have specifications that exceed the equipment being measured. Field testing need not be as comprehensive and the tests can be performed with less sophisticated instrumentation. The purpose for electrical field testing includes:

1. To determine if all system components are operating properly.
2. To diagnose electrical problems in the system, which are usually manifested by some form of distortion.
3. To establish a proper gain structure.

Electrical measurements can aid greatly in establishing the proper gain structure of the sound system. Electrical test instruments that the author feels are essential to the audio technician include:

- ac voltmeter.
- ac millivoltmeter.
- Oscilloscope.
- Impedance meter.
- Signal generator.
- Polarity test set.

It is important to note that most audio products have on-board metering and/or indicators that may suffice for setting levels, making measurements with stand-alone meters unnecessary. Voltmeters and impedance meters are often only necessary for troubleshooting a nonworking system, or checking the accuracy and calibration of the on-board metering.

There are a number of currently available instruments designed specifically for audio professionals that perform all of the functions listed. These instruments need to have bandwidths that cover the audible spectrum. Many general purpose meters are designed primarily for ac power circuits and do not fit the wide bandwidth requirement.

More information on electrical testing is included in the chapter on gain structure. The remainder of this chapter will be devoted to the acoustical tests that are required to characterize loudspeakers and rooms.

46.3 Acoustical Testing

The bulk of acoustical measurement and analysis today is being performed by instrumentation that includes or is controlled by a personal computer. Many excellent systems are available, and the would-be measurer
should select the one that best fits their specific needs. As with loudspeakers, there is no clear-cut best choice or one size fits all instrument. Fortunately an understanding of the principles of operating one analyzer can usually be applied to another after a short indoctrination period. Measurement systems are like rental cars—you know what features are there; you just need to find them. In this chapter I will attempt to provide a sufficient overview of the various approaches to allow the reader to investigate and select a tool to meet his or her measurement needs and budget. The acoustical field testing of sound reinforcement systems mainly involves measurements of the sound pressure fluctuations produced by a loudspeaker(s) at various locations in the space. Microphone positions are selected based on the information that is needed. This could be the on-axis position of a loudspeaker for system alignment purposes, or a listener seat for measuring the clarity or intelligibility of the system. Measurements must be made to properly calibrate the system, which can include loudspeaker crossover settings, equalization, and the setting of signal delays. Acoustic waveforms are complex by nature, making them difficult to describe with one number readings for anything other than broadband level.

46.3.1 Sound Level Measurements

Sound level measurements are fundamental to all types of audio work. Unfortunately, the question “How loud is it?” does not have a simple answer. Instruments can easily measure sound pressures, but there are many ways to describe the results in ways relevant to human perception. Sound pressures are usually measured at a discrete listener position. The sound pressure level may be displayed as is, integrated over a time interval, or frequency weighted by an appropriate filter. Fast meter response times produce information about peaks and transients in the program material, while slow response times yield data that correlates better with the perceived loudness and energy content of the sound.

A sound level meter consists of a pressure sensitive microphone, meter movement (or digital display), and some supporting circuitry, Fig. 46-1. It is used to observe the sound pressure on a moment-by-moment basis, with the pressure displayed as a level in decibels. Few sounds will measure the same from one instant to the next. Complex sounds such as speech and music will vary dramatically, making their level difficult to describe without a graph of level versus time, Fig. 46-2. A sound level meter is basically a voltmeter that operates in the acoustic domain.

Sound pressure measurements are converted into decibels ref. 0.00002 pascals. See Chapter 2, Fundamentals of Audio and Acoustics, for information about the decibel. Twenty micropascals are used as the reference because it is the threshold of pressure sensitivity for humans at midrange frequencies. Such measurements are referred to as sound pressure level or \( L_P \) (level of sound pressure) measurements, with \( L_P \) gaining acceptance among audio professionals because it is easily distinguished from \( L_W \) (sound power level) and \( L_I \) (sound intensity level) and a number of other \( L_X \) metrics used to describe sound levels. Sound pressure level is
measured at a single point (the microphone position). Sound power measurements must consider all of the radiated sound from a device and sound intensity measurements must consider the sound power flowing through an area. Sound power and sound intensity measurements are usually performed by acoustical laboratories rather than in the field, so neither is considered in this chapter. All measurements described in this chapter will be measurements of sound pressures expressed as levels in dB re 0.00002 Pa.

Sound level measurements must usually be processed for the data to correlate with human perception. Humans do not hear all frequencies with equal sensitivity, and to complicate things further our response is dependent on the level that we are hearing. The well-known Fletcher-Munson curves describe the frequency/level characteristics for an average listener, see Chapter 2. Sound level measurements are passed through weighting filters that make the meter “hear” with a response similar to a human. Each scale correlates with human hearing sensitivity at a different range of levels. For a sound level measurement to be meaningful, the weighting scale that was used must be indicated, in addition to the response time of the meter. Here are some examples of meaningful (if not universally accepted) expressions of sound level:

- The system produced an \( L_p = 100 \text{ dBA} \) (slow response) at mix position.
- The peak sound level was \( L_A = 115 \text{ dB} \) at my seat.
- The average sound pressure level was 100 dBC at 30 ft.
- The loudspeaker produced a continuous \( L_p \) of 100 dB at one meter (assumes no weighting used).
- The equivalent sound level \( L_{EQ} \) was 90 dBA at the farthest seat.

Level specifications should be stated clearly enough to allow someone to repeat the test from the description given. Because of the large differences between the weighting scales, it is meaningless to specify a sound level without indicating the scale that was used. An event that produces an \( L_p = 115 \text{ dB} \) using a C scale may only measure as an \( L_p = 95 \text{ dB} \) using the A scale.

The measurement distance should also be specified (but rarely is). Probably all sound reinforcement systems produce an \( L_p = 100 \text{ dB} \) at some distance, but not all do so at the back row of the audience!

\( L_{pk} \) is the level of the highest instantaneous peak in the measured time interval. Peaks are of interest because our sound system components must be able to pass them without clipping them. A peak that is clipped produces high levels of harmonic distortion that degrade sound quality. Also, clipping reduces the crest factor of the waveform, causing more heat to be generated in the loudspeaker causing premature failure. Humans are not extremely sensitive to the loudness of peaks because our auditory system integrates energy over time with regard to loudness. We are, unfortunately, susceptible to damage from peaks, so they should not be ignored. Research suggests that it takes the brain about 35 ms to process sound information (frequency-dependent), which means that sound events closer together than this are blended together with regard to loudness. This is why your voice sounds louder in a small, hard room. It is also why the loudness of the vacuum cleaner varies from room to room. Short interval reflections are integrated with the direct sound by the ear/brain system. Most sound level meters have slow and fast settings that change the response time of the meter. The slow setting of most meters indicates the approximate root-mean-square sound level. This is the effective level of the signal, and should correlate well with its perceived loudness.

A survey of audio practitioners on the Syn-Aud-Con e-mail discussion group revealed that most accept an \( L_p = 95 \text{ dBA} \) (slow response) as the maximum acceptable sound level of a performance at any listener seat for a broad age group audience. The A weighting is used because it considers the sound level in the portion of the spectrum where humans are most easily annoyed and damaged. The slow response time allows the measurement to ignore short duration peaks in the program. A measurement of this type will not indicate true levels for low-frequency information, but it is normally the mid-frequency levels that are of interest.

There exist a number of ways to quantify sound levels that are measured over time. They include:

- \( L_{pk} \)—the maximum instantaneous peak recorded during the span.
- \( L_{EQ} \)—the equivalent level (the integrated energy over a specified time interval).
- \( L_N \)—where \( L \) is the level exceeded \( N \) percent of the time.
- \( L_{DEN} \)—a special scale that weights the gathered sound levels based on the time of day. DEN stands for day-evening-night.
- \( DOSE \)—a measure of the total sound exposure.

A variety of instruments are available to measure sound pressure levels, ranging from the simple sound level meter (SLM) to sophisticated data-logging equipment. SLMs are useful for making quick checks of
sound levels. Most have at least an A- and C-weighting scale, and some have octave band filters that allow band-limited measurements. A useful feature on an SLM is an output jack that allows access to the measured data in the form of an ac voltage. Software applications are available that can log the meter’s response versus time and display the results in various ways. A plot of sound level versus time is the most complete way to record the level of an event. Fig. 46-2 is such a measurement. Note that a start time and stop time are specified. Such measurements usually provide statistical summaries for the recorded data. An increasing number of venues monitor the levels of performing acts in this manner due to growing concerns over litigation about hearing damage to patrons. SLMs vary dramatically in price, depending on quality and accuracy.

All sound level meters provide accurate indications for relative levels. For absolute level measurements a calibrator must be used to calibrate the measurement system. Many PC-based measurement systems have routines that automate the calibration process. The calibrator is placed on the microphone, Fig. 46-3, and the calibrator level (usually 94 or 114 dB ref. 20 \( \mu \text{Pa} \)) is entered into a data field. The measurement tool now has a true level to use as a reference for displaying measured data.

Noise criteria ratings provide a one-number specification for allowable levels of ambient noise. Sound level measurements are performed in octave bands, and the results are plotted on the chart shown in Fig. 46-4. The NC rating is read on the right vertical axis. Note that the NC curve is frequency-weighted. It permits an increased level of low-frequency noise, but becomes more stringent at higher frequencies. A sound system specification should include an NC rating for the space, since excessive ambient noise will reduce system clarity and require additional acoustic gain. This must be considered when designing the sound system. Instrumentation is available to automate noise criteria measurements.

46.3.1.1 Conclusion

Stated sound level measurements are often so ambiguous as to become meaningless. When stating a sound level, it is important to indicate:

1. The sound pressure level.
2. Any weighting scale used.
3. Meter response time (fast, slow or other).
4. The distance or location at which the measurement was made.

5. The type of program measured (i.e., music, speech, ambient noise).

Some correct examples:

- “The house system produced 90 dBA-Slow in section C for broadband program.”
“The monitor system produced 105 dBA-Slow at the performer’s head position for broadband program.”

“The ambient noise with room empty was NC-35 with HVAC running.”

In short, if you read the number and have to request clarification then sufficient information has not been given. As you can see, one-number SPL ratings are rarely useful.

All sound technicians should own a sound level meter, and many can justify investment in more elaborate systems that provide statistics on the measured sound levels. From a practical perspective, it is a worthwhile endeavor to train one’s self to recognize various sound levels without a meter, if for no other reason than to find an exit in a venue where excessive levels exist.

**46.3.2 Detailed Sound Measurements**

The response of a loudspeaker or room must be measured with appropriate frequency resolution to be characterized. It is also important for the measurer to understand what the appropriate response should be. If the same criteria were applied to a loudspeaker as to an electronic component such as a mixer, the optimum response would be a flat (minimal variation) magnitude and phase response at all frequencies within the required pass band of the system. In reality, we are usually testing loudspeakers to make sure that they are operating at their fullest potential. While flat magnitude and phase response are a noble objective, the physical reality is that we must often settle for far less in terms of accuracy. Notwithstanding, even with their inherent inaccuracies, many loudspeakers do an outstanding job of delivering speech or music to the audience. Part of the role of the measurer is to determine if the response of the loudspeaker or room is inhibiting the required system performance.

**46.3.2.1 Sound Persistence in Enclosed Spaces**

Sound system performance is greatly affected by the sound energy persistence in the listening space. One metric that is useful for describing this characteristic is the reverberation time, \( T_{30} \). The \( T_{30} \) is the time required for an interrupted steady-state sound source to decay to inaudibility. This will be about 60 dB of decay in most auditoriums with controlled ambient noise floors. The \( T_{30} \) designation comes from the practice of measuring 30 dB of decay and then doubling the time interval to get the time required for 60 dB of decay. A number of methods exist for determining the \( T_{30} \), ranging from simple listening tests to sophisticated analytical methods. Fig. 46-5 shows a simple gated-noise test that can provide sufficient accuracy for designing systems. The bursts for this test can be generated with a WAV editor. Burst of up to 5 seconds for each of eight octave bands should be generated. Octave band-limited noise is played into the space through a low directivity loudspeaker. The noise is gated on for one second and off for 1 second. The room decay is evaluated during the off span. If it decays completely before the next burst, the \( T_{30} \) is less than one second. If not, the next burst should be on for 2 seconds and off for 2 seconds. The measurer simply keeps advancing to the next track until the room completely decays in the off span, Figs. 46-6, 46-7, and 46-8. The advantages of this method include:

1. No sophisticated instrumentation is required.
2. The measurer is free to wander the space.
3. The nature of the decaying field can be judged.
4. A group can perform the measurement.

A test of this type is useful as a prelude to more sophisticated techniques.

**Figure 46-5. Level versus time plot of a one-octave band gated burst (2-second duration).**

**Figure 46-6. A room with \( T_{60} <2 \) seconds.**

**46.3.2.2 Amplitude versus Time**

Fig. 46-9 shows an audio waveform displayed as amplitude versus time. This representation is especially meaningful to humans since it can represent the motion of the eardrum about its resting position. The waveform shown is of a male talker recorded in an anechoic (echo-free)
environment. The 0 line represents the ambient (no signal) state of the medium being modulated. This would be ambient atmospheric pressure for an acoustical wave, or zero volts or a dc offset for an electrical waveform measured at the output of a system component.

Fig. 46-10 shows the same waveform, but this time played over a loudspeaker into a room and recorded. The waveform has now been encoded (convolved) with the response of the loudspeaker and room. It will sound completely different than the anechoic version.

Fig. 46-11 shows an impulse response and Fig. 46-12 shows the envelope-time curve (ETC) of the loudspeaker and room. It is essentially the difference between Fig. 46-9 and Fig. 46-10 that fully characterizes any effect that the loudspeaker or room has on the electrical signal fed to the loudspeaker and measured at that point in space. Most measurement systems attempt to measure the impulse response, since knowledge of the impulse response of a system allows its effect on any signal passing through it to be determined, assuming the system is linear and time invariant. This effect is called the transfer function of the system and includes both magnitude (level) and phase (timing) information for each frequency in the pass band. Both the loudspeaker and room can be considered filters that the energy must pass through en route to the listener. Treating them as filters allows their responses to be measured and displayed, and provides an objective benchmark to evaluate their effect. It also opens loudspeakers and rooms to evaluation by electrical network analysis methods, which are generally more widely

![Figure 46-7. A room with RT<sub>60</sub> > 2 seconds.](image)

![Figure 46-8. A room with RT<sub>60</sub> = 2 seconds.](image)

![Figure 46-9. Amplitude versus time plot of a male talker made in an anechoic environment.](image)

![Figure 46-10. The voice waveform after encoding with the room response.](image)

![Figure 46-11. The impulse response of the acoustic environment.](image)

![Figure 46-12. The envelope-time curve (ETC) of the same environment. It can be derived from the impulse response.](image)
known and better developed than acoustical measurement methods.

46.3.2.3 The Transfer Function

The effect that a filter has on a waveform is called its transfer function. A transfer function can be found by comparing the input signal and output signal of the filter. It matters little if the filter is an electronic component, loudspeaker, room, or listener. The time domain behavior of a system (impulse response) can be displayed in the frequency domain as a spectrum and phase (transfer function). Either the time or frequency description fully describes the filter. Knowledge of one allows the determination of the other. The mathematical map between the two representations is called a transform. Transforms can be performed at amazingly fast speeds by computers. Fig. 46-13 shows a domain chart that provides a map between various representations of a system’s response. The measurer must remember that the responses being measured and displayed on the analyzer are dependent on the test stimulus used to acquire the response. Appropriate stimuli must have adequate energy content over the pass band of the system being measured. In other words, we can’t measure a subwoofer using a flute solo as a stimulus. With that criteria met, the response measured and displayed on the analyzer is independent of the program material that passes through a linear system. Pink noise and sine sweeps are common stimuli due to their broadband spectral content. In other words, the response of the system doesn’t change relative to the nature of the program material. For a linear system, the transfer function is a summary that says, “If you put energy into this system, this is what will happen to it.”

