Preface .................................................................................................................................................. xi
Trademark Acknowledgments .................................................................................................................. xiii
Contributors ........................................................................................................................................... xv

Part 1—Acoustics

Chapter 1
Audio and Acoustic DNA—Do You Know Your Audio and Acoustic Ancestors? ............................ 3
Don and Carolyn Davis

Chapter 2
Fundamentals of Audio and Acoustics. .................................................................................................... 21
Pat Brown

Chapter 3
Psychoacoustics .................................................................................................................................. 41
Peter Xinya Zhang

Chapter 4
Acoustical Noise Control....................................................................................................................... 65
Doug Jones

Chapter 5
Acoustical Treatment for Indoor Areas .................................................................................................. 95
Jeff Szymanski

Chapter 6
Small Room Acoustics ............................................................................................................................ 125
Doug Jones

Chapter 7
Acoustics for Auditoriums and Concert Halls ...................................................................................... 145
Dr. Wolfgang Ahnert and Hans-Peter Tennhardt

Chapter 8
Stadiums and Outdoor Venues ............................................................................................................. 201
Eugene T. Patronis, Jr.

Chapter 9
Acoustical Modeling and Auralization ................................................................................................. 213
Dominique J. Chéenne
Part 2—Electronic Components

Chapter 10
Resistors, Capacitors, and Inductors ................................................................. 241
Glen Ballou

Chapter 11
Audio Transformers ......................................................................................... 273
Bill Whitlock

Chapter 12
Tubes, Discrete Solid State Devices, and Integrated Circuits ................................ 309
Glen Ballou, Les Tyler and Wayne Kirkwood

Chapter 13
Heatsinks and Relays ...................................................................................... 365
Glen Ballou and Henry Villaume

Chapter 14
Transmission Techniques: Wire and Cable ....................................................... 393
Steve Lampen and Glen Ballou

Chapter 15
Transmission Techniques: Fiber Optics ............................................................ 449
Ron Ajemian

Part 3—Electroacoustic Devices

Chapter 16
Microphones .................................................................................................... 489
Glen Ballou, Joe Ciaudelli and Volker Schmitt

Chapter 17
Loudspeakers .................................................................................................. 595
Jay Mitchell

Chapter 18
Loudspeaker Cluster Design ........................................................................ 645
Ralph Heinz
Part 4—Electronic Audio Circuits and Equipment

Chapter 19
Power Supplies ........................................................................................................... 667
Glen Ballou

Chapter 20
Amplifier Design ..................................................................................................... 701
Eugene T. Patronis, Jr.

Chapter 21
Preamplifiers and Mixers ......................................................................................... 733
Bill Whitlock, Michael Pettersen and Glen Ballou

Chapter 22
Attenuators ............................................................................................................... 765
Glen Ballou

Chapter 23
Filters and Equalizers .............................................................................................. 783
Steven McManus

Chapter 24
Delay ............................................................................................................................ 805
Steven McManus

Chapter 25
Consoles .................................................................................................................... 817
Steve Dove

Chapter 26
VI Meters and Devices ............................................................................................ 995
Glen Ballou

Part 5—Recording and Playback

Chapter 27
Analog Disc Playback ............................................................................................... 1013
George Alexandrovich and Glen Ballou

Chapter 28
Magnetic Recording and Playback ............................................................................ 1039
Dale Manquen and Doug Jones
Chapter 29
MIDI
David Mules Huber

Chapter 30
Optical Disc Formats for Audio Reproduction and Recording
Ken Pohlmann

Part 6—Design Applications

Chapter 31
DSP Technology
Dr. Craig Richardson

Chapter 32
Grounding and Interfacing.
Bill Whitlock

Chapter 33
System Gain Structure
Pat Brown

Chapter 34
Sound System Design
Chris Foreman

Chapter 35
Computer Aided Sound System Design
Dr. Wolfgang Ahnert and Stefan Feistel

Chapter 36
Designing for Speech Intelligibility.
Peter Mapp

Chapter 37
Personal Monitor Systems
Gino Sigismondi

Chapter 38
Virtual Systems
Ray Rayburn
When the first edition of the *Handbook for Sound Engineers* came out in 1987, it was subtitled the new *Audio Cyclopedi*a so that people who were familiar with Howard Tremain’s *Audio Cyclopedi*a would understand that this is an updated version of it. Today, the book stands on its own.

We have seen a tremendous change in the field of sound and acoustics since the first edition of the *Handbook for Sound Engineers* came out. Digital is certainly finding its place in all forms of audio, however, does this mean analog circuitry will soon be a thing of the past? Analog systems will still be around for a long time. After all, sound is analog and the transfer of a sound wave to a microphone signal is analog and from the electronic signal to the sound wave produced by the loudspeaker is analog.

What is changing is our methods of producing, reproducing, and measuring it. New digital circuitry and test equipment has revolutionized the way we produce, reproduce and measure sound.

When we listen to sound in different size rooms with different absorptions, reflections, and shape, we hear and feel the sound differently. The *Handbook for Sound Engineers* explains why this occurs and how to control it.

Rooms for speech are designed for intelligibility by controlling shape, reflections and absorption while rooms for music require very different characteristics as blend and reverberation time are more important than speech intelligibility. Multipurpose rooms must be designed to satisfy both speech and music, often by changing the RT60 time acoustically by use of reflecting/absorbing panels or by designing for speech and creating the impression of increased RT60 through ambisonics. Open plan rooms require absorbent ceilings and barriers and often noise masking. Studios and control rooms have a different set of requirements than any of the above.

There are many types of microphones. Each installation requires a knowledge of the type and placement of microphones for sound reinforcement and recording. It is important to know microphone basics, how they work, the various pickup patterns, sensitivity and frequency response for proper installation.

To build, install, and test loudspeakers, we need to know the basics of loudspeaker design and the standard methods of making measurements. Complete systems can be purchased, however, it is imperative the designer understand each individual component and the interrelation between them to design and install custom systems.

With the advent of digital circuitry, sound system electronics is changing. Where once each analog stage decreased the SNR of the system and increased distortion, digital circuitry does not reduce the SNR or increase distortion in the normal way. Digital circuitry is not without its problems however. Sound is analog and to transfer it to a digital signal and back to an analog signal does cause distortions. To understand this the *Handbook for Sound Engineers* delves into DSP technology, virtual systems, and digital interfacing and networking.

Analog disk and magnetic recording and playback have changed considerably in the past few years and are still used around the world. The CD has been in the United States since 1984. It is replacing records for music libraries because of its ability to almost instantly locate a spot in a 70+ minute disc. Because a disc can be recorded and rerecorded from almost any personal computer, disc jockeys and home audiophiles are producing their own CDs. Midi is an important part of the recording industry as a standardized digital communications language that allows multiple related devices to communicate with each other whether they be electronic instruments, controllers or computers.

The design of sound systems requires the knowledge of room acoustics, electroacoustic devices and electronic devices. Systems can be single source, multiple source, distributed, signal delayed, installed in good rooms, in bad rooms, in large rooms, or small rooms, all with their own particular design problems. Designing a system which should operate to our specs, but where we did not take into consideration the proper installation techniques such as grounding and common mode signal, can make a good installation poor and far from noise and trouble free. The *Handbook for Sound Engineers* covers these situations, proper installation techniques, and how to design for best speech intelligibility or music reproduction through standard methods and with computer programs.

The new integrated circuits, digital circuitry and computers have given us new sophisticated test gear unthought of a few years ago, allowing us to measure in real time, in a noisy environment, and measure to accuracies never before realized. It is important to know, not only what to measure, but how to measure it and then how to interpret the results.
Fiber optic signal transmission is solidly in the telephone industry and it is becoming more popular in the audio field as a method of transmitting signals with minimum noise, interference and increased security. This does not mean that hard-wired transmission will not be around for a long time. It is important to understand the characteristics of fiber optics, wire and cable and their affects on noise, frequency response and signal loss.

The book also covers message repeaters, interpretation systems, assistive listening systems, intercoms, modeling and auralization, surround sound, and personal monitoring.

The sound level through mega-loudspeakers at rock concerts, through personal iPods, and random noise from machinery, etc. is constantly increasing and damaging our hearing. The *Handbook for Sound Engineers* addresses this problem and shows one method of monitoring noisy environments.

Many of us know little about our audio heritage, therefore a chapter is dedicated to sharing the history of these men who, through their genius, have given us the tools to improve the sound around us.

No one person can be knowledgeable in all the fields of sound and acoustics. This book has been written by those people who are considered, by many, as the most knowledgeable in their field.

*Glen Ballou*

Contributors

Professor Dr. Ing. Habil. Wolfgang Ahnert

Dr. Wolfgang Ahnert graduated in Dresden in 1975 and from 1975 to 1990 he worked in an engineering office in Berlin and in 1990 founded ADA Acoustic Design Ahnert. In 2000 he founded SDA Software Design Ahnert GmbH to increase the output in writing source codes for acoustic and electronic applications. In 2002 the ADA foundation was established to support universities and colleges with acoustic software including EASE and the measurement tools EASERA and EASERA SysTune. The Ahnert Feistel Media Group was established in 2006 to coordinate all the above activities.

In 1993 he became an honorary professor at the Hochschule fuer Film und Fernsehen Potsdam, and in 2001 he became an honorary professor at Lomonossov University in Moscow. Since 2005 he has been a visiting professor at the Rensselaer Institute for Architecture in Troy, New York.

Dr. Ahnert has been a member of the AES since 1988 and was made a fellow of the Audio Engineering Society in 1995. He has been a fellow of the Acoustical Society of America since 2005. He is a member of the German DEGA and the British Institute of Acoustics. More than sixty five scientific lectures by Dr. Ahnert have been published.

Ronald G. Ajemian

Ronald G. Ajemian is an instructor at the Institute of Audio Research, New York, NY, where he has been teaching audio technology for over 25 years. Ron was employed with the Switched Services Department of Verizon for 32 years in New York City and recently took an early retirement.

Mr. Ajemian is a graduate of RCA Institute and the school of electrical engineering at Pratt Institute of Brooklyn, NY. He has contributed many articles in the field of audio electronics, telephony, and fiber optics.

Mr. Ajemian is a member of many professional organizations, including the Audio Engineering Society (AES), the Telephone Pioneers of America, Communication Workers of America (CWA), and the Optical Society of America to name a few. He is sometimes referred to as Dr. FO (fiber optics), for his expertise in the field of fiber optics. Mr. Ajemian is also a guest lecturer at NYU and for the Audio Engineering Society. Mr. Ajemian held the position of the Chair of the AES New York Section in 2000–2001 and is currently the Chair of the AES Standards Task Group SC-05-02-F on Fiber Optic Connections.

Mr. Ajemian is owner and consultant of Owl Fiber Optics in New York, specializing in fiber optic technology and education for proaudio/video and broadcast.
**George Alexandrovich**

George Alexandrovich, born in Yugoslavia, attended schools in Yugoslavia, Hungary, and Germany. After coming to the United States, he studied at the RCA Institute and at Brooklyn Polytech, earning a B.S.E.E. At Telectro Industries Corp., he was involved in the design and development of the first tape recorders and specialized military electronic test and communications equipment.

After service in the Korean war, he ran Sherman Fairchild’s private research lab. While with Fairchild Recording Equipment Corp., he designed and manufactured turntables, tonearms, pickups, mixing consoles and amplifiers, equalizers, reverberation chambers, the first light-activated compander, Autoten, Lumiten compressors, limiters, and a line of remote-controlled audio components. He also designed the first professional multichannel portable console, a disk-cutting lathe, and stereo cutters.

As vice president and general manager his responsibilities included designing and manufacturing the Voice of America recording facilities, NBC-TV studio consoles for Johnny Carson, Huntley-Brinkley Newsroom, KNX, KCBS, and other radio stations. When Fairchild Recording Equipment Corp. merged with Robins Corp., George also became involved in manufacturing magnetic tape along with a full line of consumer accessories in the hi-fi market.

At Stanton Magnetics, Inc., as vice president of field engineering and the professional products manager for phonograph cartridge research, he traveled extensively, holding seminars, giving lectures, and conducting conferences.

George was the author of the monthly column “Audio Engineer’s Handbook” for *dB Magazine* and of over eighty articles and papers in American and foreign trade journals. He has also presented a number of technical papers at the Audio Engineering Society (AES) conventions and is a fellow and a past governor of the AES. He holds eighteen patents in the audio field and is past chairman of the Electronics Industry Association (EIA) P8.2 Standards Committee.

At the present time George is retired after spending 11 years as principal engineer at ESD/Parker Hannifin Corp. where he conducted R&D in the field of avionics transducers. He is now president and owner of Island Audio Engineering, manufacturing and consulting firm.

**Glen Ballou**

Glen Ballou graduated from General Motors Institute in 1958 with a bachelor’s degree in Industrial Engineering and joined the Plant Engineering Department of the Pratt & Whitney Aircraft Division of United Technologies Corporation. There he designed special circuits for the newly developed tape control machine tools and was responsible for the design, installation, and operation of the 5,000,000 ft² plant public address and two-way communication system.

In 1970, Glen transferred to the Technical Presentations and Orientation section of United Technologies’ corporate office, where he was responsible for the design and installation of electronics, audio-visual, sound, and acoustics for corporate and division conference rooms and auditoriums. He was also responsible for audio-visual and special effects required for the corporation’s exhibit program.

Glen transferred to the Sikorsky Aircraft division of United Technologies as manager of Marketing Communications in 1980, where his responsibilities included the Sikorsky exhibit and special events program, plus operation and design of all conference rooms.

After his retirement from Sikorsky, Glen and his wife, Debra, opened Innovative Communications, a company specializing in sound system design and installation, and technical writing.

Glen is the editor/author of the 1st, 2nd, 3rd, and 4th editions of the *Handbook for Sound Engineers*. He also was a contributing author for *The Electrical Engineering Handbook* (CRC Press). Glen has written many article for Sound and Video Contractor and Church Production magazines.
He has been active in the Audio Engineering Society (AES) as Governor, three times Papers Chairman and four times Facilities Chairman, and Vice Chairman and Chairman of the 1989 AES Convention, for which he received the Governor’s award. He was also a member of SMPTE and the IEA.

Les Blomberg

Les Blomberg is a hearing conservation and noise policy expert. He is the inventor of a hearing test to detect temporary changes in hearing ability and is the author of numerous articles and papers on hearing conservation and noise. He is the founding Executive Director of the Noise Pollution Clearinghouse.

Alan C. Brawn CTS, ISF, ISF-C.

Alan Brawn is a principal of Brawn Consulting LLC, an audio-visual consulting, educational development, and market intelligence firm with national exposure to major manufacturers, distributors, and integrators in the industry. He was formerly President of Telanetix and previously National Business Development and Product Marketing Manager, Pro AV Group, Samsung Electronics. Alan is an AV industry veteran with experience spanning over two decades including years managing a commercial AV systems integration company after which he became one of the founding members of Hughes-JVC.

He is a recognized author for leading AV industry magazines and newsletters such as Systems Contractor News, Digital Signage Magazine, Rental & Staging, Display Daily, and Electrograph’s Emerge. Brawn is an Imaging Science Foundation Fellow and the Managing Director of ISF Commercial. Alan is CTS certified and an adjunct faculty member of InfoComm sitting on their PETC council. He is an NSCA instructor and Learning Unit Provider. He was the recipient of the Pro AV Hall of Fame recognition from rAVe in 2004.

Alan can be reached at Alan@BrawnConsulting.com.

Pat Brown

Pat Brown is president of Synergetic Audio Concepts, Inc. Syn-Aud-Con conducts educational seminars in audio and acoustics worldwide, as well as private seminars for audio manufacturers and corporations. He has owned and operated several businesses, including design build, retail, and consulting audio firms.

He received an A.A.S. from the University of Louisville in Electrical Engineering Technology. His current duties include teaching, consulting, and authoring technical articles for industry magazines and the Syn-Aud-Con Newsletter, which he and his wife, Brenda, publish from their headquarters in Greenville, Indiana.
Dominique J. Chéenne, Ph.D.

Dominique J. Chéenne holds a Brevet de Technicien Supérieur from the University of Caen, France. He received a Master’s degree and a Ph.D., both in Electrical Engineering, from the University of Nebraska, Lincoln. His doctoral dissertation dealt with the modeling of sound propagation over seating surfaces.

In 1979 he founded C & C Consultants, a consulting practice specializing in architectural acoustics and environmental noise control. Since its inception C & C Consultants has provided design services on hundreds of projects nationwide including individual residences, performing arts spaces, schools, offices, factories, churches, as well as local, state, and federal government facilities.

In 1995, Dr. Chéenne accepted an offer to join the faculty of Columbia College. He is currently serving as a tenured member of the faculty in the Audio Arts and Sciences Department where he directs the acoustics program. His main research interests are in the application of computer models to architectural and environmental acoustics issues.

Dr. Chéenne is a member of the Audio Engineering Society and of the Acoustical Society of America.

Don and Carolyn Davis

Don and Carolyn Davis form a unique husband and wife team working in audio, starting in 1951 with The Golden Ear in Lafayette, IN, selling eclectic high-fidelity equipment. Don was Paul Klipsch’s President in charge of Vice in the late 50s, and worked for Altec Lansing from 1959 until 1972 where he was co-inventor of 1/3-octave equalization.

The Davises founded Synergetic Audio Concepts in 1973 in response to the growing need in the audio industry for training in the fundamentals of sound reinforcement. Their work in equalization, speech intelligibility, and recording technologies provided the backbone for developing training seminars and workshops. When they turned Syn-Aud-Con over to Pat and Brenda Brown in 1995, Don and Carolyn had been responsible for the education of more than 10,000 sound contractors, designers, and consultants.

Don has authored three books, Acoustical Tests and Measurements in 1965; How to Build Speaker Enclosures in 1968, co-authored with Alex Badmaieff, which has sold over 200,000 copies, and Sound System Engineering, co-authored with his wife, Carolyn, in 1975. They recently completed the 3rd edition with co-author, Dr. Eugene Patronis.

In the process of communicating with the grads of their seminars on audio and acoustics, a quarterly newsletter was established. Most of the newsletter was technical in nature, but it also contained the evolving mindset that bonded teachers and grads into something not originally expected—a fraternity of people dedicated to changing an industry.

After enduring poor sound quality at a meeting of a professional audio society, Don uttered in frustration, If Bad Sound Were Fatal, Audio Would Be the Leading Cause of Death, hence the title of Don and Carolyn’s book, by that name. They used nontechnical excerpts from the Syn-Aud-Con newsletters, annotated by them in 2003, that go back to the beginning of these changes in the industry up to the Davises’ retirement in 1995. The book provides a remarkable insight into entrepreneur teachers’ communication with entrepreneur students. The typical attendees at their seminars were already successful in their chosen industry, but knew in their hearts that there was a higher standard and they actively sought it.