The domain chart provides a map between various methods of displaying the system’s response. The utility of this is that it allows measurement in either the time or frequency domain. The alternate view can be determined mathematically by use of a transform. This allows frequency information to be determined with a time domain measurement, and time information to be determined by a frequency domain measurement. This important inverse relationship between time and frequency can be exploited to yield many possible ways of measuring a system and/or displaying its response. For instance, a noise immunity characteristic not attainable in the time domain may be attainable in the frequency domain. This information can then be viewed in the time domain by use of a transform. The Fourier Transform and its inverse are commonly employed for this purpose. Measurement programs like Arta can display the signal in either domain, Fig. 46-14.

46.3.3 Measurement Systems

Any useful measurement system must be able to extract the system response in the presence of noise. In some applications, the signal-to-noise requirements might actually determine the type of analysis that will be used. Some of the simplest and most convenient tests have poor signal-to-noise performance, while some of the most complex and computationally demanding methods can measure under almost any conditions. The measurer must choose the type of analysis with these factors in mind. It is possible to acquire the impulse response of a filter without using an impulse. This is accomplished by feeding a known broadband stimulus into the filter and reacquiring it at the output. A complex comparison of the two signals (mathematical division) yields the transfer function, which is displayed in the frequency domain as a magnitude and phase or inverse-transformed for display in the time domain as an impulse response. The impulse response of a system answers the question, “If I feed a perfect impulse into this system, when will the energy exit the system?” A knowledge of “when” can characterize a system. After transformation, the spectrum or frequency response is displayed on a decibel scale. A phase plot shows the phase response of the device-under-test, and any phase shift versus frequency becomes apparent. If an impulse response is a measure of when, we might describe a frequency response as a measure of what. In other words, “If I input a broadband stimulus (all frequencies) into the system, what frequencies will be present at the output of the system and what will their phase relationship be?” A transfer function includes both magnitude and phase information.

46.3.3.1 Alternate Perspectives

The time and frequency views of a system’s response are mutually exclusive. By definition the time period of a periodic event is

$$ T = \frac{1}{f} \quad (46-1) $$

where,

- $T$ is time in seconds,
- $f$ is frequency in hertz.

Since time and frequency are reciprocals, a view of one excludes a view of the other. Frequency information cannot be observed on an impulse response plot, and
time information can’t be observed on a magnitude/phase plot. Any attempt to view both simultaneously will obscure some of the detail of both. Modern analyzers allow the measurer to switch between the time and frequency perspectives to extract information from the data.

46.3.4 Testing Methods

Compared to other components in the sound system, the basic design of loudspeakers and compression drivers has changed relatively little in the last 50 years. At over a half-century since their invention, we are still pushing air with pistons driven by voice coils suspended in magnetic fields. But the methods for measuring their performance have improved steadily since computers can now efficiently perform digital sampling and signal processing, and execute transforms in fractions of a second. Extremely capable measurement systems are now accessible and affordable to even the smallest manufacturers and individual audio practitioners. A common attribute of systems suitable for loudspeaker testing is the ability to make reflection-free measurements indoors, without the need for an anechoic chamber. Anechoic measurements in live spaces can be accomplished by the use of a time window that allows the analyzer to collect the direct field response of the loudspeaker while ignoring room reflections. Conceptually, a time window can be thought of as an accurate switch that can be closed as the desired waves pass the microphone and opened prior to the arrival of undesirable reflections from the environment. A number of implementations exist, each with its own set of advantages and drawbacks. The potential buyer must understand the trade-offs and choose a system that offers the best set of compromises for the intended application. Parameters of interest include signal-to-noise ratios, speed, resolution, and price.
46.3.4.1 FFT Measurements

The Fourier Transform is a mathematical filtering process that determines the spectral content of a time domain signal. The Fast Fourier Transform, or FFT, is a computationally efficient version of the same. Most modern measurement systems make use of the computer’s ability to quickly perform the FFT on sampled data. The cousin to the FFT is the IFFT, or Inverse Fast Fourier Transform. As one might guess, the IFFT takes a frequency domain signal as its input and produces a time domain signal. The FFT and IFFT form the bed-rock of modern measurement systems. Many fields outside of audio use the FFT to analyze time records for periodic activity, such as utility companies to find peak usage times or an investment firm to investigate cyclic stock market behavior. Analyzers that use the Fast Fourier Transform to determine the spectral content of a time-varying signal are collectively called FFTs. If a broadband stimulus is used, the FFT can show the spectral response of the device under test (DUT). One such stimulus is the unit impulse, a signal of theoretically infinite amplitude and infinitely small time duration.

Figure 46-14. The FFT can be used to view the spectral content of a time domain measurement, Arta 1.2.
The FFT of such a stimulus is a straight, horizontal line in the frequency domain.

The time-honored hand clap test of a room is a crude but useful form of impulse response. The hand clap is useful for casual observations, but more accurate and repeatable methods are usually required for serious audio work. The drawbacks of using impulsive stimuli to measure a sound system include:

1. Impulse responses have poor signal-to-noise ratios, since all of the energy enters the system at one time and is reacquired over a longer span of time along with the noise from the environment.
2. There is no way to create a perfect impulse, so there will always be some uncertainty as to whether the response characteristic is that of the system, the impulse, or some nonlinearity arising from impulsing a loudspeaker.

Even with its drawbacks, impulse testing can provide useful information about the response of a loudspeaker or room.

46.3.4.2 Dual-Channel FFT

When used for acoustic measurements, dual-channel FFT analyzers digitally sample the signal fed to the loudspeaker, and also digitally sample the acoustic signal from the loudspeaker at the output of a test microphone. The signals are then compared by division, yielding the transfer function of the loudspeaker. Dual-channel FFTs have the advantage of being able to use any broadband stimulus as a test signal. This advantage is offset somewhat by poorer signal-to-noise performance and stability than other types of measurement systems, but the performance is often adequate for many measurement chores. Pink noise and swept sines provide much better stability and noise immunity. It is a computationally intense method since both the input and output signal must be measured simultaneously and compared, often in real time. For a proper comparison to yield a loudspeaker transfer function, it is important that the signals being compared have the same level, and that any time offsets between the two signals be removed. Dual-channel FFT analyzers have set up routines that simplify the establishment of these conditions. Portable computers have A/D converters as part of their on-board sound system, as well as a microprocessor to perform the FFT. With the appropriate software and sound system interface they form a powerful, low-cost and portable measurement platform.

46.3.4.3 Maximum-Length Sequence

The maximum-length sequence (MLS) is a pseudorandom noise test stimulus. The MLS overcomes some of the shortcomings of the dual-channel FFT, since it does not require that the input signal to the system be measured. A binary string (ones and zeros) is fed to the device under test while simultaneously being stored for future correlation with the loudspeaker response acquired by the test microphone. The pseudorandom sequence has a white spectrum (equal energy per Hz), and is exactly known and exactly repeatable. Comparing the input string with the string acquired by the test microphone yields the transfer function of the system. The advantage of the MLS is its excellent noise immunity and fast measurement time, making it a favorite of loudspeaker designers. A disadvantage is that the noise-like stimulus can be annoying, sometimes requiring that measurements be done after hours. The use of MLS has waned in recent years to log-swept sine measurements made on dual-channel FFT analyzers.

46.3.4.4 Time-Delay Spectrometry (TDS)

TDS is a fundamentally different method of measuring the transfer function of a system. Richard Heyser, a staff scientist at the Jet Propulsion Laboratories, invented the method. An anthology of Mr. Heyser’s papers on TDS is available in the reference. Both the dual-channel FFT and MLS methods involve digital sampling of a broadband stimulus. TDS uses a method borrowed from the world of sonar, where a single-frequency sinusoidal “chirp” signal is fed to the system under test. The chirp slowly sweeps through the frequencies being measured, and is reacquired with a tracking filter by the TDS analyzer. The reacquired signal is then mixed with the outgoing signal, producing a series of sum and difference frequencies, each frequency corresponding to a different arrival time of sound at the microphone. The difference frequencies are transformed to the time domain with the appropriate transform, yielding the envelope-time Curve (ETC) of the system under test. TDS is based on the frequency domain, allowing the tracking filter to be tuned to the desired signal while ignoring signals outside of its bandwidth. TDS offers excellent noise immunity, allowing good data to be collected under near-impossible measurement conditions. Its downside is that good low-frequency resolution can be difficult to obtain without extended measurement times, plus the correct selection of measurement parameters requires a knowledgeable user. In spite of this, it is a favorite
among contractors and consultants, who must often perform sound system calibrations in the real world of air conditioners, vacuum cleaners, and building occupants.

While other measurement methods exist, the ones outlined above make up the majority of methods used for field and lab testing of loudspeakers and rooms. Used properly, any of the methods can provide accurate and repeatable measured data. Many audio professionals have several measurement platforms and exploit the strong points of each when measuring a sound system.

46.3.5 Preparation

There are many measurements that can be performed on a sound system. A prerequisite to any measurement is to answer the following questions:

1. What am I trying to measure?
2. Why am I trying to measure it?
3. Is it audible?
4. Is it relevant?

Failure to consider these questions can lead to hours of wasted time and a hard drive full of meaningless data. Even with the incredible technologies that we have available to us, the first part of any measurement session is to listen. It can take many hours to determine what needs to be measured to solve a sound system problem, yet the actual measurement itself can often be completed in seconds. Using an analogy from the medical field, the physician must query the patient at length to narrow down the ailment. The more that is known about the ailment, the more specific and relevant the tests that can be run for diagnosis. There is no need to test for tonsillitis if the problem is a sore back!

1. What am I measuring? A fundamental decision that precedes a meaningful measurement is how much of the room’s response to include in the measured data. Modern measurement systems have the ability to perform semianechoic measurements, and the measurer must decide if the loudspeaker, the room, or the combination needs to be measured. If one is diagnosing loudspeaker ailments, there is little reason to select a time window long enough to include the effects of late reflections and reverberation. A properly selected time window can isolate the direct field of the loudspeaker and allow its response to be evaluated independently of the room. If one is trying to measure the total decay time of the room, the direct sound field becomes less important, and a microphone placement and time window are selected to capture the entire energy decay. Most modern measurement systems acquire the complete impulse response, including the room decay, so the choice of the time window size can be made after the fact during post processing.

2. Why am I measuring? There are several reasons for performing acoustic measurements in a space. An important reason for the system designer is to characterize the listening environment. Is it dead? Is it live? Is it reverberant? These questions must be considered prior to the design of a sound system for the space. While the human hearing system can provide the answers to these questions, it cannot document them and it is easily deceived. Measurements might also be performed to document the performance of an existing system prior to performing changes or adding room treatment. Customers sometimes forget how bad it once sounded after a new or upgraded system is in place for a few weeks.

The most common reason for performing measurements on a system is for calibration purposes. This can include equalization, signal alignment, crossover selection, and a multiplicity of other reasons. Since loudspeakers interact in a complex way with their environment, the final phase of any system installation is to verify system performance by measurement.

3. Is it audible? Can I hear what I am trying to measure? If one cannot hear an anomaly, there is little reason to attempt to measure it. The human hearing system is perhaps the best tool available for determining what should be measured about a sound system. The human hearing system can tell us that something doesn’t sound right, but the cause of the problem can be revealed by measurement. Anything you can hear can be measured, and once it is measured it can be quantified and manipulated.

4. Is it relevant? Am I measuring something that is worth measuring? If one is working for a client, time is money. Measurements must be prioritized to focus on audible problems. Endless hours can be spent “chasing rabbits” by measuring details that are of no importance to the client. This is not necessarily a fruitless process, but it is one that should be done on your own time. I have on several occasions spent time measuring and documenting anomalies that had nothing to do with the customer’s reason for calling me. All venues have problems that the owner is unaware of. Communication with the client is the best way to avoid this pitfall.
46.3.5.1 Dissecting the Impulse Response

The audio practitioner is often faced with the dilemma of determining whether the reason for bad sound is the loudspeaker system, the room, or an interaction of the two. The impulse response can hold that answer to these and other perplexing questions. The impulse response in its amplitude versus time display is not particularly useful for other than determining the polarity of a system component, Fig. 46-15. A better representation comes from squaring impulse response (making all deflections positive) and displaying the square root of the result on a logarithmic vertical scale. This log-squared response allows the relative levels of energy arrivals to be compared, Fig. 46-16.

![Figure 46-15. The impulse response, SIA-SMAART.](image)

[Figure 46-15. The impulse response, SIA-SMAART.]

![Figure 46-16. The log-squared response, SIA-SMAART.](image)

[Figure 46-16. The log-squared response, SIA-SMAART.]

46.3.5.2 The Envelope-Time Curve

Another useful way of viewing the impulse response is in the form of the envelope-time curve, or ETC. The ETC is also a contribution of Richard Heyser.\(^2\) It takes the real part of the impulse response and combines it with a 90 degrees phase shifted version of the same, Fig. 46-17. One way to get the shifted version is to use the Hilbert Transform. The complex combination of these two signals yields a time domain waveform that is often easier to interpret than the impulse response. The ETC can be loosely thought of as a smoothing function for the log-squared response, showing the envelope of the data. This can be more revealing as to the audibility of an event. The impulse response, log-squared response, and energy-time curve are all different ways to view the time domain data.

![Figure 46-17. The envelope-time curve (ETC), SIA-SMAART.](image)

[Figure 46-17. The envelope-time curve (ETC), SIA-SMAART.]

46.3.5.3 A Global Look

When starting a measurement session, a practical approach is to first take a global look and measure the complete decay of the room. The measurer can then choose to ignore part of the time record by using a time window to isolate the desired part during postprocessing. The length of the time window can be increased to include the effects of more of the energy returned by the room. The time window can also be used to isolate a reflection and view its spectral content. Just like your life span represents a time window in human history, a time window can be used to isolate parts of the impulse response.

46.3.5.4 Time Window Length

The time domain response can be divided to identify the portion that can be attributed to the loudspeaker and that which can be attributed to the room. It must be emphasized that there is a rather gray and frequency-dependent line between the two, but for this discussion we will assume that we can clearly separate them. The direct field is the energy that arrives at the listener prior to any reflections from the room. The division is fairly distinct if neither the loudspeaker nor microphone is placed near any reflecting surfaces, which, by the way, is a good system design practice. At long wavelengths
(low frequencies) the direct field may include the effects of boundaries near the loudspeaker and microphone. As frequency increases, the sound from the loudspeaker becomes less affected by boundary effects (due in part to increased directivity) and can be measured independently of them. Proper loudspeaker placement produces a time gap between the sound energy arrivals from the loudspeaker and the later arriving room response. We can use this time gap to aid in selecting a time window to separate the loudspeaker response from the room response and diagnosing system problems.

46.3.5.5 Acoustic Wavelengths

Sound travels in waves. The sound waves that we are interested in characterizing have a physical size. There will be a minimum time span required to observe the spectral response of a waveform. The minimum required length of time to view an acoustical event is determined by the longest wavelength (lowest frequency) present in the event. At the upper limits of human hearing, the wavelengths are only a few millimeters in length, but as frequency decreases the waves become increasingly larger. At the lowest frequencies that humans hear, the wavelengths are many meters long, and can actually be larger than the listening (or measurement) space. This makes it difficult to measure low frequencies from a loudspeaker independently of the listening space, since low frequencies radiated from a loudspeaker interact (couple) with the surfaces around them. In an ideally positioned loudspeaker, the first energy arrival from the loudspeaker at mid- and high frequencies has already dissipated prior to the arrival of reflections and can therefore often be measured independently of them. The human hearing system tends to fuse the direct sound from the loudspeaker with the early reflections from nearby surfaces with regard to level (loudness) and frequency (tone). It is usually useful to consider them as separate events, especially since the time offset between the direct sound and first reflections will be unique for each listening position. This precludes any type of frequency domain correction (i.e., equalization) of the room/loudspeaker response other than at frequencies where coupling occurs due to close proximity to nearby surfaces. While it is possible to compensate to some extent for room reflections at a point in space (acoustic echo cancellers used for conference systems), this correction cannot be extended to include an area. This inability to compensate for the reflected energy at mid/high frequencies suggests that their effects be removed from the loudspeaker’s direct field response prior to meaningful equalization work by use of an appropriate time window.

46.3.5.6 Microphone Placement

A microphone is needed to acquire the sound radiated into the space from the loudspeaker at a discrete position. Proper microphone placement is determined by the type of test being performed. If one were interested in measuring the decay time of the room, it is usually best to place the microphone well beyond critical distance. This allows the build-up of the reverberant field to be observed as well as providing good resolution of the decaying tail. Critical distance is the distance from the loudspeaker at which the direct field level and reverberant field level are equal. It is described further in Section 46.3.5.7. If it’s the loudspeaker’s response that needs to be measured, then a microphone placement inside of critical distance will provide better data on some types of analyzers, since the direct sound field is stronger relative to the later energy returning from the room. If the microphone is placed too close to the loudspeaker, the measured sound levels will be accurate for that position, but may not accurately extrapolate to greater distances with the inverse-square law. As the sound travels further, the response at a remote listening position may bear little resemblance to the response at the near field microphone position. For this reason, it is usually desirable to place the microphone in the far free field of the loudspeaker—not too close and not too far away. The approximate extent of the near field can be determined by considering that the path length difference from the measurement position (assumed axial) and the edge of the sound radiator should be less than \( \frac{1}{4} \) wavelength at the frequency of interest. This condition is easily met for a small loudspeaker that is radiating low frequencies. Such devices closely approximate an ideal point source. As the frequency increases the condition becomes more difficult to satisfy, especially if the size of the radiator also increases. Large radiators (or groups of radiators) emitting high frequencies can extend the near field to very long distances. Line arrays make use of this principle to overcome the inverse-square law. In practice, small bookshelf loudspeakers can be accurately measured at a few meters. About 10 m is a common measurement distance for moderate-sized, full-range loudspeakers in a large space. Even greater distances are required for large devices radiating high frequencies. A general guideline is to not put the mic closer than three times the loudspeaker’s longest dimension.
46.3.5.7 Estimate the Critical Distance $D_C$

Critical distance is easy to estimate. A quick method with adequate accuracy requires a sound level meter and noise source. Ideally, the noise source should be band limited, as critical distance is frequency dependent. The 2 kHz octave band is a good place to start when measuring critical distance. Proceed as follows:

1. Energize the room with pink noise in the desired octave band from the sound source being measured. The level should be at least 25 dB higher than the background noise in the same octave band.
2. Using the sound level meter, take a reading near the loudspeaker (about 1 m) and on-axis. At this distance, the direct sound field will dominate the measurement.
3. Move away from the loudspeaker while observing the sound level meter. The sound level will fall off as you move farther away. If you are in a room with a reverberant sound field, at some distance the meter reading will quit dropping. You have now moved beyond critical distance. Measurements of the direct field beyond this point will be a challenge for some types of analysis. Move back toward the loudspeaker until the meter begins to rise again. You are now entering a good region to perform acoustic measurements on loudspeakers in this environment. The above process provides an estimate that is adequate for positioning a measurement microphone for loudspeaker testing. With a mic placement inside of critical distance, the direct field is a more dominant feature on the impulse response and a time window will be more effective in removing room reflections.

At this point it is interesting to wander around the room with the sound level meter and evaluate the uniformity of the reverberant field. Rooms that are reverberant by the classical definition will vary little in sound level beyond critical distance when energized with a continuous noise spectrum. Such spaces have low internal sound absorption relative to their volume.

46.3.5.8 Common Factors to All Measurement Systems

Let's assume that we wish to measure the impulse response of a loudspeaker/room combination. While it would not be practical to measure the response at every seat, it is good measurement practice to measure at as many seats as are required to prove the performance of the system. Once the impulse response is properly acquired, any number of postprocesses can be performed on the data to extract information from it. Most modern measurement systems make use of digital sampling in acquiring the response of the system. The fundamentals and prerequisites are not unlike the techniques used to make any digital recording, where one must be concerned with the level of an event and its time length. Some setup is required and some fundamentals are as follows:

1. The sampling rate must be fast enough to capture the highest frequency component of interest. This requires at least two samples of the highest frequency component. If one wished to measure to 20 kHz, the required sample rate would need to be at least 40 kHz. Most measurement systems sample at 44.1 kHz or 48 kHz, more than sufficient for acoustic measurements.
2. The time length of the measurement must be long enough to allow the decaying energy curve to flatten out into the room noise floor. Care must be taken to not cut off the decaying energy, as this will result in artifacts in the data, like a scratch on a phonograph record. If the sampling rate is 44.1 kHz, then 44,100 samples must be collected for each second of room decay. A 3-second room would therefore require 44.1 × 1000 × 3 or 128,000 samples. A hand clap test is a good way to estimate the decay time of the room and therefore the required number of samples to fully capture it. The time span of the measurement also determines the lowest frequency that can be resolved from the measured data, which is approximately the inverse of the measurement length. The sampling rate can be reduced to increase the sampling time to yield better low-frequency information. The trade-off is a reduction in the highest frequency that can be measured, since the condition outlined in step one may have been violated.
3. The measurement must have a sufficient signal-to-noise ratio to allow the decaying tail to be fully observed. This often requires that the measurement be repeated a number of times and the results averaged. Using a dual-channel FFT or MLS, the improvement in SNR will be 3 dB for each doubling of the number of averages. Ten averages is a good place to start, and this number can be increased or decreased depending on the environment. The level of the test stimulus is also important. Higher levels produce improved SNR, but can also stress the loudspeaker.
4. Perform the test and observe the data. It should fill the screen from top left to bottom right and be fully
decayed prior to reaching the right side of the screen. It should also be repeatable. Run the test several times to check for consistency. Background noise can dramatically affect the repeatability of the measurement and the validity of the data.

Once the impulse response is acquired, it can be further analyzed for spectral content, intelligibility information, decay time, etc. These are referred to as metrics, and some require some knowledge on the part of the measurer in properly placing markers (called cursors) to identify the parameters required to perform the calculations. Let us look at how the response of the loudspeaker might be extracted from the data just gathered.

The time domain data displays what would have resulted if an impulse were fed through the system. Don’t try to correlate what you see on the analyzer with what you heard during the test. Most measurement systems display an impulse response that is calculated from a knowledge of the input and output signal to the system, and there is no resemblance between what you hear when the test is run and what you are seeing on the screen, Fig. 46-18.

We can usually assume that the first energy arrival is from the loudspeaker itself, since any reflection would have to arrive later than the first wave front since it had to travel farther. Pre-arrivals can be caused by the acoustic wave propagating through a solid object, such as a ceiling or floor and reradiating near the microphone. Such arrivals are very rare and usually quite low in level. In some cases a reflection may actually be louder than the direct arrival. This could be due to loudspeaker design or its placement relative to the mic location. It’s up to the measurer to determine if this is normal for a given loudspeaker position/seating position. All loudspeakers will have some internal and external reflections that will arrive just after the first wave front. These are actually a part of the loudspeaker’s response and can’t be separated from the first wave front with a time window due to their close proximity without extreme compromises in frequency resolution. Such reflections are at least partially responsible for the characteristic sound of a loudspeaker. Studio monitor designers and studio control room designers go to great lengths to reduce the level of such reflections, yielding more accurate sound reproduction. Good system design practice is to place loudspeakers as far as possible from boundaries (at least at mid- and high frequencies). This will produce an initial time gap between the loudspeaker’s response and the first reflections from the room. This gap is a good initial dividing point between the loudspeaker’s response and the room’s response, with the energy to the left of the dividing cursor being the response of the loudspeaker and the energy to the right the response of the room. The placement of this divider can form a time window by having the analyzer ignore everything later in time than the cursor setting. The time window size also determines the frequency resolution of the post-processed data. In the frequency domain, improved resolution means a smaller number. For instance, 10 Hz resolution is better than 40 Hz resolution. Since time and frequency have an inverse relationship, the time window length required to observe 10 Hz will be much longer than the time window length required to resolve 40 Hz. The resolution can be estimated by $f = \frac{1}{T}$, where $T$ is the length of the time window in seconds. Since a frequency magnitude plot is made up of a number of data points connected by a line, another way to view the frequency resolution is that it is the number of Hz between the data points in a frequency domain display.

The method of determination of the time window length varies with different analyzers. Some allow a cursor to be placed anywhere on the data record, and the placement determines the frequency resolution of the spectrum determined by the window length. Others require that the measurer select the number of samples to be used to form the time window, which in turn determines the frequency resolution of the time window. The window can then be positioned at different places on the time domain plot to observe the spectral content of the energy within the window, Figs. 46-19, 46-20, and 46-21.

For instance, a 1 second total time (44,100 samples) could be divided into about twenty two time windows of 2048 samples each (about 45 ms). Each window would allow the observation of the spectral content down to $(\frac{1}{48}) \times 1000$ or 22 Hz. The windows can be overlapped and moved around to allow more precise selection of the time span to be observed. Displaying a
number of these time windows in succession, each separated by a time offset, can form a 3D plot known as a waterfall.

46.3.5.9 Data Windows

There are some conditions that must be observed when placing cursors to define the time window. Ideally, we would like to place the cursor at a point on the time record where the energy is zero. A cursor placement that cuts off an energy arrival will produce a sharp rise or fall time that produces artifacts in the resultant calculated spectral response. Discontinuities in the time domain have broad spectral content in the frequency domain. A good example is a scratch on a phonograph record. The discontinuity formed by the scratch manifests itself as a broadband click during playback. If an otherwise smooth wheel has a discontinuity at one point, it would thump annoyingly when it was rolled on a smooth surface. Our measurement systems treat the data within the selected window as a continuously repeating event. The end of the event must line up with the beginning or a discontinuity occurs resulting in the generation of high-frequency artifacts called spectral leakage. In the same manner that a physical discontinuity in a phonograph record or wheel can be corrected by polishing, a discontinuity in a sampled time measure-

Figure 46-19. A room response showing the various sound fields that can exist in an enclosed space, SIA-SMAART.

Figure 46-20. A time window can be used to isolate the loudspeaker’s response from the room reflections.
Test and Measurement

ment can be remedied by tapering the energy at the beginning and end of the window to zero using a mathematical function. A number of data window shapes are available for performing the smoothing.

These include the Hann, Hamming, Blackman-Harris, and others. In the same way that a physical polishing process removes some good material from what is being rubbed, data windows remove some good data in the process of smoothing the discontinuity. Each window has a particular shape that leaves the data largely untouched at the center of the window but tapers it to varying degrees toward the edges. Half windows only smooth the data at the right edge of the time record while full windows taper both (start and stop) edges. Since all windows have side effects, there is no clear preference as to which one should be used. The Hann window provides a good compromise between time record truncation and data preservation. Figs. 46-22 and 46-23 show how a data window might be used to reduce spectral leakage.

46.3.5.10 A Methodical Approach

Since there are an innumerable number of tests that can be performed on a system, it makes sense to establish a methodical and logical process for the measurement session. One such scenario may be as follows:

1. Determine the reason for and scope of the measurement session. What are you looking for? Can you hear it? Is it repeatable? Why do you need this information?

2. Determine what you are going to measure. Are you looking at the room or at the sound system? If it is the room, possibly the only meaningful measurements will be the overall decay time and the noise floor. If you are looking at the sound system, decide if you need to switch off or disconnect some loudspeakers. This may be essential to determine whether the individual components are working properly, or that an anomaly is the result of interaction between several components. “Divide and conquer” is the axiom.

Figure 46-21. Increasing the length of the time window increases the frequency resolution, but lets more of the room into the measurement, SIA-SMAART.

Figure 46-22. The impulse response showing both early and late energy arrivals.
3. Select the microphone position. I usually begin by looking at the on-axis response of the loudspeaker as measured from inside of critical distance. If multiple loudspeakers are on, turn all of them off but one prior to measuring. The microphone should be placed in the far free field of the loudspeaker as previously described. When measuring a loudspeaker’s response, care should be taken to eliminate the effects of early reflections on the measured data, as these will generate acoustic comb filters that can mask the true response of the loudspeaker. In most cases the predominant offending surface will be the floor or other boundaries near the microphone and loudspeaker. These reflections can be reduced or eliminated by using a ground plane microphone placement, a tall microphone stand (when the loudspeaker is overhead), or some strategically placed absorption. I prefer the tall microphone stand for measuring installed systems with seating present since it works most anywhere, regardless of the seating type. The idea is to intercept the sound on its way to a listener position, but before it can interact with the physical boundaries around that position. These will always be unique to that particular seat, so it is better to look at the free field response, as it is the common denominator to many listener seats.

4. Begin with the big picture. Measure an impulse response of the complete decay of the space. This yields an idea of the overall properties of the room/system and provides a good point of reference for zooming in to smaller time windows. Save this information for documentation purposes, as later you may wish to reopen the file for further processing.

5. Reduce the size of the time window to eliminate room reflections. Remember that you are trading off frequency resolution when truncating the time record, Fig. 46-24. Be certain to maintain sufficient resolution to allow adequate low-frequency detail. In some cases, it may be impossible to maintain a sufficiently long window to view low frequencies and at the same time eliminate the effects of reflections at higher frequencies, Fig. 46-25. In such cases, the investigator may wish to use a short window for looking at the high-frequency direct field, but a longer window for evaluating the woofer. Windows appropriate for each part of the spectrum can be used. Some measurement systems provide variable time windows, which allow low frequencies to be viewed in great detail (long time window) while still providing a semianechoic view (short time window) at high frequencies. There is evidence to support that this is how humans process sound information, making this method particularly interesting, Fig. 46-26.

6. Are other microphone positions necessary to characterize this loudspeaker? The off-axis response of some loudspeakers is very similar to the on-axis response, reducing the need to measure at many angles. Other loudspeakers have very erratic responses, and a measurement at any one point around the loudspeaker may bear little resemblance to the response at other positions. This is a design issue, but one that must be considered by the measurer.

7. Once an accurate impulse response is measured, it can be postprocessed to yield information on spectral content, speech intelligibility, and music clarity. There are a number of metrics that can provide this information. These are interpretations of the measured data and generally correlate with subjective perception of the sound at that seat.

8. An often overlooked method of evaluating the impulse response is the use of convolution to encode it onto anechoic program material. An excellent freeware convolver called GratisVol is available from www.catt.se. Listening to the IR can often reveal subtleties missed by the various metrics, as well as provide clues as to what postprocess must be used to observe the event of interest.
46.3.6 Human Perception

Useful measurement systems can measure the impulse response of a loudspeaker/room combination with great detail. Information regarding speech intelligibility and music clarity can be derived from the impulse response. In nearly all cases, this involves postprocessing the impulse response using one of several clarity measure metrics.

46.3.6.1 Percentage Articulation Loss of Consonants—(%Alcons)

For speech, one such metric is the percentage articulation loss of consonants, or %Alcons. Though not in widespread use today, a look at it can provide insight into the requirements for good speech intelligibility. A %Alcons measurement begins with an impulse response, which is usually displayed as a log-squared response or ETC. Since the calculation essentially...
examines the ratio between early energy, late energy, and noise, the measurer must place cursors on the display to define these parameters. These cursors may be placed automatically by the measurement program. The result is weighted with regard to decay time, so this too must be defined by the measurer. Analyzers such as the TEF25™ and EASERA include best guess default placements based on the research of Peutz, Davis, and others, Fig. 46-27.

These placements were determined by correlating measured data with live listener scores in various acoustic environments, and represent a defined and
orderly approach to achieving meaningful results that correlate with the perception of live listeners. The measurer is free to choose alternate cursor placements, but great care must be taken to be consistent. Also, alternate cursor placements make it difficult if not impossible to compare your results with those obtained by other measurers. In the default %Alcons placement, the early energy (direct sound field) includes the first major sound arrival and any energy arrivals within the next 7–10 ms. This forms a tight time span for the direct sound. Energy beyond this span is considered late energy and an impairment to communication. As one might guess, a later cursor placement yields better intelligibility scores, since more of the room response is being considered beneficial to intelligibility. As such, the default placement yields a worst-case scenario. The default placement considers the effects of the early-decay time (EDT) rather than the classical $T_{30}$ since short EDTs can yield good intelligibility, even in rooms with a long $T_{30}$. Again, the measurer is free to select an alternative cursor placement for determining the decay time used in the calculation, with the same caveats as placing the early-to-late dividing cursor. The %Alcons score is displayed instantly upon cursor placement and updates as the cursors are moved.