They have spent their professional careers writing and lecturing on sound system engineering. The audio industry has generously recognized their efforts as instrumental in the better sound quality we enjoy today. Don and Carolyn are both Fellows of the Audio Engineering Society and have received many awards in the audio industry, including the Distinguished Award in Sound Design and Technology from USITT.

Don and Carolyn reside in Arizona in the winter and on their farm in southern Indiana in the summer.
Steve Dove

Steve Dove is a native to Oxfordshire, England, and is now a resident of Pennsylvania. He has designed mixing consoles in every genre from valves to DSP. On the basis of an early foray with ICs, he became initially a wireman for—until fired for his atrocious soldering—a designer for, and later a director of Alice, a major manufacturer of broadcast, film, and recording consoles. Concurrently, he provided engineering and acoustics expertise to major rock bands, theatres, and studios worldwide.

As a design consultant his clients included Sony Broadcast, Shure Bros., Solid State Logic, Altec Lansing, Clair Bros., Harman/JBL, Crest, and Peavey. He is now Minister of Algorithms for Wheatstone Corporation.

A widely published author with a long list of innovative design techniques and award-winning products to his credit, he is presently realizing an ambition to achieve the class and fluidity of the best of analogue audio in digital signal processing.

Dipl.-Phys. Stefan Feistel

Stefan Feistel studied physics at the University of Rostock and at the Humboldt University of Berlin and graduated with a Master’s degree in Theoretical Physics in 2004.

His collaboration with Dr. Wolfgang Ahnert, the owner of ADA Acoustic Design Ahnert, started in 1996. The main target was, and still is, the development of the electro- and room-acoustic simulation software EASE.

In 2000, Wolfgang Ahnert and Stefan Feistel founded the company SDA Software Design Ahnert GmbH, which is dedicated to the development of acoustic modeling and measuring software. In 2003, the nonprofit organization ADA Foundation was established to support universities and colleges with software products such as the simulation software EASE and the measurement tool EASERA. To coordinate all these activities, the Ahnert Feistel Media Group (AFMG) was established in 2006.

Stefan Feistel has authored or co-authored more than thirty articles as a result of the continuously progressing work on software projects like EASE, EASE SpeakerLab, EASE Focus, and EASERA and the related mathematical, numerical, and experimental background studies.

Chris Foreman

Chris Foreman is Vice President and Chief Operating Officer for Community Professional, a loudspeaker manufacturer in Chester, Pennsylvania.

During his pro audio career, Chris has worked in manufacturing, contracting, and tour sound. Chris is widely published, having written numerous magazine articles and technical papers. Chris co-authored the book Audio Engineering for Sound Reinforcement with the late John Eargle and he is author of the sound reinforcement chapter of the 1st, 2nd, and 3rd editions of the Handbook for Sound Engineers edited by Glen Ballou. He can be reached at chris@proaudioweb.com.
Ralph Heinz

Ralph Heinz joined Renkus-Heinz in 1990 with a background in mechanical engineering. Very quickly he developed a thorough understanding of acoustics and has made many proprietary loudspeaker technologies and patients including Complex-Conic Horns, CoEntrant Topology, and True Array Principle.

David Miles Huber

David Miles Huber has written such books as the industry standard text Modern Recording Techniques (www.modrec.com), The MIDI Manual, and Professional Microphone Techniques. He’s also a producer and musician in the dance, chill and downtempo genres, whose CDs, have sold over the million mark. His latest music and collaborations with artists in the United States, United Kingdom, and Europe can be heard at www.51bpm.com and www.MySpace/51bpm.

Joe Hull

Joe Hull started his career in audio in the early 1960s working as a retail salesman in Cambridge, Massachusetts, at a time when some customers still needed convincing that stereo really was better than mono. In 1970, he joined the legendary Advent Corporation, where he worked for 8 years in a variety of sales and marketing positions, concluding that what he liked best was writing about high-technology products, such as the first cassette decks with Dolby B, for a lay audience. He’s been doing just that for Dolby Laboratories since 1978, with a few years’ hiatus out on his own as a freelance writer. Joe works and lives in San Francisco.
Doug Jones

Doug Jones has worked in recording and small-room acoustics for more than 20 years and still consults on such projects. He has earned a Master’s degree from Columbia College, Chicago, where he is Professor of Acoustics and the founding chairman of the Sound Department. There, he directs accredited Bachelor’s-degree programs in recording, architectural acoustics, live-sound reinforcement, sound-for-picture, and sound installation.

Mr. Jones is a member of the Acoustical Society of America and the Audio Engineering Society, where he is active in committee work. His publications have appeared in IEEE Proceedings and International Computer Music Proceedings, and he is an every-month columnist in Live Sound International magazine. In addition to his teaching duties at the College, he organizes advanced TEF workshops and other in-service technical training for the audio industry.

Steve Lampen

Steve Lampen has worked for Belden for 17 years and is currently Multimedia Technology Manager. Prior to Belden, Steve had an extensive career in radio broadcast engineering and installation, film production, and electronic distribution. Steve holds an FCC Lifetime General License (formerly a First Class FCC License) and is an SBE Certified Radio Broadcast Engineer. On the data side he is a BICSI Registered Communication Distribution Designer. His latest book, The Audio-Video Cable Installer’s Pocket Guide is published by McGraw-Hill. His column “Wired for Sound” appears in Radio World Magazine.

Noland Lewis

Noland Lewis is a graduate of University of San Francisco and has served as Chief Engineer for HC Electronics/Phonic Ear—a manufacturer of Auditory Trainers and Hearing Aids. Noland has also served on FDA committees relative to hearing aids and has conducted FCC presentations relative to new rule making.

He was the Chief Engineer of HC Electronics (Phonic Ear) where he developed a line of FM Auditory Trainers and Wireless Microphones serving the needs of hearing-impaired children and adults worldwide. He has served on FDA committees relative to hearing aid regulations and submitted new laws that became part of the FCC regulations.

Noland is founder and president of ACO Pacific, Inc., a company he established in 1978—now celebrating 30 years of serving the worldwide community. Over the past 30 years ACO Pacific, Inc. has become a major international supplier of measurement microphones and systems.

Noland created the SLARM™ several years ago to provide a means to assist businesses and communities in the resolution of noise pollution issues.

ACO Pacific is a sustaining member of INCE, INCE USA, AES, ASA, and the Canadian Acoustical Society. He has been a member of numerous committees in these organizations.
Peter Mapp, BSc, MSc, FIOA, FASA, FAES, CPhys, CEng, MinstP, FinstSCE MIEE.

Peter Mapp is principal of Peter Mapp Associates, an acoustic consultancy, based in Colchester, England, that specializes in the fields of room acoustics, electro-acoustics, and sound system design. He holds an honors degree in applied physics and a master’s degree in acoustics. He is a Fellow of the Institute of Acoustics, the Acoustical Society of America, and the Audio Engineering Society.

Peter has a special interest in speech intelligibility prediction and measurement and has authored and presented numerous papers and articles on this subject both in Europe and the United States. He currently serves on both British and International Standards committees concerning the sound system design and speech intelligibility.

Peter has been responsible for the design and commissioning of over 500 sound systems, varying from concert halls and theatres, to churches, cathedrals, and other religious buildings, to arenas, stadiums, power stations, and transportation terminals. He is also known for his extensive research work into Distributed Mode Loudspeakers and their application to sound reinforcement.

Peter is a regular contributor to the audio technical press, having written over 100 articles and papers. He is also a contributing author to a number of international reference books including the Loudspeaker Handbook. He is currently the chairman of the AES international working group on speech intelligibility and convenor of IEC 60268-16, the standard relating to the measurement of STI and Speech Intelligibility.

Steven McManus

Steven McManus graduated from the University of Edinburgh in 1990 with a B. E. in Electrical and Electronic Engineering. During this time he also worked on a computer-aided navigation and charting project through the University of Dundee.

An early interest in sound recording expanded into a production and installation company that he ran for 8 years. Steve moved to the United States in 1999 after returning to Herriot-Watt University for an update in programming skills.

He was with the TEF division of Gold Line for 6 years working on both software and hardware. He is currently working for Teledyne Benthos in Massachusetts with underwater acoustic communication and navigation systems.

James E. Mitchell

James (Jay) Mitchell began work in the fields of music and audio in 1972. He was awarded a Bachelor of Science in Physics in 1983 and a Master of Science in Physics in 1985, both from the Georgia Institute of Technology.

Since 1985, he has been involved in the design and development of loudspeakers and associated electronics. His design credits include the IMAX Proportional Point Source loudspeaker and the line of loudspeakers currently manufactured by Frazier Loudspeakers.

He is currently president of Frazier Loudspeakers, in Dallas, Texas. He is a member of the Audio Engineering Society.
Eugene T. Patronis, Jr.

Eugene T. Patronis, Jr. is Professor Emeritus of Physics at the Georgia Institute of Technology in Atlanta, Georgia, where he has taught for over 50 years. During the majority of that time he has also served as an industrial and governmental consultant in the fields of acoustics and electronics.

He is the co-author with Don Davis of the 3rd edition of Sound System Engineering.

Michael Pettersen

Michael Pettersen is the Director of Applications Engineering for Shure Incorporated. Fascinated by sound and audio since building a crystal radio set as a lad, he earned a B.A. in Music Theory from the University of Illinois in 1974.