46.3.6.2 Speech Transmission Index—(STI)

The STI can be calculated from the measured impulse response with a routine outlined by Schroeder and detailed by Becker in the reference. The STI is probably the most widely used contemporary measure of intelligibility. It is supported by virtually all measurement platforms, and some handheld analyzers are available for quick checks. In short, it is a number ranging from 0 to 1, with fair intelligibility centered at 0.5 on the scale. For more details on the Speech Transmission Index, see the chapter on speech intelligibility in this text.

46.3.7 Polarity

Good sound system installation practice dictates maintaining proper signal polarity from system input to system output. An audio signal waveform always swings above and below some reference point. In acoustics, this reference point is the ambient atmospheric pressure. In an electronic device, the reference is the 0 VA reference of the power supply (often called signal ground) in push-pull circuits or a fixed dc offset in class A circuits. Let’s look at the acoustic situation first. An increase in the air pressure caused by a sound wave will produce an inward deflection of the diaphragm of a pressure microphone (the most common type) regardless of the microphone’s orientation toward the source. This inward deflection should cause a positive-going voltage swing at the output of the microphone on pin 2 relative to pin 3, as well as at the output of each piece of equipment that the signal passes through. Ultimately the electrical signal will be applied to a loudspeaker, which should deflect outward (toward an axial listener) on the positive-going signal, producing an increase in the ambient atmospheric pressure. Think of the microphone diaphragm and loudspeaker diaphragm moving in tandem and you will have the picture. Since most sound reinforcement equipment uses bipolar power supplies (allowing the audio signal to swing positive and negative about a zero reference point), it is possible for signals to become inverted in polarity (flipped over). This causes a device to output a negative-going voltage when it is fed a positive-going voltage. If the loudspeaker is reverse-polarity from the microphone, an increase in sound pressure at the microphone (compression) will cause a decrease in pressure in front of the loudspeaker (rarefaction). Under some conditions, this can be extremely audible and destructive to sound quality. In other scenarios it can be irrelevant, but it is always good to check.

System installers should always check for proper polarity when installing the sound system. There are a number of methods, some simple and some complex. Let’s deal with them in order of complexity, starting with the simplest and least-costly method.

46.3.7.1 The Battery Test

Low-frequency loudspeakers can be tested using a standard 9 V battery. The battery has a positive and negative terminal, and the spacing between the terminals is just about right to fit across the terminals of most woofers. The loudspeaker cone will move outward when the battery is placed across the loudspeaker terminals with the battery positive connected to the loudspeaker positive. While this is one of the most accurate methods for testing polarity, it doesn’t work for most electronic devices or high-frequency drivers. Even so, it’s probably the least-costly and most accurate way to test a woofer.

46.3.7.2 Polarity Testers

There are a number of commercially available polarity test sets in the audio marketplace. The set includes a sending device that outputs a test pulse, Fig. 46-28,
through a small loudspeaker (for testing microphones) or an XLR connector (for testing electronic devices) and a receiving device that collects the signal via an internal microphone (loudspeaker testing) or XLR input jack. A green light indicates correct polarity and a red light indicates reverse polarity. The receive unit should be placed at the system output (in front of the loudspeaker) while the send unit is systematically moved from device to device toward the system input. A polarity reversal will manifest itself by a red light on the receive unit.

46.3.7.3 Impulse Response Tests

The impulse response is perhaps the most fundamental of audio and acoustic measurements. The polarity of a loudspeaker or electronic device can be determined from observing its impulse response, Figs. 46-29 and 46-30. This is one of the few ways to test flown loudspeakers from a remote position. It is best to test the polarity of components of multiway loudspeakers individually, since all of the individual components may not be polarized the same. Filters in the signal path (i.e., active crossover network) make the results more difficult to interpret, so it may be necessary to carefully test a system component (i.e., woofer) full-range for definitive results. Be sure to return the crossover to its proper setting before continuing.

46.4 Conclusion

The test and measurement of the sound reinforcement system are a vital part of the installation and diagnostic processes. The FFT and the analyzers that use it have revolutionized the measurement process, allowing sound practitioners to pick apart the system response and look at the response of the loudspeaker, roo, or both. Powerful analyzers that were once beyond the reach of most technicians are readily available and affordable, and cost can no longer be used as an excuse for not measuring the system. The greatest investment by far is the time required to grasp the fundamentals of acoustics to allow interpretation of the data. Some of this information is general, and some of it is specific to certain measurement systems.

The acquisition of a measurement system is the first step in ascending the capability and credibility ladder. The next steps include acquiring proper instruction on its use by self-study or short course. The final and most important steps are the countless hours in the field required to correlate measured data with the hearing process. As proficiency in this area increases, the speed of execution, validity, and relevance of the measurements will increase also. While we can all learn how to make the measurements in a relatively short time span, the rest of our careers will be spent learning how to interpret what we are measuring.

47.1 What’s the Ear For?

An ear is for listening, and for the lucky few, listening to music is their job. But an ear is for much more—lose your hearing, and besides not hearing music, you lose your connection with other people. Hearing is the sense most related to learning and communication, and is the sense that connects you to ideas and other people. Helen Keller, who lost both her sight and hearing at a young age, said that hearing loss was the greater affliction for this reason.

To professionals in the music industry, their hearing is their livelihood. To be able to hear well is the basis for sound work. Protecting your hearing will determine whether you are still working in the industry when you are 64, or even whether you can still enjoy music, and it will determine whether you will hear your spouse and grandchildren then, too.

47.1.1 What Does Hearing Damage Sound Like?

Hearing loss is the most common preventable workplace injury. Ten million Americans have noise-induced hearing loss. Ears can be easily damaged, resulting in partial or complete deafness or persistent ringing in the ears.

Hearing loss isn’t necessarily quiet. It can be a maddening, aggravating buzz or ringing in the ear, called tinnitus. Or it may result in a loss of hearing ability, the ability to hear softer sounds at a particular frequency. The threshold of hearing, the softest sounds that are audible for each frequency, increases as hearing loss progresses. Changes in this threshold can either be a temporary threshold shift (TTS) or a permanent threshold shift (PTS). Often these changes occur in the higher frequencies of 3000 to 6000 Hz, with a notch or significant reduction in hearing ability often around 4000 Hz.

A single exposure to short-duration, extreme loud noise or repeated and prolonged exposure to loud noises are the two most common causes of hearing loss. Examples of the first might be exposure to noise from discharging firearms, while the second might be the cumulative effects of working in a noisy environment such as manufacturing or in loud concert venues. Some antibiotics, drugs, and chemicals can also cause permanent injury.

Hearing damage isn’t the only health effect of noise. Workers in noisy workplaces have shown a higher likelihood of heart disease and heart attacks. Numerous other stress-related effects have been documented, including studies that have shown that women in noisy environments tend to gain weight.

47.2 How Loud Is Too Loud? OSHA, NIOSH, EPA, WHO

As in other industries, workers in the sound industry are covered by the occupational noise exposure standard found in the Code of Federal Regulations (29 CFR 1910.95). Occupational Safety and Health (OSHA) regulation requires that workers’ exposures not exceed those in Table 47-1.

Noise levels are measured with a sound level meter or dosimeter (a sound level meter worn on the employee) that can automatically determine the average noise level. Often, noise levels are represented in terms of a daily dose. For example, a person who was exposed to an average level of 90 dBA for four hours would have received a 50% dose, or half of her allowable exposure.

Administrative controls—such as the boss saying, “Don’t work in noisy areas, or do so for only short times,” and/or engineering controls—such as quieter machines—are required to limit exposure. Hearing protection may also be used, although it is not the preferred method. Moreover, the regulation requires that, for employees whose exposure may equal or exceed an 8-hour time-weighted average of 85 dB, the employer shall develop and implement a monitoring program in which employees receive an annual hearing test. The testing must be provided for free to the employee. The employer is also required to provide a selection of hearing protectors and take other measures to protect the worker.

Compliance by employers with the OSHA regulations, as well as enforcement of the regulation, is quite variable, and often it is only in response to requests from employees. It is quite possible that professionals in the field have never had an employer-sponsored hearing test, and are not participating in a hearing conservation program as required.
Unfortunately, OSHA’s regulations are among the least protective of any developed nation’s hearing protections standards. Scientists and OSHA itself have known for more than a quarter-century that between 20 and 30% of the population exposed to OSHA-permitted noise levels over their lifetime will suffer substantial hearing loss, see Table 47-2. As a result, the National Institute of Occupational Safety and Health (NIOSH), a branch of the Centers for Disease Control and Prevention (CDC), has recommended an 85 dB standard as shown in Table 47-3. Nevertheless, NIOSH recognizes that approximately 10% of the population exposed to the lower recommended level will still develop hearing loss.

</tbody>
</table>

While 25–30% of the population will suffer substantial hearing loss at OSHA permitted levels, everyone would suffer some hearing damage.

Table 47-3 compares the permissible or recommended daily exposure times for noises of various levels. The table is complicated but instructive. The first three columns represent the recommendations of the Environmental Protection Agency (EPA) and World Health Organization (WHO) and starts with the recommendation that the 8-hour average of noise exposure not exceed 75 dBA. The time of exposure is reduced by half for each 3 dBA that is added; a 4-hour exposure is 78 dBA, and a 2-hour exposure is 81 dBA. This is called a 3 dB exchange rate, and is justified on the principle that a 3 dB increase is a doubling of the energy received by the ear, and therefore exposure time ought to be cut in half. The EPA and WHO recommendations can be thought of as safe exposure levels. The NIOSH recommendations in the next three columns represent an increased level of risk of hearing loss and are not protective for approximately 10% of the population. NIOSH uses a 3 dB exchange rate, but the 8-hour exposure is 10 dB higher than EPA—that is, 85 dBA. Finally, the OSHA limits are in the last two columns. OSHA uses a 5 dB exchange rate, which results in much longer exposure times at higher noise levels, and the 8-hour exposure is 90 dBA. Between 20 and 30% of people exposed to OSHA-permitted levels will experience significant hearing loss over a lifetime of expo-

</tbody>
</table>
It is important to note that everyone exposed to the OSHA-permitted levels over their lifetime will experience some hearing loss.

It is important to remember that each of these recommendations assumes that one is accounting for all of the noise exposure for the day. Someone who is working in a noisy environment, then goes home and uses power tools or lawn equipment, is further increasing the risk and exposure.

The U.S. Environmental Protection Agency (EPA) and the World Health Organization (WHO) have recommended a 75 dB limit, as shown in Table 47-3, as a safe exposure with minimal risk of hearing loss. The WHO goes on to recommend that exposure such as at a rock concert be limited to four times per year.

47.3 Indicators of Hearing Damage

There are several indicators of hearing damage. Since the damage is both often slow to manifest itself and progressive, the most important indicators are the ones that can be identified before permanent hearing damage has occurred.

The first and most obvious indicator is exceeding the EPA and WHO safe noise levels. As noise 8 hours, risk of suffering hearing loss also increases.

Exceeding the safe levels by, for example, working at OSHA-permitted noise levels doesn’t necessarily mean you will suffer substantial hearing loss; some people will suffer substantial loss, but everyone will suffer some level of hearing damage. The problem is that there is no way to know if you are in the one quarter to one third of the population who will suffer substantial hearing loss at a 90 dBA level or the two thirds to three quarters of the population who will lose less—at least, not until it is too late and the damage has occurred. Of course, by greatly exceeding OSHA limits, you can be assured that you will have significant hearing loss.

There are two types of temporary hearing damage that are good indicators that permanent damage will occur if exposure continues. The first is tinnitus, a temporary ringing in the ears following a loud or prolonged noise exposure. Work that induces tinnitus is clearly too loud, and steps should immediately be taken to limit exposure in the future.

The second type of temporary damage that is a useful indicator of potential permanent damage is a temporary threshold shift (TTS). Temporary changes in the threshold of hearing, the softest sounds that are audible for each frequency, are a very good indicator that continued noise exposure could lead to permanent hearing loss. Although ways to detect TTS without costly equipment are now being developed, the subjective experience of your hearing sounding different after noise exposure currently provides the best indication of problems.

It is important to remember that the absence of either of these indicators does not mean you will not suffer hearing loss. The presence of either is a good indication that noise exposure is too great.

Regular hearing tests can’t detect changes in hearing before they become permanent, but if frequent enough, they can detect changes before they become severe. It is particularly important, therefore, that people exposed to loud noises receive regular hearing tests.

Finally, there are often indicators that serious hearing damage has occurred, such as difficulties understanding people in crowded, noisy situations (loud restaurants, for example), the need to say “What?” frequently, or asking people to repeat themselves. Often it is not the person with the hearing loss, but rather others around him or her, who are the first to recognize these problems due to the slow changes to hearing ability and denial that often accompany them. While it is impossible to reverse hearing damage, hearing loss can be mitigated somewhat by the use of hearing aids, and further damage can be prevented. It is important to remember that just because you have damaged your hearing doesn’t mean you can’t still make it much worse.

47.4 Protecting Your Hearing

Protecting your hearing is reasonably straightforward: avoid exposure to loud sounds for extended periods of time. This can be accomplished by either turning down the volume or preventing the full energy of the sound from reaching your ears.

There are several strategies for protecting your hearing if you believe or determine that your exposure exceeds safe levels. As Table 47-3 indicates, you can reduce the noise level or reduce the exposure time, or both.

While reducing exposure time is straightforward it is not always possible, in which case turning down the volume by using quieter equipment, maintaining a greater distance from the noise source, using barriers or noise-absorbing materials, or utilizing hearing protection (either earplugs or over-the-ear muffs, or both) are required.

Typical earplugs or earmuffs are often criticized for changing the sound and hindering communication. Hearing protection in general is far better at reducing noise in the higher frequencies than the lower frequen-
cies, so typical hearing protection significantly changes the sound a wearer is hearing. Consonant sounds in speech occur in the frequencies that are more greatly attenuated by some hearing protectors.

There are, however, a number of hearing protection devices designed to reduce noise levels in all frequencies equally. Often referred to as musician’s earplugs, these can come in inexpensive models or custom-molded models. The advantage of a flat or linear attenuation of noise across all frequencies is that the only change to the sound is a reduction in noise level.

47.4.1 Protecting Concert-Goers and Other Listeners

Ears are for listening, and when it comes to music, there are often many ears listening to the music. They too, like music professionals, are at risk of hearing loss. Loud music is exciting; that is the physiology of loud. It gives us a shot of adrenaline. Also, more neurons are firing in our brain and our chest is resonating with the low-frequency sounds.

When humans evolved, the world was much quieter than it is today. Infrequent thunder was about it for loud noise. Hearing evolved to be a very important sense with respect to our survival, working 24/7 to keep us informed about the changing conditions of our environment. Noise wakes us up, because if it didn’t wake our forebears up when trouble entered the camp, they might not live long enough to create descendants. Noise is an important warning device—think of a child’s crying or screaming. During most of human history, when it was loud, trouble was involved. Physiologically, loud noises give us a shot of adrenaline, gearing us up to either fight or flee. Today, while neither fight nor flight is an appropriate response to loud noise, we still receive that shot of adrenaline. This is the reason for the popularity of loud movie soundtracks, loud exercise gyms, and loud music. It adds excitement and energy to activities. But it is also the reason for the stress-related effects of noise.

There is great incentive to turn it up, especially since the consequences are often not experienced until years later when the extent of hearing damage becomes apparent. People come to concert venues for excitement, not to be bored, and they come willingly; in fact, they pay to inflict whatever damage might be caused. Still, it is not a well-informed decision, and often minors are in the audience. But mostly, it isn’t necessary. The desired physiological responses occur at lower noise levels. Moreover, it makes little sense for an industry to degrade the experience of listening to music in the future for whatever marginal gain comes from turning it up a few more decibels now.

Fortunately, even small gestures to turn it down have noticeable impacts. Because every 3 dB decrease halves exposure, small decreases in sound pressure level can vastly increase public safety.

47.4.2 Protecting the Community

Noise can spill over from a venue into the community. The term noise has two very different meanings. When discussing hearing loss, noise refers to a sound that is loud enough to risk hearing loss. In a community setting, noise is aural litter. It is audible trash. Noise is to the soundscape as litter is to the landscape. When noise spills over into the community, it is the aural equivalent of throwing McDonald’s wrappers onto someone else’s property.

When noise reaches the community, often it has lost its higher-frequency content, as that is more easily attenuated by buildings, barriers, and even the atmosphere. What is often left is the bass sound.

Solutions to community noise problems are as numerous as the problems themselves, and usually require the expertise of architectural acousticians. In general, carefully aimed distributed speaker systems are better than large stacks for outdoor venues. Barriers can help, but not in all environmental conditions, and their effectiveness tends to be limited to nearer neighbors. Moreover, barriers need to be well designed, with no gaps.

Indoor walls with higher sound transmission class (STC) ratings are better than ones with lower ratings. STC ratings, however, do not address low-frequency sounds that are most problematic in community noise situations, so professional advice is important when seeking to design better spaces or remedy problems.

Windows and doors are particularly problematic, as even these small openings can negate the effects of very well-soundproofed buildings. They also tend to be the weakest point, even when shut.

Sound absorption is useful for reducing transmission through walls, but in general, decoupling the interior and exterior so that the sound vibrations that hit the interior wall do not cause the exterior wall to vibrate and reradiate the noise is more effective. There are numerous products available to achieve both decoupling and sound absorption.

Often, however, employing these techniques is not an option for the sound engineer. In that case, controlling sound pressure levels and low-frequency levels are the best solution.
47.5 Too Much of a Good Thing

In today’s world, noise represents one of the more serious pollutants, Fig. 47-1. Some are the by-product of our society such as lawn mowers, jackhammers, traffic, and public transportation. We deliberately subject ourselves to a Pandora’s box of sounds that threaten not only our hearing but our general health. Personal sources like MP3 players, car stereos, or home theaters are sources we can control, yet many remain oblivious to their impact, Fig. 47-2. In the public domain clubs, churches, auditoriums, amphitheaters, and stadiums are part of the myriad of potential threats to hearing health. From a nuisance to a serious health risk, these sources impact attendees, employees, and neighbors alike. As pointed out previously, levels of 105 dBA for 1 hour or less may result in serious and permanent hearing damage. Recent studies have shown other factors such as smoking, drugs of all types, and that overall health appear to accelerate the process.

47.5.1 A Compliance and Enforcement Tool

There are various tools to monitor noise. One very useful tool is “the SLARM™ by ACO Pacific. The following will use the SLARM™ to explain the importance of noise-monitoring test gear. The SLARM™ tool was developed to meet the needs of the noise abatement market. The SLARM™ performs both compliance and enforcement roles, offering accurate measurement, alarm functions, and very important history.

For the business owner dealing with neighborhood complaints, the SLARM™ provides a positive indication of SPL limits—permitting employees to control the levels or even turn off the sound. The History function offers a positive indication of compliance.

On the enforcement side, no longer does enforcement have to deal with finger-pointing complaints. They now may be addressed hours or days after the event and resolved. There is also the uniform effect. Police pull up armed with a sound level meter (SLM) and the volume goes down. Businesses now can demonstrate compliance. Yes—it is an oversimplification—but the concept works. Agreements are worked out. Peace and quiet return to the neighborhood.

47.5.1.1 The SLARMSolution™

The SLARM™ (Sound Level Alarm and Monitor) is a package of three basic subsystems in a single standalone device:

1. A sound level meter designed to meet or exceed Type 1 specifications.
2. Programmable threshold detectors providing either SPL or Leq alarm indications.
3. Monitor—a data recorder storing SPL data, and Led values for about 3 weeks on a rolling basis, as well as logging unique Alarm events, scheduled
threshold changes, maintenance events, and calibration information.

The SLARM™ may operate standalone. A PC is not required for normal Alarm operation. The data is maintained using flash and ferro-ram devices.

The SLARM™ provides USB and serial connectivity. It may be connected directly to a PC or via optional accessories directly to an Ethernet or radio link such as Bluetooth™.

PC operation is in conjunction with the included SLARMSoft™ software package.

47.5.1.2 SLARMSoft™ Software Suite

**SLARMWatch™.** A package with password-protected setup, calibration, downloading, display, and clearing of the SLARM™’s SPL history. The history data may be saved and imported for later review and analysis, Fig. 47-3.

**SLARMAnalysis™.** Part of SLARMWatch™ provides tools for the advanced user to review the SLARM™ history files. SLARMWatch™ allows saving and storage of this file for later review and analysis. SLARMAnalysis™ provides Leq, Dose and other calculations with user parameters, Fig. 47-4.

**SLARMScheduler™.** Part of the SLARMWatch™ package, allows 24/7 setting of the Alarm thresholds. This permits time of day and day of the week adjustments to meet the needs of the community, Fig. 47-5.

**WinSLARM™.** A display of SPL, Leqs, Range, and Alarm settings with digital, analog bar graph, and meter displays, as well as a Histogram window that provides a

25 second view of recent SPL on a continuous basis. The WinSlarm™ display may be sized permitting single or multiple SLARM™s to be shown, Fig. 47-6.

**SLARMAlarm™.** Operates independently from SLARMWatch™. The package monitors SLARM™s providing digital display of SPL and Leqs values while also offering SMS, text, and email messaging of Alarm events via an Internet connection from the PC, Fig. 47-7.

**SLARMNet™.** The SLARM™ and the SLARMSoft™ package allow multiple SLARM™s to be
What’s the Ear For? How to Protect It

47.5.1.3 SLARM™ Operation

The SLARM™ operates in the following manner, Fig. 47-8.

The Microphone and Microphone Preamplifier. The 7052/4052 microphone and preamplifier are supplied with the SLARM™ system. The 7052 is a Type 1.5™ ½ inch free-field measurement microphone featuring a titanium diaphragm. The microphone has a frequency response from <5 Hz to 22 kHz and an output level of 22 mV/Pa (~33 dBV/Pa). The 4052 preamplifier is powered from 12 Vdc supplied by the SLARM™ and has a response <20 Hz to >100 kHz. Together they permit measurements approaching 20 dBA. The MK224 electret capsule is available, offering 8 Hz to 20 kHz response, and 50 mV/Pa (~26 dBV/Pa) performance providing a lower noise floor. The diaphragm is quartz coated nickel.

The Preamplifier (Gain Stage). A low noise gain stage is located after the microphone input. This stage performs two tasks. The first limits the low-frequency input to just under 10 Hz. This reduces low-frequency interference from wind or doors slamming, things we do not hear due to the roll-off of our hearing below 20 Hz. The gain of this stage is controlled by the microcontroller providing two 100 dB measurement ranges 20 to 120 dB and 40 to 140 dBSPL. Most measurements are performed with the 20 to 120 dBSPL ranges. Custom ranges to >170 dBSPL are available as options. The output of the gain stage is supplied to three analog filter stages “A”, “C” and “Z” (Linear).

Analog A- and C-Weighted Filters. The gain stage is fed to the C-weighted filter. C-weighted filters have a ~3 dB response limit of 31.5 Hz to 8 kHz. C-weighted filters are very useful when resolving issues with low frequencies found in music and industrial applications. The output of the C-weighted filter is connected to both the analog switch providing filter selection and the input of the A-weighted element of the filter system. Sound levels measured with the C-weighted filter are designated as dBC (dBSPL C weighted).

The A-weighted response is commonly found in industrial and community noise ordinances. A weighting rolls off low-frequency sounds. Relative to 1 kHz, the roll-off is ~19.4 dB at 100 Hz (a factor of 1:10) and ~39.14 at 31.5 Hz (a factor of 1:100). The A response significantly deemphasizes low-frequency sounds. Sound levels measured with the A-weighted filter are designated as dBA (dBSPL A weighted). The output of the A-weighted filter is sent to the analog switch.

Analog Z-Weighting (Linear) Filter. The Z designation basically means the electrical output of the microphone is not weighted. The SLARM™ Z-weighting response is 2 Hz to >100 kHz. The response of the system is essentially defined by the response of the microphone and preamp. Z weighting is useful where measurements of frequency response are desired, or

connected to a network providing real-time data with alarm indications to multiple locations.
where low or high frequencies are important. Remember the microphone response determines the response. Sound levels measured with the Z weighted filter are designated as dBZ (dB SPL Z weighted).

**Analog Switch.** The outputs of the A-, C-, and Z-weighted filters connect to the analog switch. The switch is controlled by the microcontroller. The selection of the desired filter is done at setup using the utilities found in SLARMWatch™.

Selection of the filter as with the other SLARM™ settings is password protected. Permission must be assigned to the user by the administrator before selection is possible. This is essential to minimize the possibility of someone changing measurement profiles that may result in improper ALarm activation or inaccurate measurements.

**RMS Detection and LOG Conversion.** The output of the analog switch goes to the RMS detection and Logarithmic conversion section of the SLARM™. The RMS detector is a true RMS detector able to handle crest factors of 5–10. This is different from an averaging detector set up provide rms values from sine wave (low crest factor) inputs. The response of the detector exceeds the response limits of the SLARM™.

The output of the RMS detector is fed to the Log (Logarithmic) converter. A logarithmic conversion range of over 100 dB is obtained. The logarithmic output then goes to the A/D section of the microcontroller.

**Microcontroller.** The microcontroller is the digital heart of the SLARM™. A microcontroller (MCU) does all the internal calculations and system maintenance.

**SPL, Leq.** The digital data from the internal A/D is converted by the MCU to supply dBSPL, and Leq values for both storage in the on-board flash memory and inclusion in the data stream supplied to the USB and serial ports. These are complex mathematical calculations involving log and anti-log conversation and averaging.

The SPL values are converted to a rolling average. The results are sent to the on-board flash memory that maintains a rolling period of about 2 to 3 weeks.

Leq generation in the SLARM™ involves two independent calculations with two programmable periods. A set of complex calculations generates the two Leq values.

**Thresholds and Alarms.** The results of the Averaging and Leq calculations are compared by the micro-
controller with the Threshold levels stored in the on-board ferro-ram. Threshold levels and types—SPL or Leq—are set using the Settings tools provided in SLARMWatch™. These thresholds are updated by the SLARMScheduler™ routine.

If the programmed threshold limits are exceeded the microcontroller generates an output to an external driver IC. The IC decodes the value supplied by the microcontroller, lighting the correct front panel ALARM LED, and also activating an opto-isolator switch. The opto-switch contacts are phototransistors. The transistor turns on when the opto-isolator LED is activated. The result—a contact closure signaling the outside world of the ALarm.

**Real-time Clock.** The SLARM™ has an on-board real-time clock. Operating from an internal lithium cell, the real-time clock timestamps all of the recorded history, event logging, and controls the SLARMScheduler™ operation. The Settings panel in SLARMWatch™ allows user synchronization with a PC.

**Communicating with the Outside World.** SLARM™ may be operated Standalone (without a PC). The SLARM™ provides both USB 2.0 and RS232 serial connections. The USB port is controlled by the microcontroller and provides full access to the SLARM settings, History flash memory, and firmware update capability.

The RS232 is a fully compliant serial port capable of up to 230 k Baud. The serial port may be used to monitor the data stream from the SLARM™. The serial port may also be used to control the SLARM™ settings.

**Ethernet and Beyond.** Utilizing the wide variety of after-market accessories available, the USB and Serial ports of the SLARM™ may be connected to the Ethernet and Internet. RF links like Bluetooth® and WiFi are also possible. Some accessories will permit the SLARM™ to become an Internet accessory without a PC, permitting remote access from around the world.

The SLARMSoft™ package permits the monitoring of multiple SLARM™s through the SLARMNet™. The SLARMAAlarm™ software not only provides a simple digital display of multiple SLARM™s also permits transmission of SMS, text and email of ALARM events. This transmission provides the SLARM™ ID, Time, Type, and Level information in a short message. The world is wired.

**History.** The on-board flash and ferro-ram memories save measurements, events, settings, user access, and the SLARM™ Label. The SLARM™ updates the flash memory every second. SPL/Leq data storage is on a rolling 2 to 3 week basis. ALARM events, user access, and setting changes are also logged. These maybe downloaded, displayed, and analyzed using features found in SLARMWatch™.

### 47.5.1.3.1 Applications

SLARM™ applications are virtually unlimited. Day-to-day applications are many. Children’s day care centers, hospitals, classrooms, offices, clubs, rehearsal halls, auditoriums, amphitheaters, concert halls, churches, health clubs, and broadcast facilities are among the locations benefitting from sound level monitoring. Industrial and community environments include: machine shops, assembly lines, warehouses, marshaling yards, construction sites and local law enforcement of community noise ordinances.

The following are examples of recent SLARMSolution™.

**A Healthy Solution.** Located in an older building with a lot of flanking problems, the neighbors of a small women’s health club were complaining about the music used with the exercise routines. Negotiations were at a standstill until measurements were made.

Music levels were measured in the health club and a mutually acceptable level established. A SLARM™ (operating standalone—no PC) was installed to monitor the sound system and a custom control accessory developed to the customer’s specifications. If the desired SPL limits were exceeded for a specific period of time, the SLARM™ disabled the sound system, requiring a manual reset. The result, a Healthy Solution.

**Making a Dam Site Safer.** A SLARM™ (operating standalone—no PC) combined with an Outdoor Microphone assembly (ODM) located 300 ft away, monitors the 140+ dBSPL of a Gate Warning Horn. The operator over 100 miles away controls the flood gates of the dam, triggering the horn. The PLC controls the gate operation and monitors power to the horn but not the acoustic output. The SLARMSolution™ monitors the sound level from the horn. The thresholds were set for the normal level and a minimum acceptable level. The minimum level alarm or no alarm signal prompts maintenance action. The SLARM™s history provides proof of proper operation. Alarm events are time-stamped and logged.

**Is It Loud Enough?** Tornado, fire, nuclear power plant alarms and sirens as well as many other public safety and industrial warning devices can benefit from monitoring. Using the SLARM™s standalone operation and
the ODM microphone assembly make these remote installations feasible.

**A Stinky Problem.** A Medivac helicopter on its life-saving mission quickly approaches the hospital helipad and sets down. On the ground, the helicopter engines idle, prepared for a quick response to the next emergency.

The problem: the exhaust fumes from the engines drift upward toward the HVAC vents eight stories above. Specialized carbon filters and engineering staff run to the HVAC controls to turn them off—often forgetting to turn them back on, costing the hospital over $50,000 a year and hundreds of manhours provided limited success.

A standalone SLARM™ with an ODM microphone mounted on the edge of the helipad detects arriving helicopters and turns off the HVAC intakes. As the helicopter departs, the vents are turned back on automatically. The SLARM™ not only provides control of the HVAC but also logs the arrival and departure events for future review, Fig. 47-9.

**Too Much of a Good Thing Is a Problem.** Noise complaints are often the result of Too Much of a Good Thing. A nightclub housed on the ground floor of a condo complex faced increased complaints from both condo owners and patrons alike.

The installation of a SLARM™ connected to the DJ’s and sound staff’s PC allowed them to monitor actual sound levels and alarm them of exceedance. The combination of the SLARM™’s positive indication of compliance and accidence assures maintenance of proper levels.

**Protecting the Audience.** Community and national regulations often specify noise limits for patrons and employees alike. Faced with the need to assure their audiences’ hearing was not damaged by Too Much of a Good Thing, a major broadcast company chose the SLARMSolution™.

Two SLARM™s were used to monitor stage and auditorium levels. These units made use of both SPL and Leq Alarm settings. In addition, SLARMA nalysis™ is utilized to extrapolate daily Leq and dose estimates. The installations used the standard SLARM™ mic package and ACO Pacific’s 7052PH phantom microphone system. The phantom system utilized the miles of microphone cables running through the complex. This made microphone placement easier. The results were proof of compliance, and the assurance that audience ears were not damaged.

**NAMM 2008 – Actual Measurements from the Show Floor.** A SLARM™ was installed in a booth at the Winter NAMM 2008 show in Anaheim, CA. The microphone was placed at the back of the booth about 8 ft above the ground away from the booth traffic (people talking).

The following charts utilized SLARMWatch™’s History display capability as well as the SLARMA nalysis™ package. The SLARM™ operated standalone in the booth with the front panel LEDs advising the booth staff of critical noise levels.

The charts show the results of all four days of NAMM and Day 2. Day 2 was extracted from the data using the Zoom feature in SLARMWatch™. The booth was powered down in the evening, thus the Quiet periods shown and the break in the history sequence. The floor traffic quickly picked up at the beginning of the show day.