Employed by Shure since 1976, Michael helped develop and market five different models of automatic microphone mixers. He has presented papers on automatic microphone mixers to the National Association of Broadcasters, the Acoustical Society of America, the National Systems Contractor Association, the European Institute of Acoustics, the Michigan Bar Association, the Voice of America, and others.

He is a member of the Acoustical Society of America and directs Shure’s Consultant Liaison Program, a program that informs acoustical consultants worldwide about new product developments from Shure. Michael also plays guitar with jazz big bands in the Chicago area.

Ken C. Pohlmann

Ken Pohlmann serves as an engineering consultant in the design of digital audio systems, in the development of mobile audio systems for automobile manufacturers, and as an expert witness in technology patent litigation. Some of his consulting clients include Alpine Electronics, Analog Devices, AOL Time Warner, Apple, Bertelsmann, Blockbuster, Cirrus Logic, DaimlerChrysler, Ford, Fujitsu Ten, Harman International, Hughes, Hyundai, IBM, Kia, Lexus, Matsushita, Microsoft, Motorola, Nippon Columbia, Onkyo, Philips, Real Networks, Recording Industry Association of America, Samsung, Sony, TDK, Toyota, and United Technologies.

Mr. Pohlmann is a Professor Emeritus at the University of Miami in Coral Gables, Florida, where he served as a tenured full professor and director of the Music Engineering Technology program in the Frost School of Music. He initiated new undergraduate and graduate courses in acoustics and psychoacoustics, digital audio, advanced digital audio, Internet audio, and studio production and founded the first Master’s degree in Music Engineering in the United States. Mr. Pohlmann holds B.S. and M.S. degrees in electrical engineering from the University of Illinois in Urbana-Champaign.

(1991, Sams). He has written over 2,500 articles for audio magazines and is contributing editor, columnist, and blogger for *Sound & Vision* magazine.

Mr. Pohlmann chaired the Audio Engineering Society’s International Conference on Digital Audio in Toronto in 1989 and co-chaired the Society’s International Conference on Internet Audio in Seattle in 1997. He was presented two AES Board of Governor’s Awards (1989 and 1998) and an AES Fellowship Award (1990) by the Audio Engineering Society for his work as an educator and author in the field of audio engineering. In 1991 he was elected to serve on the AES Board of Governors and in 1993 to serve as the AES Vice President of the Eastern U.S. and Canada Region. In 1992 he was awarded the Philip Frost Award for Excellence in Teaching and Scholarship. In 2000 he was elected as a nonboard member of the National Public Radio Distribution/Interconnection Committee. In 2000 he was elected as a member of the Board of Directors of the New World Symphony.

**Ray A. Rayburn**

Ray A. Rayburn has an ASET from New York Institute of Technology and has worked in the fields of audio, electroacoustics and telecommunications for over 38 years. He has taught audio at Eastman School of Music, Institute of Audio Research, and InfoComm. He designed recording facilities for Broadway Video, Eurosound, Photo-Magnetic Sound, db Studios, and *Saturday Night Live*. His recording credits range from the Philadelphia Orchestra to Frank Zappa. Equipment he has designed includes film dubbers, tape duplicators, specialty telecommunications equipment for the stock brokerage industry, and a polymer analyzer. He has been a consultant on sound systems for the U.S. Senate, U.S. House, Wyoming Senate and House, Georgia Dome, Texas House of Representatives, and University of Hawaii Special Events Arena, among many others.

Currently, Ray is a Senior Consultant with K2 Audio of Boulder, Colorado. He is a member of the Audio Engineering Society (AES), the Acoustical Society of America, the National Systems Contractor’s Association, and InfoComm. He is Chairman of the AES Standards Subcommittee on Interconnections and the working group on Audio Connectors. He is a member and former Chairman of the AES Technical Committee on Signal Processing. He was a member of the American National Standards Institute (ANSI) Accredited Standards Committee (ASC) S4 on Audio Engineering. He is a member of the AES Standards working group on Microphone Measurement and Characteristics and of several other Standards working groups. He devotes much of his spare time to educating churches worldwide on how to improve their sound and acoustics through Curt Taipale’s Church Sound Check email discussion group.

Ray has a personal web site at www.SoundFirst.com.

**Dr. Craig Richardson**

Dr. Craig Richardson is a vice president and general manager of Polycom’s Installed Voice Business. In this role, Richardson leads the development of installed voice products and recently introduced the Sound Structure audio conferencing products—the first installed conferencing products that provide both mono and stereo echo cancellation capabilities for an immersive conferencing experience.

Prior to joining Polycom, Richardson was president and CEO of ASPI Digital and focused the company on creating the EchoFree™ teleconferencing products for the audio/video integrator marketplace. ASPI’s products allowed users to experience full-duplex communication in situations never before thought possible, such as distance learning, telemedicine and courtroom applications. In 2001, ASPI Digital was acquired by Polycom Inc., the leader in unified collaborative communication.

Richardson led algorithm development at ASPI Digital as the director of Algorithm Development working on an advanced low-bit-rate video coder, the MELP military standard voice coder, digital filter design products, computer telephony products, multimedia algorithms for speech, audio, and image processing applications for TMS320 family of digital signal processors. He has written
numerous papers and book chapters, has been granted four patents, and is the co-author (with Thomas P. Barnwell, III, and Kambiz Nayebi) of *Speech Coding A Computer Laboratory Textbook*, a title in the Georgia Tech Digital Signal Processing Laboratory Series published by John Wiley & Sons.

Richardson is a member of Tau Beta Pi, Sigma Xi, and a senior member of the IEEE. He was graduated from Brown University with a bachelor’s degree in electrical engineering and received both his Master’s and doctoral degrees in electrical engineering from the Georgia Institute of Technology.

### Gino Sigismondi

Gino Sigismondi, a Chicago native and Shure Associate since 1997, has been active in the music and audio industry for nearly 15 years. Currently managing the Technical Training division, Gino brings his years of practical experience in professional audio to the product training seminars he conducts for Shure customers, dealers, distribution centers, and internal staff. Gino spent over 9 years as a member of Applications Engineering, assisting Shure customers with choosing and using the company’s vast array of products, and is the author of the Shure educational publications *Selection and Operation of Personal Monitors*, *Audio Systems Guide for Music Educators*, and *Selection and Operation of Audio Signal Processors*. He was recently awarded status as an Adjunct Instructor by the InfoComm Academy.

Gino earned his B.S. degree in Music Business from Elmhurst College, where he was a member of the jazz band as both guitar player and sound technician. After college, he spent several years working as a live sound engineer for Chicago-area sound companies, night clubs, and several local acts. Gino continues to remain active as a musician and sound engineer, consulting musicians on transitioning to in-ear monitors and expanding his horizons beyond live music to include sound design for modern dance and church sound.

### Jeff D. Szymanski

Jeff D. Szymanski is an Acoustical Engineer with Black & Veatch Corporation, a leading global engineering, consulting, and construction company specializing in infrastructure development in energy, water, information, and government market sectors. Jeff’s experience covers many areas of acoustics, including architectural acoustics design, industrial noise and vibration control, environmental noise control, and A/V systems design. He has over 13 years of experience in the acoustical manufacturing and consulting industries.

Prior to joining Black & Veatch, Jeff was the Chief Acoustical Engineer for Auralex Acoustics, Inc., where he was the key designer on several award-winning projects. In 2004–5, he and the Auralex team collaborated with members of the Russ Berger Design Group to develop and launch the award-winning pArtScience brand of acoustic treatment products.

Jeff has written and presented extensively on the subjects of acoustics and noise control. He is a full member of the Acoustical Society of America and the Institute of Noise Control Engineering, holds two U.S. patents for acoustic treatment products, is a licensed professional engineer, and he plays guitar pretty well, too.
Hans-Peter Tennhardt

Hans-Peter Tennhardt was born in Annaberg/Erzgebirge, Germany in 1942. From 1962–1968, Mr. Tennhardt studied at the Technical University Dresden, Department of Electrotechnics—Low-current Engineering. His field of study was Electroacoustics with Professor Reichardt.

Mr. Tennhardt graduated in 1968 as a Diploma’d Engineer for Electrotechnics—Low-current Engineering at the TU Dresden, with an extension of the basic study at the Academy of Music Dresden. His Diploma thesis was on the subject “Model Investigations in Town Planning.”

From 1968–1991, Mr. Tennhardt was a Scientific Collaborator in the Department Building and Room Acoustics at the Building Academy in Berlin, with Professor Fasold. He became Deputy Head of the Department Building and Room Acoustics of the Institute for Heating, Ventilation, and Fundamentals of Structural Engineering at the Building Academy in 1991.

In 1992 Mr. Tennhardt became Group Leader for room acoustics at the Institute of Building Physics (IBP) of the Frauenhofer Institute Stuttgart, Berlin Branch.

Since then he has been Head of the Department Building Physics and of the Special Section Building and Room Acoustics at the Institute for Maintenance and Modernization of Buildings (IEMB) of the Technical University Berlin.

Bill Whitlock

Bill Whitlock was born in 1944 and was building vacuum-tube electronics at the age of 8 and running a radio repair business at the age of 10. He grew up in Florida, attended St. Petersburg Junior College, and graduated with honors from Pinellas County Technical Institute in 1965. He held various engineering positions with EMR/Schlumberger Telemetry, General Electric Neutron Devices, and RCA Missile Test Project (on a ship in the Pacific) before moving to California in 1971.