An 8 hour exposure at these levels has the potential of permanent hearing damage. The booth was located in one of the quieter areas of the NAMM Exhibition floor. Levels on the main show floor were at least 10–15 dB higher than those shown on the graphs.

**47.6 Summary**

We live in a world of sounds and noise. Some is enjoyable, some annoying, and all potentially harmful to health. Devices like the SLARM™ represent a unique approach to sound control and monitoring and a useful tool for sound and noise pollution control. We hope we have provided insight into how much sound—noise to some—is part of our world to enjoy responsibly. Also so alerting you to the potential harm sound represents.
Figure 47-10. This is a dBA (A weighted SPL) for all 4 days of NAMM. The booth power was shut down in the evening and then turned on for the exhibition. The SLARM™ restarted itself each morning and logged automatically during this time. It was not connected to a computer. The black indications are of sound levels exceeding the thresholds set in the SLARM™. Courtesy ACO Pacific.

48.1 Units of Measurement

Measurements are the method we use to define all things in life. A dimension is any measurable extent such as length, thickness, or weight. A measurement system is any group of related unit names that state the quantity of properties for the items we see, taste, hear, smell, or touch.

A unit of measurement is the size of a quantity in the terms of which that quantity is measured or expressed, for instance, inches, miles, centimeters, and meters.

The laws of physics, which includes sound, are defined through dimensional equations that are defined from their units of measurements of mass, length, and time. For instance,

\[
\text{Area} = L \times W
\]

\[
\text{Velocity} = \frac{D}{T}
\]

where

- \(L\) is length,
- \(W\) is width,
- \(D\) is distance,
- \(T\) is time.

A physical quantity is specified by a number and a unit, for instance: 16 ft or 5 m.

48.1.1 SI System

The SI system (from the French Système International d’Unités) is the accepted international modernized metric system of measurement. It is used worldwide with the exception of a few countries including the United States of America.

The SI system has the following advantages:

1. Internationally accepted.
2. All values, except time, are decimal multiples or submultiples of the basic unit.
3. It is easy to use.
4. It is easy to teach.
5. It improves international trade and understanding.
6. It is coherent. All derived units are formed by multiplying and dividing other units without introducing any numerical conversion factor except one.
7. It is consistent. Each physical quantity has only one primary unit associated with it.

When using the SI system, exponents or symbol prefixes are commonly used. Table 48-1 is a chart of the accepted name of the number, its exponential form, symbol, and prefix name. (Note because of their size, the numbers from sextillion to centillion have not been shown in numerical form and symbols and prefix names have not been established for these numbers.)

48.1.2 Fundamental Quantities

There are seven fundamental quantities in physics: length, mass, time, intensity of electric current, temperature, luminous intensity, and molecular substance. Two supplementary quantities are plane angle and solid angle.
48.1.3 Derived Quantities

Derived quantities are those defined in terms of the seven fundamental quantities, for instance, speed = length/time. There are sixteen derived quantities with names of their own: energy (work, quantity of heat), force, pressure, power, electric charge, electric potential difference (voltage), electric resistance, electric conductance, electric capacitance, electric inductance, frequency, magnetic flux, magnetic flux density, luminous flux, illuminance, and customary temperature. Following are thirteen additional derived quantities that carry the units of the original units that are combined. They are area, volume, density, velocity, acceleration, angular velocity, angular acceleration, kinematic viscosity, dynamic viscosity, electric field strength, magnetomotive force, magnetic field strength, and luminance.

48.1.4 Definition of the Quantities

The quantities will be defined in SI units, and their U.S. customary unit equivalent values will also be given.

Length (L). Length is the measure of how long something is from end to end. The meter (abbreviated m) is the SI unit of length. (Note: in the United States the spelling “meter” is retained, while most other countries use the spelling “metre.”) The meter is the 1 650 763.73 wavelengths, in vacuum, of the radiation corresponding to the unperturbed transition between energy level 2P_{10} and 5D_{5} of the krypton-86 atom. The result is an orange-red line with a wavelength of 6057.802 × 10^{-10} meters. The meter is equivalent to 39.370 079 inches.

Mass (M). Mass is the measure of the inertia of a particle. The mass of a body is defined by the equation

\[ M = \frac{A_s}{a} M_s \]  

(48-1)

where,

- \( A_s \) is the acceleration of the standard mass \( M_s \),
- \( a \) is the acceleration of the unknown mass, \( M \), when the two bodies interact.

The kilogram (kg) is the unit of mass. This is the only base or derived unit in the SI system that contains a prefix. Multiples are formed by attaching prefixes to the word gram. Small masses may be described in grams (g) or milligrams (mg) and large masses in megagrams. Note the term tonnes is sometimes used for the metric ton or megagram, but this term is not recommended.

The present international definition of the kilogram is the mass of a special cylinder of platinum iridium alloy maintained at the International Bureau of Weights and Measures, Sevres, France. One kilogram is equal to 2.204 622 6 avoirdupois pounds (lb). A liter of pure water at standard temperature and pressure has a mass of 1 kg ± one part in 10^4.

Mass of a body is often revealed by its weight, which the gravitational attraction of the earth gives to that body.

If a mass is weighed on the moon, its mass would be the same as on earth, but its weight would be less due to the small amount of gravity.

\[ M = \frac{W}{g} \]

(48-2)

where,

- \( W \) is the weight,
- \( g \) is the acceleration due to gravity.

Time (t). Time is the period between two events or the point or period during which something exists, happens, etc.

The second (s) is the unit of time. Time is the one dimension that does not have powers of ten multipliers in the SI system. Short periods of time can be described in milliseconds (ms) and microseconds (μs). Longer periods of time are expressed in minutes (1 min = 60 s) and hours (1 h = 3600 s). Still longer periods of time are the day, week, month, and year. The present international definition of the second is the time duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the atom of caesium 133. It is also defined as 1/86,400 of the mean solar day.

Current (I). Current is the rate of flow of electrons. The ampere (A) is the unit of measure for current. Small currents are measured in milliamperes (mA) and microamperes (μA), and large currents are in kiloamperes (kA). The international definition of the ampere is the constant current that, if maintained in two straight parallel conductors of infinite length and negligible cross-sectional area and placed exactly 1 m apart in a vacuum, will produce between them a force of \( 2 \times 10^{-7} \) N/m² of length.

A simple definition of one ampere of current is the intensity of current flow through a 1 ohm resistance under a pressure of 1 volt of potential difference.

Temperature (T). Temperature is the degree of hotness or coldness of anything. The kelvin (K) is the unit of temperature. The kelvin is 1/273.16 of the thermody-
namic temperature of the triple point of pure water. Note: the term degree (°) is not used with the term kelvin as it is with other temperature scales.

Ordinary temperature measurements are made with the celsius scale on which water freezes at 0°C and boils at 100°C. A change of 1°C is equal to a change of 1 kelvin, therefore 0°C = 273.15 K: 0°C = 32°F.

Luminous Intensity \((I)\). Luminous intensity is the luminous flux emitted per unit solid angle by a point source in a given direction. The candela (cd) is the unit of luminous intensity. One candela will produce a luminous flux of 1 lumen within a solid angle of 1 steradian.

The international definition of the candela is the luminous intensity, perpendicular to the surface, of 1/600 000 m² of a black body at the temperature of freezing platinum under a pressure of 101 325 N/m² (pascals).

Molecular Substance \((n)\). Molecular substance is the amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kg of carbon 12.

The mole is the unit of molecular substance. One mole of any substance is the gram molecular weight of the material. For example, 1 mole of water \((H₂O)\) weighs 18.016 g.

\[
H₂ = 2 \text{ atoms } \times 1.008 \text{ atomic weight}
\]

\[
O = 2 \text{ atoms } \times 16 \text{ atomic weight}
\]

\[
H₂O = 18.016 \text{ g}
\]

Plane Angle \((α)\). The plane angle is formed between two straight lines or surfaces that meet. The radian (rad) is the unit of plane angles. One radian is the angle formed between two radii of a circle and subtended by an arc whose length is equal to the radius. There are \(2\pi\) radians in 360°.

Ordinary measurements are still made in degrees. The degree can be divided into minutes and seconds or into tenths and hundredths of a degree. For small angles, the latter is most useful.

One degree of arc \((1°)\) = \(\frac{π}{180}\) Rad

\[
1 \text{ Rad} = 57.2956°
\]

Solid Angle \((A)\). A solid angle subtends three dimensions. The solid angle is measured by the area, subtended (by projection) on a sphere of unit radius by the ratio of the area \(A\), intercepted on a sphere of radius \(r\) to the square of the radius \((A/r²)\).

The steradian \((sr)\) is the unit of solid angle. The steradian is the solid angle at the center of a sphere that subtends an area on the spherical surface, which is equal to that of a square whose sides are equal to the radius of the sphere.

Energy \((E)\). Energy is the property of a system that is a measure of its ability to do work. There are two main forms of energy—potential energy and kinetic energy.

1. Potential energy \((U)\) is the energy possessed by a body or system by virtue of position and is equal to the work done in changing the system from some standard configuration to its present state. Potential energy is calculated with the equation

\[
U = Mgh
\]

where,

\[M\] is the mass,
\[g\] is the acceleration due to gravity.
\[h\] is the height.

For example, a mass \(M\) placed at a height \(h\) above a datum level in a gravitational field with an acceleration of free fall \((g)\), has a potential energy given by \(U = mgh\). This potential energy is converted into kinetic energy when the body falls between the levels.

2. Kinetic energy \((T)\) is the energy possessed by virtue of motion and is equal to the work that would be required to bring the body to rest. A body undergoing translational motion with velocity, \(v\), has a kinetic energy given by

\[
T = 0.5Mv²
\]

where,

\[M\] is the mass of the body,
\[v\] is the velocity of the body.

For a body undergoing rotational motion

\[
T = 0.5Iω²
\]

where,

\[I\] is the moment of inertia of the body about its axis of rotation,
\[ω\] is the angular velocity.

The joule \((J)\) is the unit of energy. The mechanical definition is the work done when the force of 1 newton is applied for a distance of 1 m in the direction of its application, or 1 Nm. The electrical unit of energy is the kilowatt-hour \((kWh)\), which is equal to \(3.6 \times 10⁶\) J.

In physics, the unit of energy is the electron volt \((eV)\), which is equal to \((1.602 10 ± 0.000 07) \times 10⁻¹⁹\) J.
Force \((F)\). Force is any action that changes, or tends to change, a body’s state of rest or uniform motion in a straight line.

The newton \((N)\) is the unit of force and is that force which, when applied to a body having a mass of 1 kg, gives it an acceleration of 1 m/s\(^2\). One newton equals 1 J/m, 1 kg(m)/s\(^2\), 10\(^5\) dynes, and 0.224 809 lb force.

Pressure. Pressure is the force (in a fluid) exerted per unit area on an infinitesimal plane situated at the point. In a fluid at rest, the pressure at any point is the same in all directions. A fluid is any material substance which in static equilibrium cannot exert tangential force across a surface but can exert only pressure. Liquids and gases are fluids.

The pascal \((\text{Pa})\) is the unit of pressure. The pascal is equal to the newton per square meter \((\text{N/m}^2)\).

\[
1\text{Pa} = 10^{-6}\text{bars} = 1.45038 \times 10^{-4}\text{lb/in}^2
\]  
(48-7)

Power \((W)\). Power is the rate at which energy is expended or work is done. The watt \((W)\) is the unit of power and is the power that generates energy at the rate of 1 J/s.

\[
1\text{W} = 1\text{J/s} = 3.141442\text{BTU/h} = 44.2537\text{ft-lb/min} = 0.00134102\text{hp}
\]  
(48-8)

Electric Charge \((Q)\). Electric charge is the quantity of electricity or electrons that flows past a point in a period of time. The coulomb \((C)\) is the unit of electric charge and is the quantity of electricity moved in 1 second by a current of 1 ampere. The coulomb is also defined as 6.24196 \times 10^{18} \text{electronic charges}.

Electric Potential Difference \((V)\). Often called electromotive force \((\text{emf})\) and voltage \((V)\), electric potential difference is the line integral of the electric field strength between two points. The volt \((V)\) is the unit of electric potential. The volt is the potential difference that will cause a current flow of 1 A between two points in a circuit when the power dissipated between those two points is 1 W.

A simpler definition would be to say a potential difference of 1 V will drive a current of 1 A through a resistance of 1 \(\Omega\).

\[
V = \frac{W}{A} = \frac{J}{A(s)} = \frac{\text{kg(m}^2\text{)}}{s^3A} = \text{A} \Omega
\]  
(48-9)

Electric Resistance \((R)\). Electric resistance is the property of conductors that, depending in their dimensions, material, and temperature, determines the current produced by a given difference of potential. It is also that property of a substance that impedes current and results in the dissipation of power in the form of heat.

The ohm \((\Omega)\) is the unit of resistance and is the resistance that will limit the current flow to 1 A when a potential difference of 1 V is applied to it.

\[
R = \frac{V}{A} = \frac{\text{kg(m}^2\text{)}}{s^3A^2}
\]  
(48-10)

Electric Conductance \((G)\). Electric conductance is the reciprocal of resistance. The siemens \((S)\) is the unit of electric conductance. A passive device that has a conductance of 1 S will allow a current flow of 1 A when 1 V potential is applied to it.

\[
S = \frac{1}{\Omega} = \frac{A}{V}
\]  
(48-11)

Electric Capacitance \((C)\). Electric capacitance is the property of an isolated conductor or set of conductors and insulators to store electric charge. The farad \((F)\) is the unit of electric capacitance and is defined as the capacitance that exhibits a potential difference of 1 V when it holds a charge of 1 C.

\[
F = \frac{C}{V} = \frac{AS}{V}
\]  
(48-12)

where,
C is the electric charge in coulombs,
\(V\) is the electric potential difference in volts,
\(A\) is the current in amperes,
Fundamentals and Units of Measurement

\( S \) is the conductance in siemens.

**Electric Inductance (L).** *Electric inductance* is the property that opposes any change in the existing current. Inductance is only present when the current is changing. The henry (H) is the unit of inductance and is the inductance of a circuit in which an electromotive force of 1 V is developed by a current change of 1 A/s.

\[
H = \frac{Vs}{A} \quad (48-13)
\]

**Frequency (f).** *Frequency* is the number of recurrences of a periodic phenomenon in a unit of time. The hertz (Hz) is the unit of frequency and is equal to one cycle per second, 1 Hz = 1 cps. Frequency is often measured in hertz (Hz), kilohertz (kHz), and megahertz (MHz).

**Sound Intensity (W/m²).** *Sound intensity* is the rate of flow of sound energy through a unit area normal to the direction of flow. For a sinusoidally varying sound wave the intensity \( I \) is related to the sound pressure \( p \) and the density \( \beta \) of the medium by

\[
I = \frac{p^2}{\beta c} \quad (48-14)
\]

where,
\( c \) is the velocity of sound.

The watt per square meter (W/m²) is the unit of sound intensity.

**Magnetic Flux (ϕ).** *Magnetic flux* is a measure of the total size of a magnetic field. The weber (Wb) is the unit of magnetic flux, and is the amount of flux that produces an electromotive force of 1 V in a one-turn conductor as it reduces uniformly to zero in 1 s.

\[
Wb = W(s) = 10^8 \text{lines of flux} = \frac{kg(m^2)}{s^2A} \quad (48-15)
\]

**Magnetic Flux Density (B).** The *magnetic flux density* is the flux passing through the unit area of a magnetic field in the direction at right angles to the magnetic force. The vector product of the magnetic flux density and the current in a conductor gives the force per unit length of the conductor.

The tesla (T) is the unit of magnetic flux density and is defined as a density of 1 Wb/m².

\[
T = \frac{Wb}{m^2}
= \frac{V(s)}{m^2}
= \frac{kg}{s^2A}.
\]

**Luminous Flux (Φv).** *Luminous flux* is the rate of flow of radiant energy as evaluated by the luminous sensation that it produces. The lumen (lm) is the unit of luminous flux, which is the amount of luminous flux emitted by a uniform point source whose intensity is 1 steradian.

\[
\text{lm} = cd \left( \frac{sr}{m^2} \right)
= 0.0795774 \text{ candlepower}
\]

where,
\( cd \) is the luminous intensity in candelas,
\( sr \) is the solid angle in steradians.

**Luminous flux Density (E_v).** The *luminous flux density* is the luminous flux incident on a given surface per unit area. It is sometimes called illumination or intensity of illumination. At any point on a surface, the illumination is given by

\[
E_v = \frac{d\Phi_v}{dA} \quad (48-18)
\]

The lux (lx) is the unit of luminous flux density, which is the density of radiant flux of lm/m²,

\[
lx = \frac{lm}{m^2}
= cd \frac{sr}{m^2}
= 0.0929030 \text{ fc}
\]

**Displacement.** *Displacement* is a change in position or the distance moved by a given particle of a system from its position of rest, when acted on by a disturbing force.

**Speed/Velocity.** *Speed* is the rate of increase of distance traveling by a body. Average speed is found by the equation

\[
S = \frac{l}{t} \quad (48-20)
\]

where,
Speed is a scalar quantity as it is not referenced to direction. Instantaneous speed = \( \frac{dl}{dt} \). Velocity is the rate of increase of distance traversed by a body in a particular direction.

Velocity is a vector quantity as both speed and direction are indicated. The \( \frac{dl}{dt} \) can often be the same for the velocity and speed of an object, however, when speed is given, the direction of movement is not known. If a body describes a circular path and each successive equal distances along the path is described in equal times, the speed would be constant but the velocity would constantly change due to the change in direction.

Weight. Weight is the force exerted on a mass by the gravitational pull of the planet, star, moon, etc., that the mass is near. The weight experienced on earth is due to the earth’s gravitational pull, which is 9.806 65 m/s\(^2\), and causes an object to accelerate toward earth at a rate of 9.806 65 m/s\(^2\) or 32 ft/s\(^2\).

The weight of a mass \( M \) is \( M \times g \). If \( M \) is in kg and \( g \) in m/s\(^2\), the weight would be in newtons (N). Weight in the U.S. system is in pounds (lb).

Acceleration. Acceleration is the rate of change in velocity or the rate of increase or decrease in velocity with time. Acceleration is expressed in meters per second squared (m/s\(^2\)), or ft/s\(^2\) in the U.S. system.

Amplitude. Amplitude is the magnitude of variation in a changing quantity from its zero value. Amplitude should always be modified with adjectives such as peak, rms, maximum, instantaneous, etc.

Wavelength (\( \lambda \)). In a periodic wave, the distance between two points of the corresponding phase of two consecutive cycles is the wavelength. Wavelength is related to the velocity of propagation (\( c \)) and frequency (\( f \)) by the equation

\[
\lambda = \frac{c}{f} \quad (48-21)
\]

The wavelength of a wave traveling in air at sea level and standard temperature and pressure (STP) is

\[
\lambda = \frac{331.4 \text{ m/s}}{f} \quad (48-22)
\]

or

\[
\lambda = \frac{1087.42 \text{ ft/s}}{f} \quad (48-23)
\]

For instance, the length of a 1000 Hz wave would be 0.33 m, or 1.09 ft.

Phase. Phase is the fraction of the whole period that has elapsed, measured from a fixed datum. A sinusoidal quantity may be expressed as a rotating vector \( OA \). When rotated a full 360 degrees, it represents a sine wave. At any position around the circle, \( OA \) is equal in length but said to be \( X \) degrees out of phase with \( OA \).

It may also be stated that the phase difference between \( OA \) and \( OX \) is \( \alpha \). When particles in periodic motion due to the passage of a wave are moving in the same direction with the same relative displacement, they are said to be in phase. Particles in a wave front are in the same phase of vibration when the distance between consecutive wave fronts is equal to the wavelength. The phase difference of two particles at distances \( X_1 \) and \( X_2 \) is

\[
\begin{align*}
\alpha &= \frac{2\pi(X_2 - X_1)}{\lambda} \\
&= \frac{2\pi f}{c}(X_2 - X_1) \quad (48-24)
\end{align*}
\]

Periodic waves, having the same frequency and waveform, are said to be in phase if they reach corresponding amplitudes simultaneously.

Phase Angle. The angle between two vectors representing two periodic functions that have the same frequency is the phase angle. Phase angle can also be considered the difference, in degrees, between corresponding stages of the progress of two cycle operations.

Phase Difference (\( \phi \)). Phase difference is the difference in electrical degrees or time, between two waves having the same frequency and referenced to the same point in time.

Phase Shift. Any change that occurs in the phase of one quantity or in the phase difference between two or more quantities is the phase shift.

Phase Velocity. The phase velocity is when a point of constant phase is propagated in a progressive sinusoidal wave.

Temperature. Temperature is the measure of the amount of coldness or hotness. While kelvin is the SI standard, temperature is commonly referenced to °C (degrees Celsius) or °F (degrees Fahrenheit).
The lower fixed point (the ice point) is the temperature of a mixture of pure ice and water exposed to the air at standard atmospheric pressure.

The upper fixed point (the steam point) is the temperature of steam from pure water boiling at standard atmospheric pressure.

In the Celsius scale, named after Anders Celsius (1701–1744) and originally called Centigrade, the fixed points are 0°C and 100°C. This scale is used in the SI system.

The Fahrenheit scale, named after Gabriel Daniel Fahrenheit in 1714, has the fixed points at 32°F and 212°F.

To interchange between °C and °F, use the following equations.

\[ ^\circ C = (^\circ F - 32) \times \frac{5}{9} \]
\[ ^\circ F = \left( ^\circ C \times \frac{9}{5} \right) + 32 \]  

The absolute temperature scale operates from absolute zero of temperature. Absolute zero is the point where a body cannot be further cooled because all the available thermal energy is extracted.

Absolute zero is 0 kelvin (0 K) or 0°F Rankine (0°R). The Kelvin scale, named after Lord Kelvin (1850), is the standard in the SI system and is related to °C.

\[ 0^\circ C = 273.15K \]

The Rankine scale is related to the Fahrenheit system.

\[ 32^\circ F = 459.67^\circ R \]

The velocity of sound is affected by temperature. As the temperature increases, the velocity increases. The approximate formula is

\[ C = 331.4 \text{ m/s} + 0.607T \quad \text{SI units} \]  

where, 
\[ T \text{ is the temperature in } ^\circ C. \]

\[ C = 1052 \text{ ft/s} \times 1.106T \quad \text{U.S. units} \]  

where, 
\[ T \text{ is the temperature in } ^\circ F. \]

Another simpler equation to determine the velocity of sound is

\[ C = 49.00\sqrt{459.69^\circ + ^\circ F} \]  

Things that can affect the speed of sound are the sound wave going through a temperature barrier or going through a stream of air such as from an air conditioner. In either case, the wave is deflected the same way that light is refracted in glass.

Pressure and altitude do not affect the speed of sound because at sea level the molecules bombard each other, slowing down their speed. At upper altitudes they are farther apart so they do not bombard each other as often so they reach their destination at the same time.

**Thevenin’s Theorem.** *Thevenin’s Theorem* is a method used for reducing complicated networks to a simple circuit consisting of a voltage source and a series impedance. The theorem is applicable to both ac and dc circuits under steady-state conditions.

The theorem states: the current in a terminating impedance connected to any network is the same as if the network were replaced by a generator with a voltage equal to the open-circuit voltage of the network, and whose impedance is the impedance seen by the termination looking back into the network. All generators in the network are replaced with impedance equal to the internal impedances of the generators.

**Kirchhoff’s Laws.** The laws of Kirchhoff can be used for both dc and ac circuits. When used in ac analysis, phase must also be taken into consideration.

**Kirchhoff’s Voltage Law (KVL).** *Kirchhoff’s voltage law* states that the sum of the branch voltages for any closed loop is zero at any time. Stated another way, for any closed loop, the sum of the voltage drops equal the sum of the voltage rises at any time.

In the laws of Kirchhoff, individual electric circuit elements are connected according to some wiring plan or schematic. In any closed loop, the voltage drops must equal the voltage rises. For example, in the dc circuit of Fig. 48-1, \( V_1 \) is the voltage source or rise such as a battery and \( V_2, V_3, V_4, \) and \( V_5 \) are voltage drops (possibly across resistors) so

\[ V_1 = V_2 + V_3 + V_4 + V_5 \]  

or,

\[ V_1 - V_2 - V_3 - V_4 - V_5 = 0 \]  

In an ac circuit, phase must be taken into consideration, therefore, the voltage would be

\[ V_1 e^{jot} - V_2 e^{jot} - V_3 e^{jot} - V_4 e^{jot} - V_5 e^{jot} = 0 \]
Kirchhoff’s Current Law (KCL). Kirchhoff’s current law states that the sum of the branch currents leaving any node must equal the sum of the branch currents entering that node at any time.

Stated another way, the sum of all branch currents incident at any node is zero.

In Fig. 48-2 the connection on node current in a dc circuit is equal to 0 and is equal to the sum of currents \( I_1, I_2, I_3, I_4, \) and \( I_5 \) or

\[
I_1 = I_2 + I_3 + I_4 + I_5 \tag{48-32}
\]

or

\[
I_1 - I_2 - I_3 - I_4 - I_5 = 0 \tag{48-33}
\]

where, \( e^{j\omega t} \) is \( \cos \omega t + j\sin \omega t \) or Euler’s identity.

**Ohm’s Law.** Ohm’s Law states that the ratio of applied voltage to the resultant current is a constant at every instant and that this ratio is defined to be the resistance.

If the voltage is expressed in volts and the current in amperes, the resistance is expressed in ohms. In equation form it is

\[
R = \frac{V}{I} \tag{48-35}
\]

or

\[
R = \frac{e}{i} \tag{48-36}
\]

where,

\( e \) and \( i \) are instantaneous voltage and current,

\( V \) and \( I \) are constant voltage and current,

\( R \) is the resistance.

Through the use of Ohm’s Law, the relationship between voltage, current, resistance or impedance, and power can be calculated.

Power is the rate of doing work and can be expressed in terms of potential difference between two points (voltage) and the rate of flow required to transform the potential energy from one point to the other (current). If the voltage is in volts or \( J/C \) and the current is in amperes or \( C/s \), the product is joules per second or watts:

\[
P = VI \tag{48-37}
\]

or

\[
J = \frac{J(C)}{C(s)} \tag{48-38}
\]

where,

\( J \) is energy in joules,

\( C \) is electric charge in coulombs.

Fig. 48-3 is a wheel chart that relates current, voltage, resistance or impedance, and power. The power factor (PF) is \( \cos I \) where \( I \) is the phase angle between \( e \) and \( i \). A power factor is required in ac circuits.

### 48.2 Radio Frequency Spectrum

The radio frequency spectrum of 30 Hz–3,000,000 MHz (\( 3 \times 10^{12} \) Hz) is divided into the various bands shown in Table 48-2.
48.3 Decibel (dB)

Decibels are a logarithmic ratio of two numbers. The decibel is derived from two power levels and is also used to show voltage ratios indirectly (by relating voltage to power). The equations or decibels are

\[ \text{Power dB} = 10 \log \frac{P_1}{P_2} \]  

(48-39)

\[ \text{Voltage dB} = 20 \log \frac{E_1}{E_2} \]  

(48-40)

Fig. 48-4 shows the relationship between the power, decibels, and voltage. In the illustration, “dBm” is the decibels referenced to 1 mW.

Table 48-3 shows the relationship between decibel, current, voltage, and power ratios.

Volume unit (VU) meters measure decibels that are related to a 600 Ω impedance. O VU is actually +4 dBm (see Chapter 26). When measuring decibels referenced to 1 mW at any other impedance than 600 Ω, use
Table 48-3. Relationships between Decibel, Current, Voltage, and Power Ratios

</table>
Example: The dBm for a 32 \Omega load is
\[
\text{dBm}_{32} = 4 \text{ dBm} + 10 \log \frac{600 \ \Omega}{32 \ \Omega} = 16.75 \text{ dBm}
\]

This can also be determined by using the graph in Fig. 48-5.

To find the logarithm of a number to some other base than the base 10 and 2.718, use
\[
n = b^L \tag{48-42}
\]
A number is equal to a base raised to its logarithm,
\[
\ln(n) = \ln(bL) \tag{48-43}
\]
therefore,
\[
\frac{\ln(n)}{\ln(b)} = L \tag{48-44}
\]

The natural log is a number divided by the natural log of the base equals the logarithm.

Example: Find the logarithm of the number 2 to the base 10:
\[
\frac{\ln 2}{\ln 10} = \frac{0.693147}{2.302585} = 0.301030
\]

In information theory work, logarithms to the base 2 are quite commonly employed. To find the log\(_2\) of 26
\[
\frac{\ln 26}{\ln 2} = 4.70
\]
To prove this, raise 2 to the 4.70 power
\[2^{4.70} = 26\]

### 48.4 Sound Pressure Level

The sound pressure level (SPL) is related to acoustic pressure as seen in Fig. 48-6.
48.5 Sound System Quantities and Design Formulas

Various quantities used for sound system design are defined as follows:

- $D_1$. $D_1$ is the distance between the microphone and the loudspeaker, Fig. 48-7.

- $D_2$. $D_2$ is the distance between the loudspeaker and the farthest listener, Fig. 48-7.

- $D_o$. $D_o$ is the distance between the talker (sound source) and the farthest listener, Fig. 48-7.

- $D_s$. $D_s$ is the distance between the talker (sound source) and the microphone, Fig. 48-7.

- $D_{limit}$. $D_{limit}$ is the limiting distance and is equal to $3.16 D_c$ for 15% $\text{Alcons}$ in a room with a reverberation time of 1.6 s. This means that $D_2$ cannot be any longer than $D_{limit}$ if $\text{Alcons}$ is to be kept at 15% or less. As the $\text{RT}_{60}$ increases or the required $\%\text{Alcons}$ decreases $D_2$ becomes less than $D_{limit}$.

- $EAD$. The equivalent acoustic distance (EAD) is the maximum distance from the talker that produces adequate loudness of the unamplified voice. Often an $EAD$ of 8 ft is used in quiet surroundings as it is the distance at which communications can be understood comfortably. Once the $EAD$ has been determined, the sound system is designed to produce that level at every seat in the audience.

- $D_c$. Critical distance ($D_c$) is the point in a room where the direct sound and reverberant sound are equal. $D_c$ is found by the equation

$$D_c = 0.141 \frac{QRM}{N}$$  \hspace{1cm} (48-45)

where,

- $Q$ is the directivity of the sound source,
- $R$ is the room constant,
- $M$ is the critical distance modifier for absorption coefficient,
- $N$ is the modifier for direct-to-reverberant speaker coverage.

It can also be found with the equation
The critical distance modifier ($M$) corrects for the effect of a different absorption coefficient within the path of the loudspeaker’s coverage pattern.

$$M = \frac{1 - \bar{a}_{\text{total room}}}{1 - \bar{a}_{\text{loudspeaker coverage area}}}$$  \hspace{1cm} (48-47)

The critical distance modifier ($N$) corrects for multiple sound sources. $N$ is the number describing the ratio of acoustic power going to the reverberant sound field without supplying direct sound versus the acoustic power going from the loudspeakers providing direct sound to a given listener position.

$$N = \frac{\text{Total number of loudspeakers}}{\text{Number providing direct sound}}$$  \hspace{1cm} (48-48)

The $\%$Alcons. The English language is made up of consonants and vowels. The consonants are the harsh letters that determine words. If the consonants of words are understood, the sentences or phrases will be understood. V. M. A. Peutz and W. Klein of Holland developed and published equations for the $\%$ articulation loss of consonants ($\%$Alcons). The equation is

$$\%\text{Alcons} = 656^{**} \frac{RT_{60}^{2}D_{2}^{2}N}{VQM}$$  \hspace{1cm} (48-49)

** 200 for SI units

where,

$Q$ is the directivity of the sound source,

$V$ is the volume of the enclosure,

$M$ is the critical distance modifier for absorption,

$N$ is the critical distance modifier for multiple sources,

$D_{2}$ is the distance between the loudspeaker and the farthest listener.

When $D_{c} \geq D_{L}$, then $\%\text{Alcons} = 9RT_{60}$.