His professional audio career began in 1972 when he was interviewed by Deane Jensen and hired as chief engineer by custom console maker Quad-Eight. There he developed Compumix®, a pioneering console automation system, and other innovations. From 1974 to 1981, he designed automated image synthesis and control systems, several theater sound systems, and patented a multichannel PCM audio recording system for producers of the Laserium® laser light show. In 1981, Bill became manager of Electronic Development Engineering for Capitol Records/EMI where he designed high-speed cassette duplicator electronics and other specialized audio equipment. He left Capitol in 1988 to team with colleague Deane Jensen, developing hardware for Spatializer Audio Labs, among others. After Deane’s tragic death in 1989, Bill became President and Chief Engineer of Jensen Transformers.

His landmark paper on balanced interfaces was published in the June 1995 AES Journal. He is an active member and former chairman of the AES Standards Committee Working Group that produced AES48-2005. Over the years, Bill has presented many tutorial seminars and master classes for the AES as well as presentations to local AES chapters around the world. He suggested major changes to IEC test procedures for CMRR, which the IEC adopted in 2000. He has written numerous magazine articles and columns for Mix, EDN, S&VC, System Contractor News, Live Sound, Multi-Media Manufacturer, and others. Since 1994, he has taught myth-busting seminars on grounding and interfacing to thousands at industry trades shows, Syn-Aud-Con workshops, private companies, and universities—most recently as an invited lecturer at MIT.

Bill is a Fellow of the Audio Engineering Society and a Senior Member of the Institute of Electrical and Electronic Engineers. His patents include a bootstrapped balanced input stage, available as the InGenius® IC from THAT Corporation, and a high-speed, feed-forward AC power regulator, available from ExactPower®. Bill currently designs audio, video, and other signal interfacing devices at Jensen and handles much of their technical support. He also does
consulting work as time permits. In his leisure time, Bill enjoys travel, hiking, music, and restoring vintage radio and TV sets.

**Peter Xinya Zhang**

Peter Xinya Zhang is a faculty member at Columbia College, Chicago. His field is psychoacoustics, specifically sound localization. He received a B.S. in physics from Peking University, P.R. China, and received his Ph.D. in physics from Michigan State University, Lansing.

In his doctoral thesis, he investigated human binaural pitch effects to test various binaural models, and developed a new technique to simulate a 3D sound field for virtual reality with loudspeakers. He has published papers in the *Journal of Acoustical Society of America*, presented at various conferences, and served as co-chair in the session of psychological and physiological acoustics at the 4th Joint Conference of the Acoustical Society of America and Acoustical Society of Japan. He has lectured on psychoacoustics and sound localization at various institutes including Loyola University in Chicago, Peking University (China), Institute of Acoustics at Chinese Academy of Sciences (China), and Shanghai Conservatory (China). Dr. Zhang is a member of the Acoustical Society of America and of the Audio Engineering Society.

Introduction

This chapter is the DNA of my ancestors, the giants who inspired and influenced my life. If you or a hundred other people wrote this chapter, your ancestors would be different. I hope you find reading the DNA of my ancestors worthwhile and that it will provoke you into learning more about them.

Interest in my audio and acoustic ancestors came about by starting the first independent Hi-Fi shop, The Golden Ear, in Lafayette, Indiana in early 1952. The great men of hi-fi came to our shop to meet with the audio enthusiasts from Purdue: Paul Klipsch, Frank McIntosh, Gordon Gow, H.H. Scott, Saul Marantz, Rudy Bozak, Avery Fisher—manufacturers who exhibited in the Hi-Fi shows at the Hollywood Roosevelt and the Hilton in New York City. We sold our shops in Indianapolis and Lafayette in 1955, and took an extended trip to Europe. In 1958 I went to work for Paul Klipsch as his “President in charge of Vice.” Mr. Klipsch introduced me to Lord Kelvin, the Bell Labs West Street personnel, as well as his untrammeled genius.

Altec was the next stop, with my immediate manager being “the man who made the motion picture talk.” At Altec I rubbed against and was rubbed against by the greats and those who knew the greats of the inception of the Art. This resulted in our awareness of the rich sense of history we have been a part of and we hope that sharing our remembrance will help you become alert to the richness of your own present era.

In 1972 we were privileged to work with the leaders in our industry who came forward to support the first independent attempt at audio education, Synergetic Audio Concepts (Syn-Aud-Con). These manufacturers represented the best of their era and they shared freely with us and our students without ever trying to “put strings on us.”

Genesis

The true history of audio consists of ideas, men who envisioned the ideas, and those rare products that represented the highest embodiment of those ideas. The men and women who first articulated new ideas are regarded as discoverers. Buckminster Fuller felt that the terms realization and realizer were more accurate.

Isaac Newton is credited with “We stand on the shoulders of giants” regarding the advancement of human thought. The word science was first coined in 1836 by Reverend William Hewell, the Master of Trinity College, Cambridge. He felt the term, natural philosopher, was too broad, and that physical science deserved a separate term. The interesting meaning of this word along with entrepreneur-tinkerer allows one a meaningful way to divide the pioneers whose work, stone by stone, built the edifice we call audio and acoustics.

Mathematics, once understood, is the simplest way to fully explore complex ideas but the tinkerer often was the one who found the “idea” first. In my youth I was aware of events such as Edwin Armstrong’s construction of the entire FM transmitting and reception system on breadboard circuits. A successful demonstration then occurred followed by detailed mathematical analysis by the same men who earlier had used mathematics to prove its impossibility. In fact, one of the mathematician’s papers on the impossibility of FM was directly followed at the same meeting by a working demonstration of an FM broadcast by Armstrong.

The other side of the coin is best illustrated by James Clerk Maxwell (1831–1879), working from the non-mathematical seminal work of Michael Faraday.

Michael Faraday had a brilliant mind that worked without the encumbrance of a formal education. His experiments were with an early Volta cell, given him by Volta when he traveled to Italy with Sir Humphry Davy as Davy’s assistant. This led to his experiments with the electric field and compasses. Faraday envisioned fields of force around wires where others saw some kind of electric fluid flowing through wires. Faraday was the first to use the terms electrolyte, anode, cathode, and ion. His examination of inductance led to the electric motor. His observations led his good friend, James Clerk Maxwell, to his remarkable equations that defined electromagnetism for all time.

A conversation with William Thomson (later Lord Kelvin) when Thomson was 21 led Faraday to a series of experiments that showed that Thomson’s question as to whether light was affected by passing through an electrolyte—it wasn’t—led to Faraday’s trying to pass polarized light past a powerful magnet to the discover the magneto-optical effect (the Faraday effect). Diamagnetism demonstrated that magnetism was a property of all matter.

Faraday was the perfect example of not knowing mathematics freed him from the prejudices of the day.
James Clerk Maxwell was a youthful friend of Faraday and a mathematical genius on a level with Newton. Maxwell took Faraday’s theories of electricity and magnetic lines of force into a mathematical formulation. He showed that an oscillating electric charge produces an electromagnetic field. The four partial differential equations were first published in 1873 and have since been thought of as the greatest achievement of the 19th century of physics.

Maxwell’s equations are the perfect example of mathematics predicting a phenomenon that was unknown at that time. That two such differing mind-sets as Faraday and Maxwell were close friends bespeaks the largeness of both men.

These equations brought the realization that, because charges can oscillate with any frequency, visible light itself would form only a small part of the entire spectrum of possible electromagnetic radiation. Maxwell’s equations predicted transmittable radiation which led Hertz to build apparatus to demonstrate electromagnetic transmission.

J. Willard Gibbs, America’s greatest contributor to electromagnetic theory, so impressed Maxwell with his papers on thermodynamics that Maxwell constructed a three-dimensional model of Gibbs’s thermodynamic surface and, shortly before his death, sent the model to Gibbs.

G.S. Ohm, Alessandro Volta, Michael Faraday, Joseph Henry, Andre Marie Ampere, and G.R. Kirchhoff grace every circuit analysis done today as resistance in ohms, potential difference in volts, current in amperes, inductance in henrys, and capacity in farads and viewed as a Kirchhoff diagram. Their predecessors and contemporaries such as Joule (work, energy, heat), Charles A. Coulomb (electric charge), Isaac Newton (force), Hertz (frequency), Watt (power), Weber (magnetic flux), Tesla (magnetic flux density), and Siemens (conductance) are immortalized as international S.I. derived units. Lord Kelvin alone has his name inscribed as an S.I. base unit.

As all of this worked its way into the organized thinking of humankind, the most important innovations were the technical societies formed around the time of Newton where ideas could be heard by a large receptive audience. Some of the world’s best mathematicians struggled to quantify sound in air, in enclosures, and in all manner of confining pathways. Since the time of Euler (1707–1783), Lagrange (1736–1813), and d’Alembert (1717–1783), mathematical tools existed to analyze wave motion and develop field theory.

By the birth of the 20th century, workers in the telephone industry comprised the most talented mathematicians and experimenters. Oliver Heaviside’s operational calculus had been superseded by Laplace transforms at MIT (giving them an enviable technical lead in education).

1893—The Magic Year

At the April 18, 1893 meeting of the American Institute of Electrical Engineers in New York City, Arthur Edwin Kennelly (1861–1939) gave a paper entitled “Impedance.”

That same year General Electric, at the insistence of Edwin W. Rice, bought Rudolph Eickemeyer’s company for his transformer patents. The genius Charles Proteus Steinmetz (1865–1923) worked for Eickemeyer. In the saga of great ideas, I have always been as intrigued by the managers of great men as much as the great men themselves. E.W. Rice of General Electric personified true leadership when he looked past the misshapened dwarf that was Steinmetz to the mind present in the man. General Electric’s engineering preeminence proceeded directly from Rice’s extraordinary hiring of Steinmetz.
Dr. Michael I. Pupin of Columbia University was present at the Kennelly paper. Pupin mentioned Oliver Heaviside’s use of the word impedance in 1887. This meeting established the correct definition of the word and established its use within the electric industry. Kennelly’s paper, along with the ground-work laid by Oliver Heaviside in 1887, was instrumental in introducing the terms being established in the minds of Kennelly’s peers.