The feedback stability margin ($FSM$) is required to insure that a sound reinforcement system will not ring. A room and sound system, when approaching feedback, gives the effect of an long reverberation time. A room, for instance, with an $RT_{60}$ of 3 s could easily have an apparent $RT_{60}$ of 6–12 s when the sound system approaches feedback. To insure that this long reverberation time does not happen, a feedback stability margin of 6 dB is added into the needed acoustic gain equation.

The number of open microphones ($NOM$) affects the gain of a sound reinforcement system. The system gain will be reduced by the following equation:

$$\text{Gain reduction}_{dB} = 10\log NOM$$  \hspace{1cm} (48-50)

Every time the number of microphones doubles, the gain from the previous microphones is halved as the total gain is the gain of all the microphones added together.

The needed acoustic gain ($NAG$) is required to produce the same level at the farthest listener as at the $EAD$. $NAG$ in its simplest form is

$$NAG = 20\log D_{o} - 20\log EAD$$  \hspace{1cm} (48-51)

$NAG$, however, is also affected by the number of open microphones ($NOM$) in the system. Each time the $NOM$ doubles, the $NAG$ increases 3 dB. Finally, a 6 dB feedback stability margin ($FSM$) is added into the $NAG$ formula to ensure that the system never approaches feedback. The final equation for $NAG$ is

$$NAG = \Delta D_{o} - \Delta EAD + 10\log NOM + 6 \text{ dB FSM}$$  \hspace{1cm} (48-52)

where,

$\Delta D_{o}$ and $\Delta EAD$ are the level change per the Hopkins-Stryker equation.

The potential acoustic gain ($PAG$) of a sound system is

$$PAG = \Delta D_{o} + \Delta D_{1} - \Delta D_{s} - \Delta D_{2}$$  \hspace{1cm} (48-53)

where,
$\Delta D_s$, $\Delta D_1$, $\Delta D_2$, and $\Delta D_2$ are found as in *NAG*.

**Q.** The directivity factor ($Q$) of a transducer used for sound emission is the ratio of sound pressure squared, at some fixed distance and specified direction, to the mean sound pressure squared at the same distance averaged over all directions from the transducer. The distance must be great enough so that the sound appears to diverge spherically from the effective acoustic center of the source. Unless otherwise specified, the reference direction is understood to be that of maximum response.

Geometric $Q$ can be found by using the following equations:

1. For rectangular coverage between 0 degrees and 180 degrees,

$$Q_{geom} = \frac{180}{\text{arc} \sin \left( \frac{\sin \theta}{2} \right) \left( \sin \phi \right)}$$

(48-54)

2. For angles between 180 degrees and 360 degrees when one angle is 180 degrees, and the other angle is some value between 180 degrees and 360 degrees

$$Q_{geom} = \frac{360}{\text{angle}}$$

(48-55)

3. For conical coverage,

$$Q_{geom} = \frac{2}{1 - \cos \frac{\theta}{2}}$$

(48-56)

$C_{\zeta}$. $C_{\zeta}$ is the included angle of the coverage pattern. Normally $C_{\zeta}$ is expressed as an angle between the −6 dB points in the coverage pattern.

**EPR.** EPR is the electrical power required to produce the desired SPL at a specific point in the coverage area. It is found by the equation

$$\text{EPR}_{\text{watts}} = 10^{\frac{\text{SPL}_{\text{des}} + 10 \text{dB}_{\text{crest}} + \Delta D_s - \Delta D_{\text{ref}} - L_{\text{sens}}}{10}}$$

(48-57)

**a.** The absorption coefficient ($a$) of a material or surface is the ratio of absorbed sound to reflected sound or incident sound

$$a = \frac{I_A}{I_R}$$

(48-58)

If all sound was reflected, $a$ would be 0. If all sound were absorbed, $a$ would be 1.

**\bar{a}.** The average absorption coefficient ($\bar{a}$) for all the surfaces together and is found by

$$\bar{a} = \frac{S_1a_1 + S_2a_2 + \ldots S_na_n}{S}$$

(48-59)

where,

- $S_1,2\ldots n$ are individual surface areas,
- $a_1,2\ldots n$ are the individual absorption coefficients of the areas,
- $S$ is the total surface area.

**MFP.** The mean-free path (MFP) is the average distance between reflections in a space. MFP is found by

$$MFP = \frac{4V}{S}$$

(48-60)

where,

- $V$ is the space volume,
- $S$ is the space surface area.

$\Delta D_s$. $\Delta D_s$ is an arbitrary level change associated with the specific distance from the Hopkins-Stryker equation so that

$$\Delta D_s = -10\log \left[ \frac{Q}{4\pi D_s^2} + \frac{4N}{Sa} \right]$$

(48-61)

In semireverberant rooms, Peutz describes $\Delta D_s$ as

$$\Delta D_s = -10\log \left[ \frac{Q}{4\pi D_s^2} + \frac{4N}{Sa} \right] + \frac{0.734*0.734}{hRT_{60}} \log \frac{D_s}{D_c}$$

(48-62)

**200 for SI units**

where,

- $h$ is the ceiling height.

**SNR.** SNR is the acoustical signal-to-noise ratio. The signal-to-noise ratio required for intelligibility is

$$\text{SNR} = 35\left( \frac{2 - \log_{10}(\% \text{Alcons})}{2 - \log_{10}(9RT_{60})} \right)$$

(48-63)

**SPL.** SPL is the sound pressure level in dB-SPL re 0.00002 N/m². SPL is also called $L_p$. 

**
Max Program Level. Max program level is the maximum program level attainable at a specific point from the available input power. Max program level is

\[
program \ level_{\text{max}} = 10\log\frac{\text{watts}_{\text{avail}}}{10} - (\Delta D_2 - \Delta D_{\text{ref}}) + L_{\text{sens}}
\]

\(L_{\text{sens}}\). Loudspeaker sensitivity \((L_{\text{sens}})\) is the on-axis SPL output of the loudspeaker with a specified power input and at a specified distance. The most common \(L_{\text{sens}}\) are at 4 ft, 1 W and 1 m, and 1 W.

\(\text{Sa}\). \(\text{Sa}\) is the total absorption in sabines of all the surface areas times their absorption.

\(\text{dB-SPL}_T\). The \(\text{dB-SPL}_T\) is the talker’s or sound source’s sound pressure level.

\(\text{dB-SPL}_D\). The \(\text{dB-SPL}_D\) is the desired sound pressure level.

\(\text{dB-SPL}\). The dB-SPL is the sound pressure level in decibels.

\(\text{EIN}\). \(\text{EIN}\) is the equivalent input noise.

\[
\text{EIN} = -198 \text{ dB} + 10\log BW + 10\log Z - 6 \text{ dB} - 20\log 0.775
\]

where,

\(BW\) is the bandwidth,

\(Z\) is the impedance.

Thermal Noise. Thermal noise is the noise produced in any resistance, including standard resistors. Any resistance that is at a temperature above absolute zero generates noise due to the thermal agitation of free electrons in the material. The magnitude of the noise can be calculated from the resistance, absolute temperature, and equivalent noise bandwidth of the measuring system. A completely noise-free amplifier whose input is connected to its equivalent source resistance will have noise in its output equal to the product of amplification and source resistor noise. This noise is said to be the theoretical minimum.

Fig. 48-8 provides a quick means for determining the rms value of thermal noise voltage in terms of resistance and circuit bandwidth.

For practical calculations, especially those in which the resistive component is constant across the bandwidth of interest, use

\[
E_{\text{rms}} = \sqrt{4 \times 10^{-23}(f_1 - f_2)R}
\]

where,

\(f_1 - f_2\) is the 3 dB bandwidth,

\(R\) is the resistive component of the impedance across which the noise is developed,

\(T\) is the absolute temperature in K.

\(\text{RT}_{60}\). \(\text{RT}_{60}\) is the time required for an interrupted steady-state signal in a space to decay 60 dB. \(\text{RT}_{60}\) is normally calculated using one of the following equations: the classic Sabine method, the Norris Eyring modification of the Sabine equation, and the Fitzroy equation. The Fitzroy equation is best used when the walls in the \(X\), \(Y\), and \(Z\) planes have very different absorption materials on them.

Sabine:

\[
\text{RT}_{60} = 0.049\frac{V}{\text{Sa}}
\]

** 0.161 for SI units

Norris Eyring:

\[
\text{RT}_{60} = 0.049\frac{V}{-\text{Sln}(1 - a)}
\]

** 0.161 for SI unit.

Fitzroy:
\[ RT_{60} = \frac{0.049 \times V}{S^2} \left[ \frac{2XY}{-\ln(1 - \bar{a}_{XY})} + \frac{2XZ}{-\ln(1 - \bar{a}_{XZ})} + \frac{2YZ}{-\ln(1 - \bar{a}_{YZ})} \right] \] (48-69)

** 0.161 for SI units

where,

\( V \) is the room volume,
\( S \) is the surface area,
\( a \) is the total absorption coefficient,
\( X \) is the space length,
\( Y \) is the space width,
\( Z \) is the space height.

**Signal Delay.** Signal delay is the time required for a signal, traveling at the speed of sound, to travel from the source to a specified point in space

\[ SD = \frac{Distance}{c} \] (48-70)

where,

\( SD \) is the signal delay in milliseconds,
\( c \) is the speed of sound.

**48.6 ISO Numbers**

“Preferred Numbers were developed in France by Charles Renard in 1879 because of a need for a rational basis for grading cotton rope. The sizing system that resulted from his work was based upon a geometric series of mass per unit length such that every fifth step of the series increased the size of rope by a factor of ten.” (From the American National Standards for Preferred Numbers). This same system of preferred numbers is used today in acoustics. The one-twelfth, one-sixth, one-third, one-half, two-thirds, and one octave preferred center frequency numbers are not the exact \( n \) series number. The exact \( n \) series number is found by the equation

\[ n \text{ Series number} = 10^n \left( \frac{1}{10^n} \right) \left( \frac{1}{10^n} \right) \ldots \] (48-71)

where,

\( n \) is the ordinal numbers in the series.

For instance, the third \( n \) number for a 40 series would be

\[ \frac{1}{10^{40}} \left( \frac{1}{10^{40}} \right) \left( \frac{1}{10^{40}} \right) = 1.1885022 \]

The preferred ISO number is 1.18. Table 48-4 is a table of preferred International Standards Organization (ISO) numbers.

48.9 Audio Frequency Range

The audio spectrum is usually considered the frequency range between 20 Hz and 20 kHz, Fig. 48-10. In reality, the upper limit of hearing pure tones is between 12 kHz and 18 kHz, depending on the person’s age and sex and how well the ears have been trained and protected against loud sounds. Frequencies above 20 kHz cannot be heard as a sound, but the effect created by such frequencies (i.e., rapid rise time) can be heard.

The lower end of the spectrum is more often felt than heard as a pure tone. Frequencies below 20 Hz are difficult to reproduce. Often the reproducer actually reproduces the second harmonic of the frequency, and the brain translates it back to the fundamental.

48.10 Common Conversion Factors

Conversion from U.S. to SI units can be made by multiplying the U.S. unit by the conversion factors in Table 48-8. To convert from SI units to U.S. units, divide by the conversion factor.

### 48.11 Technical Abbreviations

Many units or terms in engineering have abbreviations accepted either by the U.S. government or by the acousticians and audio consultants and engineers. Table 48-9 is a list of many of these abbreviations. Symbols for multiple and submultiple prefixes are shown in Table 48-1.

48.12 Audio Frequency Range

The audio spectrum is usually considered the frequency range between 20 Hz and 20 kHz, Fig. 48-9. In reality, the upper limit of hearing pure tones is between 12 kHz and 18 kHz, depending on the person’s age and sex and how well the ears have been protected against loud sounds. Frequencies above 20 kHz cannot be heard as a sound, but the effect created by such frequencies (i.e., rapid rise time) can be heard.

48.13 Surface Area and Volume Equations

To find the surface area and volume of complex areas, the area can often be divided into a series of simpler areas and handled one at a time. Figs. 48-10A–H are equations for various and unusual volumes.

</tr>
<tr>
<td>Spandrel or fillet</td>
<td>( A = r^2 - \frac{\pi r^2}{4} = 0.215 r^2 ) ( = 0.1075 c^2 )</td>
</tr>
</tbody>
</table>
### Elipse

A = area; P = perimeter or circumference.

\[
A = \pi ab = 3.1416 \, ab.
\]

An approximate formula for the perimeter is:

\[
P = 3.1416 \sqrt{2(a^2+b^2)}
\]

### Hyperbola

\[
A = \frac{xy}{2} - \frac{ab}{2} \log \left( \frac{x}{a} + \frac{y}{b} \right)
\]

### Parabola

\[
l = \frac{p}{2} \left[ \sqrt{\frac{2x}{p} \left( 1 + \frac{2x}{p} \right)} + \log \sqrt{\frac{2x}{p} + 1 + \frac{2x}{p}} \right]
\]

When \( x \) is small in proportion to \( y \), the following is a close approximation:

\[
l = y \left[ 1 + \frac{2}{3} \left( \frac{x}{y} \right)^2 - \frac{2}{5} \left( \frac{x}{y} \right)^4 \right] \quad \text{or} \quad l = \sqrt{y^2 + \frac{4}{3} x^2}
\]

### Parabola

A = area.

\[
A = \frac{1}{2} xy
\]

(The area is equal to two-thirds of the rectangle which has \( x \) for its base and \( y \) for its height.)

### Segment of Parabola

A = area.

Area \( BFC = A = \frac{1}{2} \) area of parallelogram BCDE.

If \( FG \) is the height of the segment, measured at right angles to \( BC \), then:

Area of segment \( BFC = \frac{1}{2} BC \times FG \)

### Cycloid

A = area; \( l \) = length of cycloid.

\[
A = 3\pi r^2 = 9.4248 \, r^2 = 2.3562 \, d^2
\]

\[
= 3 \times \text{area of generating circle}
\]

\[
l = 8 \, r = 4 \, d
\]

**Figure 48-14.** Equations for finding surface areas for complex shapes.
Figure 48-15. Equations for finding surface areas for complex shapes.

### Ellipsoid

- **Volume**: \( V = \frac{4\pi}{3} abc = 4.1888 \, abc \)
- In an ellipsoid of revolution, or spheroid, where \( b = c \):
  \[ V = 4.1888 \, ab^2 \text{ and } A = \frac{4}{\sqrt{2}} \, b \sqrt{a^2+b^2} \]

### Paraboloid

- **Volume** (where \( h \) is the height):
  \[ V = \frac{1}{2} \pi r^2 h = 0.3927 \, d^2 h \]
- **Area**: \( A = \frac{2}{3} \pi \left[ \sqrt{\left(\frac{d^2}{4} + p^2\right)^3} - p^3 \right] \) in which
  \[ p = \frac{d^2}{8h} \]

### Paraboloidal segment

- **Volume**:
  \[ V = \frac{\pi}{2} \, h \, (R^2 + r^2) = 1.5708 \, h \, (R^2 + r^2) \]
  \[ = \frac{\pi}{8} \, h \, (D^2 + d^2) = 0.3927 \, h \, (D^2 + d^2) \]

### Torus

- **Volume**: \( V = 2\pi^2 \, Rr^2 = 19.739 \, Rr^2 \)
  \[ = \frac{\pi^2}{4} \, Dd^2 = 2.4674 \, Dd^2 \]
- **Area**: \( A = 4\pi^2 \, Rr = 39.478 \, Rr \)
  \[ = \pi^2 \, Dd = 9.8696 \, Dd \]

### Barrel

- **Volume**: \( V \) = approx. volume
  - If the sides are bent to the arc of a circle:
    \[ V = \frac{1}{12} \pi h \left( 2 \, D^2 + d^2 \right) = 0.262 \, h \left( 2 \, D^2 + d^2 \right) \]
  - If the sides are bent to the arc of a parabola:
    \[ V = 0.209 \, h \left( 2 \, D^2 + Dd + \frac{3}{4} d^2 \right) \]

### Comparisons

- If \( d \) = base diameter and height of a cone, a paraboloid and a cylinder, and the diameter of a sphere, then the volumes of these bodies are to each other as below:
  - Cone: paraboloid: sphere: cylinder = \( \frac{1}{3} : \frac{1}{2} : \frac{2}{3} : 1 \)
<table>