The truly extraordinary Arthur Edwin Kennelly (1861–1939) left school at the age of thirteen and taught himself physics while working as a telegrapher. He is said to “have planned and used his time with great efficiency,” which is evidenced by his becoming a member of the faculty at Harvard in 1902 while also holding a joint appointment at MIT from 1913–1924. He was the author of ten books and the co-author of eighteen more, as well as writing more than 350 technical papers.

Edison employed A.E. Kennelly to provide physics and mathematics to Edison’s intuition and cut-and-try experimentation. His classic AIEE paper on impedance in 1893 is without parallel. The reflecting ionosphere theory is jointly credited to Kennelly and Heaviside and known as the Kennelly-Heaviside layer. One of Kennelly’s Ph.D. students was Vannevar Bush, who ran American’s WWII scientific endeavors.

In 1893 Kennelly proposed impedance for what had been called apparent resistance, and Steinmetz suggested reactance to replace inductance speed and wattless resistance. In the 1890 paper, Kennelly proposed the name henry for the unit of inductance. A paper in 1892 that provided solutions for RLC circuits brought out the need for agreement on the names of circuit elements. Steinmetz, in a paper on hysteresis, proposed the term reluctance to replace magnetic resistance. Thus, by the turn of the 20th century the elements were in place for scientific circuit analysis and practical realization in communication systems.

Arthur E. Kennelly’s writings on impedance were meaningfully embellished by Charles Proteus Steinmetz’s use of complex numbers. Michael Pupin, George A. Campbell, and their fellow engineers developed filter theory so thoroughly as to be worthwhile reading today.

Steinmetz was not at the April 18, 1893 meeting, but sent in a letter of comment which included,

*It is, however, the first instance here, so far as I know, that the attention is drawn by Mr. Kennelly to the correspondence between the electric term “impedance” and the complex numbers.*

*The importance hereof lies in the following: The analysis of the complex plane is very well worked out, hence by reducing the technical problems to the analysis of complex quantities they are brought within the scope of a known and well understood science.*

The fallout from this seminal paper, its instantaneous acceptance by the other authorities of the day, its coalescing of the earlier work of others, and its utilization by the communication industry within a decade, makes it easily one of the greatest papers on audio ever published, even though Kennelly’s purpose was to aid the electric power industry in its transmission of energy.

The generation, transmission, and distribution of electromagnetic energy today has no meaning in itself, but only gains meaning if information is conveyed, thus the tragedy of the use of mankind’s precious resources to convey trash.

Nikola Tesla (1856–1943) working with Westinghouse designed the AC generator that was chosen in 1893 to power the Chicago World’s Fair.

Bell Laboratories and Western Electric

The University of Chicago, at the end of the turn of the 19th century into the 20th century, had Robert Millikan, America’s foremost physicist. Frank Jewett, who had a doctorate in physics from MIT, and now worked for Western Electric, was able to recruit Millikan’s top students.
George A. Campbell (1870–1954) of the Bell Telephone Laboratories, had by 1899 developed successful “loading coils” capable of extending the range and quality of the, at that time, unamplified telephone circuits. Unfortunately, Professor Michael Pupin had also conceived the idea and beat him to the patent office. Bell Telephone paid Pupin $435,000 for the patent and by 1925 the Campbell-designed loading coils had saved Bell Telephone Co. $100,000,000 in the cost of copper wire alone.

To sense the ability of loading coils to extend the range of unamplified telephone circuits, Bell had reached New York to Denver by their means alone. Until Thomas B. Doolittle evolved a method in 1877 for the manufacture of hard drawn copper, the metal had been unusable for telephony due to its inability to support its own weight over usable distances. Copper wire went from a tensile strength of 28,000 lbs/in² with an elongation of 37% to a tensile strength of 65,000 lbs/in², an elongation of 1%.

Campbell’s paper in 1922, “Physical Theory of the Electric Wave Filter” is still worthwhile reading today. I remember asking Dr. Thomas Stockham, “Do digital filters ring under transient conditions?” Dr. Stockham, (his wife, Martha, said that she worshipped the air he walked on), replied “Yes” and pointed out that it’s the math and not the hardware that determines what filters do. Papers like Campbell’s are pertinent to Quantum filters, when they arrive, for the same reasons Dr. Stockham’s answer to my question about digital filters was valid.

Bell Telephone Laboratories made an immense step when H.D. Arnold designed the first successful electronic repeater amplifier in 1913. H.D. Arnold at Bell Laboratories had taken DeForest’s vacuum tube, discarded DeForest’s totally false understanding of it, and, by establishing a true vacuum, improved materials and a correct electrical analysis of its properties enabled the electronic amplification of voice signals. DeForest is credited with putting a “grid” into a Fleming value.

Sir Ambrose J. Fleming (1848–1945) is the English engineer who invented the two-electrode rectifier which he called the thermionic valve. It later achieved fame as the Fleming valve and was patented in 1904. DeForest used the Fleming valve to place a grid element in between the filament and the plate. DeForest didn’t understand how a triode operated, but fortunately Armstrong, Arnold, and Fleming did.

Another Fleming—Sir Arthur (1881–1960)—invented the demountable high power thermionic valves that helped make possible the installation of the first radar stations in Great Britain just before the outbreak of WWII. The facts are that DeForest never understood what he had done, and this remained true till his death. DeForest was never able, in court or out, to correctly describe how a triode operated. He did however; provide a way for large corporations to challenge in court the patents of men who did know.

With the advent of copper wire, loading coils, and Harold D. Arnold’s vacuum tube amplifier, transcontinental telephony was established in 1915 using 130,000 telephone poles, 2500 tons of copper wire, and three vacuum tube devices to strengthen the signal.

The Panama Pacific Exposition in San Francisco had originally been planned for 1914 to celebrate the completion of the Panama Canal but the canal was not completed until 1915. Bell provided not only the first transcontinental telephony, but also a public address system at those ceremonies.

The advances in telephony led into recording technologies and by 1926–1928 talking motion pictures. Almost in parallel was the development of radio. J.P. Maxfield, H.C. Harrison, A.C. Keller, D.G. Blattner were the Western Electric Electrical recording pioneers. Edward Wente’s 640A condenser microphone made that component as uniform as the amplifiers, thus insuring speech intelligibility and musical integrity.
In 1933, Harvey Fletcher, Steinberg and Snow, Wente and Thuras and a host of other Bell Lab engineers gave birth to “Audio Perspective” demonstrations of three-channel stereophonic sound capable of exceeding the dynamic range of the live orchestra. In the late 60s, William Snow was working with John Hilliard at Ling Research, just down the street from Altec. It was a thrill to talk with him. He told me that hearing the orchestra level raised several dB was more astounding to him than the stereophonic part of the demonstration.

Edward C. Wente and Albert L. Thuras were responsible for full range, low distortion, high-powered sound reproduction using condenser microphones, compression drivers, multicellular exponential horns, heavy duty loaded low-frequency enclosures, the bass reflex enclosures, and both amplifiers and transmission lines, built to standards still challenging today. The Fletcher loudspeaker was a three-way unit consisting of an 18 inch low-frequency driver, horn loaded woofer, the incomparable W.E. 555 as a midrange, and the W.E. 597A high-frequency unit.

In 1959, I went with Paul W. Klipsch to Bell Labs where we jointly presented our redo of their 1933 Audio Perspective geometry tests. The demo was held in the Arnold Auditorium and afterward we were shown one of the original Fletcher loudspeakers. Western Electric components like the 555 and 597 are to be found today in Japan where originals sell for up to five figures. It is estimated that 99% of the existing units are in Japan. (As a side note, I genuinely earned a “Distinguished Fear of Flying Cross” with Paul Klipsch in his Cessna 180, the results of which entertained many Syn-Aud-Con classes.

The Western Electric 640A was superseded by the 640AA condenser microphone in 1942, still used today as a measurement standard by those fortunate enough to own one. The 640A was a key component in the reproduction of the full orchestra in 1933. When redesigned in 1942 as the 640AA, Bell Labs turned over the manufacturing of the capsule to Bruel and Kjaer as the B&K 4160.

Rice and Kellogg’s seminal 1925 paper and Edward Wente’s 1925 patent #1,333,744 (done without knowledge of Rice and Kellogg’s work) established the basic principle of the direct-radiator loudspeaker with a small coil-driven mass controlled diaphragm in a baffle possessing a broad mid-frequency range of uniform response.

Rice and Kellogg also contributed a more powerful amplifier design and the comment that for reproduced music the level should be that of the original intensity.
**Negative Feedback—1927**

In 1927 Harold S. Black, while watching a Hudson River ferry use reverse propellers to dock, conceived negative feedback for power amplifiers. With associates of the caliber of Harry Nyquist and Hendrik Bode, amplifier gain, phase, and stability, became a mathematical theory of immense use in remarkably diverse technical fields. Black’s patent took nine years to issue because the U.S. Navy felt it revealed too much about how they adjusted their big guns and asked that its publication be delayed.

The output signal of an amplifier is fed back and compared with the input signal, developing a “difference signal” if the two signals are not alike. This signal, a measure of the error in amplification, is applied as additional input to correct the functioning of the amplifier, so as to reduce the error signal to zero. When the error signal is reduced to zero, the output corresponds to the input and no distortion has been introduced. Nyquist wrote the mathematics for allowable limits of gain and internal phase shift in negative feedback amplifiers, insuring their stability.

**Harry Nyquist (1889–1976)**

Harry Nyquist worked at AT&T’s Department of Development and Research from 1917 to 1934 and continued when it became Bell Telephone Laboratories in that year, until his retirement in 1954.

The word inspired means “to have been touched by the hand of God.” Harry Nyquist’s 37 years and 138 U.S. patents while at Bell Telephone Laboratories personifies “inspired.” In acoustics the Nyquist plot is by far my favorite for first look at an environment driven by a known source. The men privileged to work with Harry Nyquist in thermal noise, data transmission, and negative feedback all became giants in their own right through that association.

Nyquist worked out the mathematics that allowed amplifier stability to be calculated leaving us the Nyquist plot as one of the most useful audio and acoustic analysis tools ever developed. His cohort, Hendrik Bode, gave us the frequency and phase plots as separate measurements.

Karl Kupfmuller (1897–1977) was a German engineer who paralleled Nyquist’s work independently, deriving fundamental results in information transmission and closed-loop modeling, including a stability criterion. Kupfmuller as early as 1928 used block diagrams to represent closed-loop linear circuits. He is believed to be the first to do so. As early as 1924 he had published papers on the dynamic response of linear filters. For those wishing to share the depth of understanding these men achieved, Ernst Guillemin’s book, Introductory Circuit Theory, contains clear steps to that goal.

Today’s computers as well as digital audio devices were first envisioned in the mid-1800s by Charles Babbage and the mathematics discussed by Lady Lovelace, the only legitimate daughter of Lord Byron. Lady Lovelace even predicted the use of a computer to generate musical tones. Harry Nyquist later defined the necessity for the sampling rate for a digital system to be at least twice that of the highest frequency desired to be reproduced.

Nyquist and Shannon went from Nyquist’s paper on the subject to develop “Information Theory.” Today’s audio still uses and requires Nyquist plotting, Nyquist frequency, the Nyquist-Shannon sampling theorem, the Nyquist stability criterion, and attention to the Johnson-Nyquist noise. In acoustics the Nyquist plot is by far my favorite for first look at an environment driven by a known source.

**The dB, dBm and the VI**

The development of the dB from the mile of standard cable by Bell Labs, their development and sharing of the decibel, dB, the dBm, and the VU via the design of VI devices changed system design into engineering design.

Of note here to this generation, the label VU is just that, VU, and has no other name, just as the instrument is called a volume indicator, or VI. In today’s world, a majority of technicians do not understand the dBm and its remarkable usefulness in system design. An engineer must know this parameter to be taken seriously.
Bell Labs and Talking Motion Pictures

Bell Telephone Laboratories by the mid to late 1930s had from the inception of talking motion pictures in 1927–1928 brought forth the condenser microphone, exponential high frequency horns, exponential low frequency loudspeakers, compression drivers, the concepts of gain and loss, the dBm, the VU, in cooperation with the broadcasting industry, and installed sound in 80% of the existing theater market.

Yes, there were earlier dabblers thinking of such ideas but their ideas remained unfulfilled. What generated the explosive growth of motion picture sound—even through the deepest depression—was that only (1) entertainment, (2) tobacco, and (3) alcohol were affordable to the many and solaced their mental depression.

For physicists, motion picture sound was that age’s “space race” and little boys followed the sound engineers down the street saying, “He made the movie talk.” Dr. Eugene Patronis sent me a picture of the W.E. loudspeaker system installed in the late 1930s in which the engineer had actually aligned the H.F. and L.F. drivers. Dr. Patronis had worked in the projector booth as a teenager. He later designed an outstanding loudspeaker system for the AMC theater chain that was aligned and installed above rather than behind the screen, thereby allowing much brighter images. The system maintained complete spatial location screen-center for the audio.

Motion Pictures—Visual versus Auditory

The first motion pictures were silent. Fortunes were made by actors who could convey visual emotion. When motion pictures acquired sound in 1928, a large number of these well-known personalities failed to make the transition from silent to sound. The faces and figures failed to match the voices the minds of the silent movie viewers had assigned them. Later, when radio became television, almost all the radio talent was able to make a transition because the familiar voices predominated over any mental visual image the radio listener had assigned to that performer.

Often, at the opera, the great voices will not look the part but, just a few notes nullify any negative visual impression for the true lover of opera, whereas appearance will not compensate for a really bad voice.

The Transition from Western Electric to Private Companies

A remarkable number of the giants in the explosion in precision audio products after WWII were alumni of Western Electric-Bell Labs, MIT, and General Radio, and in some cases, all three.

In 1928, a group of Western Electric engineers became the Electrical Research Products, Inc. (ERPI), to service the theaters. Finally a consent decree came down, as a result of litigation with RCA, for W.E. to divest itself of ERPI. At this point the engineers formed All Technical Services or Altec. That is why it is pronounced all-tech, not al-tech. They lived like kings in a depressed economy. As one of these pioneer engineers told me, “Those days were the equivalent of one ohm across Fort Knox.” They bought the W.E. Theater inventory for pennies on the dollar.

The motion picture company MGM had assembled, via Douglas Shearer, head of the sound department, John Hilliard, Dr. John Blackburn, along with Jim Lansing, a machinist, and Robert Stephens, a draftsman. A proprietary theater loudspeaker was named the Shearer horn. Dr. Blackburn and Jim Lansing did the high frequency units with Stephens, adapting the W.E. multi-cell to their use. It was this system that led to John Hilliard’s correction of the blurred tapping of Eleanor Powell’s very rapid tap dancing by signal aligning the high and low frequency horns. They found that a 3 inch misalignment was small enough to not smear the tapping. (Late in the 1980s, I demonstrated that from 0 to 3 inch misalignment resulted in a shift in the polar response.) Hilliard had previously found that there was on the order of 1500° in phase shift in the early studio amplification systems. He corrected the problem and published his results in the 1930s.

After WWII, Hilliard and Blackburn, who both were at MIT doing radar work during the war, went their separate ways, with Hilliard joining Altec Lansing. Hilliard received an honorary Ph.D. with a degree from the Hollywood University run by Howard Termaine, the author.
of the original Audio Encyclopedia, the forerunner to this present volume, The Handbook for Sound Engineers.

Robert Lee Stephens left MGM in 1938 to found his own company. In the early 1950s I witnessed demonstrations of the Altec 604, the Stephens TruSonic co-axial and the Jensen Triaxial, side by side in my hi-fi shop, The Golden Ear. The Tru-Sonics was exceptionally clean and efficient. Stephens also made special 15 inch low-frequency drivers for the early Klipschorns.

Hilliard, Stephens, Lansing and Shearer defined the theater loudspeaker for their era with much of the design of the Shearer multicells manufactured by Stephens.

When James Lansing (aka James Martinella) first came west he adopted the Hollywood technique of a name change. His brother, who worked for Altec through his entire career, shortened his name to Bill Martin, a truly skilled machinist who could tool anything. In 1941, Altec bought Lansing Manufacturing Company and changed the Altec name to Altec Lansing Corp. James Lansing was enjoined by Altec to the use of JBL rather than Lansing for product names. He committed suicide in 1949, and JBL would have vanished except Edmond May, considered the most valuable engineer ever at JBL, stepped into the design breach with a complete series of high quality products.

In 1947, Altec purchased Peerless Electrical Products Co. This brought in not only the first designers of 20–20,000 Hz output transformer, Ercel Harrison and his talented right-hand man, Bob Wolpert, but also the ability to manufacture what they designed. Ercel Harrison’s Peerless transformers are still without peer even today.

In 1949, Altec acquired the Western Electric Sound Products Division and began producing the W.E. product lines of microphones and loudspeakers. It was said that all the mechanical product tooling, such as turntables and camera items were dumped in the channel between Los Angeles and Catalina.

Jim Noble, H.S. Morris, Ercel Harrison, John Hillard, Jim Lansing, Bob Stevens and Alex Badmiff (my co-author for How to Build Speaker Enclosures) were among the giants who populated Altec and provided a glimpse into the late 1920s, the fabulous 1930s, and the final integration of W.E. Broadcasting and Recording technologies into Altec in the 1950s.

Paul Klipsch in 1959 introduced me to Art Crawford, the owner of a Hollywood FM station, who developed the original duplex speaker. The Hollywood scene has always had many clever original designers whose ideas were for “one only” after which their ideas migrated to manufacturers on the West coast.

Running parallel through the 20s and 30s with the dramatic developments by Western Electric, Bell Labs, and RCA were the entrepreneurial start-ups by men like Sidney N. Shure of Shure Brothers, Lou Burroughs and Al Kahn of what became Electro-Voice, and E. Norman Rauland who from his early Chicago radio station WENR went on to become an innovator in cathode ray tubes for radar and early television.

When I first encountered these men in the 50s, they sold their products largely through parts distributors. Starting the 1960s they sold to sound contractors. Stromberg-Carlson, DuKane, RCA, and Altec were all active in the rapidly expanding professional sound contractor market.

A nearly totally overlooked engineer in Altec Lansing history is Paul Veneklasen, famous in his own right for the Western Electro Acoustic Laboratory, WEAL. During WWII, Paul Veneklasen researched and designed, through extensive outdoor tests with elaborate towers, what became the Altec Voice of the Theater in postwar America. Veneklasen left Altec when this and other important work (the famed “wand” condenser microphone) were presented as Hilliard’s work in Hilliard’s role as a figurehead. Similar tactics were used at RCA with Harry Olson as the presenter of new technology. Peter Goldmark of the CBS Laboratories was given credit for the 33 1/3 long playing record. Al Grundy was the engineer in charge of developing it, but was swept aside inasmuch as CBS used Goldmark as an icon for their introductions. Such practices were not uncommon when large companies attempted to put an “aura” around personnel who introduced their new products, to the chagrin and disgust of the actual engineers who had done the work.

“This is the west, sir, and when a legend and the facts conflict, go print the legend.”
From Who Shot Liberty Valance

**Audio Publications**

Prior to WWII, the IRE, Institute of Radio Engineers, and the AIEE, American Institute of Electrical Engineers, were the premier sources of technology applicable to audio. The Acoustical Society of America filled the role in matters of acoustics. I am one year older than the JASA, which was first published in 1929. In 1963, the IRE and AIEE merged to become the IEEE, the Institute of Electrical and Electronic Engineers.
In 1947, C.G. McProud published Audio Engineering that featured construction articles relevant to Audio. Charles Fowler and Milton Sleeper started High Fidelity in 1954. Sleeper later published Hi Fi Music at Home. These magazines were important harbingers of the explosive growth of component sound equipment in the 1950s.

The Audio Engineering Society, AES, began publication of their journal in January 1953. The first issue contained an article written by Arthur C. Davis entitled, “Grounding, Shielding and Isolation.”

Readers need to make a clear distinction in their minds between magazines designed as advertising media for “fashion design” sound products and magazines that have the necessary market information requiring the least reader screening of foolish claims. The right journals are splendid values and careful perusal of them can bring the disciplined student to the front of the envelope rapidly.

The “High” Fidelity Equipment Designers

By the beginning of WWII, Lincoln Walsh had designed what is still today considered the lowest distortion power amplifier using all triode 2A3s. Solid state devices, even today, have yet to match the perfection of amplifiers such as Lincoln Walsh’s Brook with its all triode 2A3s or Marantz’s EL34 all triode amplifier. The Walsh amplifiers, with the linearity and harmonic structure achieved by these seminal tube amplifiers, are still being constructed by devotees of fidelity who also know how to design reasonable efficiency loudspeakers. One engineer that I have a high regard for tells the story,

*It wasn’t that long ago I was sitting with the editor of a national audio magazine as his $15,000 transistor amplifier expired in a puff of smoke and took his $22,000 speakers along for the ride. I actually saw the tiny flash of light as the woofer voice coil vaporized from 30 A of dc offset—true story folks.*

In the 1950s, a group of Purdue University engineers and I compared the Brook 10 W amplifier to the then very exciting and unconventional 50 W McIntosh. The majority preferred the 10 W unit. Ralph Townsley, chief engineer at WBAA, loaned us his peak reading meter. This was an electronic marvel that weighed about 30 lbs but could read the true full peak side-by-side with the VU reading on two beautiful VI instruments. We found that the ticks on a vinyl record caused clipping on both amplifiers but the Brook handled these transients with far more grace than the McIntosh.

We later acquired a 200 W tube-type McIntosh and found that it had sufficient headroom to avoid clipping over the Klipschorns, Altec 820s, etc.

When Dr. R.A. Greiner of the University of Wisconsin published his measurements of just such effects, our little group were appreciative admirers of his extremely detailed measurements. Dr. Greiner could always be counted on for accurate, timely, and when necessary, myth-busting corrections. He was an impeccable source of truth. The home entertainment section of audio blithely ignored his devastating examination of their magical cables and went on to fortunes made on fables.

Music reproduction went through a phase of, to this writer, backward development, with the advent of extremely low efficiency book shelf loudspeaker packages with efficiencies of 20–40 dB below the figures which were common for the horn loudspeakers that dominated the home market after WWII. Interestingly, power amplifiers today are only 10–20 dB more powerful than a typical 1930s triode amplifier.

I had the good fortune to join Altec just as the fidelity home market did its best to self-destruct via totally unreliable transistor amplifiers trying to drive “sink-holes” for power loudspeakers in a marketing environment of spiffs, department store products, and the introduction of source material not attractive to trained music listeners.

I say “good fortune” as the professional sound was, in the years of the consumer hiatus, to expand and develop in remarkable ways. Here high efficiency was coupled to high power, dynamic growth in directional control of loudspeaker signals, and the growing awareness of the acoustic environment interface.

Sound System Equalization

Harry Olson and John Volkmann at RCA made many advances with dynamical analogies, equalized loudspeakers, and an array of microphone designs.

Dr. Wayne Rudmose was the earliest researcher to perform meaningful sound system equalization. Dr. Rudmose published a truly remarkable paper
in Noise Control (a supplementary journal of the Acoustical Society of America) in July 1958. At the AES session in the fall of 1967, I gave the first paper on the \( \frac{1}{3} \) octave contiguous equalizer. Wayne Rudmose was the chairman of the session.

In 1969, a thorough discussion of acoustic feedback that possessed absolute relevance to real-life equalization appeared in the Australian Proceedings of the IREE. “A Feedback-Mode Analyzer/Suppressor Unit for Auditorium Sound System Stabilization” by J.E. Benson and D.F. Craig, illustrating the step-function behavior of the onset and decay of regeneration in sound systems.

These four sources constitute the genesis of modern system equalization. Fixed equalization was employed by many early experimenters including Kellogg and Rice in the early 1920s, Volkmann of RCA in the 1930s, and Dr. Charles Boner in the 1960s.

Dr. Boner is shown here in the midst of installing filters hardwired one at a time “until the customer ran out of money”— was a famous quote. His demonstrations of major improvements in sound systems installed in difficult environments encouraged many to further investigate sound system design and installation practices, followed by custom \( \frac{1}{3} \) octave equalization. His view of himself was “that the sound system was the heart patient and he was the Dr. DeBakey of sound.”

The equalization system developed at Altec in 1967 by Art Davis (of Langevin fame), Jim Noble, chief electronics engineer, and myself was named Acousta-Voicing. This program, coupled precision measurement equipment and specially trained sound contractors, resulted in larger more powerful sound systems once acoustic feedback was tamed via band rejection filters spaced at \( \frac{1}{3} \) octave centers.

Equalization dramatically affected quality in recording studios and motion picture studios. I introduced variable system equalization in special sessions at the screening facilities in August 1969 to the sound heads of MGM—Fred Wilson, Disney — Herb Taylor, and Al Green—Warner Bros/7 Arts.

Sound system equalization, room treatment such as Manfred Schroeder’s Residue Diffusers designed and manufactured by Peter D’Antonio, and the signal alignment of massive arrays led to previously unheard of live sound levels in large venues.

**Acoustics**

As Kelvin was to electrical theory so was John William Strutt, Third Baron Rayleigh, to acoustics. He was known to later generations as Lord Rayleigh (1842–1919). I was employed by Paul W. Klipsch, a designer and manufacturer of high quality loudspeaker systems in the late 1950s. He told me to obtain and read Lord Rayleigh’s *The Theory of Sound*. I did so to my immense long term benefit. This remarkable three-volume tome remains the ultimate example of what a gentleman researcher can achieve in a home laboratory. Lord Rayleigh wrote,

> The knowledge of external things which we derive from the indications of our senses is for the most part the result of inference.

The illusionary nature of reproduced sound, the paper cone moving back and forth being inferred to be a musical instrument, a voice, or other auditory stimuli, was vividly reinforced by the famous Chapter 1.

In terms of room acoustics, Wallace Clement Sabine was the founder of the science of architectural acoustics. He was the acoustician for Boston Symphony Hall, which is considered to be one of the three finest concert halls in the world. He was the mountain surrounded by men like Hermann, L.F. von Helmholtz, Lord Rayleigh, and

![Wallace Clement Sabine](image)
Modern communication theory has revealed to us a little of the complexity of the human listener. The human brain has from $10^{15}$ to $10^{17}$ bits of storage and we are told an operating rate of 100,000 Teraflops per second. No wonder some “sensitives” found difficulties in early digital recordings and even today attendance at a live unamplified concert quickly dispels the notion that reproduced sound has successfully modeled live sound.

We have arrived in the 21st century with not only fraudulent claims for products (an ancient art) but deliberately fraudulent technical society papers hoping to deceive the reader. I once witnessed a faulty technical article in a popular audio magazine that caused Mel Sprinkle (authority on the gain and loss of audio circuits) to write a Letter to the Editor. The Editor wrote saying Mel must be the one in error as a majority of the Letters to the Editor sided with the original author—a case of engineering democracy. We pray that no river bridges will be designed by this democratic method.

Frederick Vinton Hunt of Harvard was one of the intellectual offspring of men like Wallace Clement Sabine. As Leo Beranek wrote,

> At Harvard, Hunt worked amid a spectacular array of physicists and engineers. There was George Washington Pierce, inventor of the crystal oscillator and of magnetostriction transducers for underwater sound; Edwin H. Hall of the Hall effect; Percy Bridgeman, Nobel Laureate, whose wife had been secretary to Wallace Sabine; A.E. Kennelly of the Kennelly-Heaviside layer; W.F. Osgood, the mathematician; O.D. Kellog of potential theory; and F.A. Saunders, who was the technical heir at Harvard to Sabine.

Hunt’s success in 1938 of producing a wide range 5 gram phonograph pickup that replaced the 5 oz units then in use led to Hunt and Beranek building large exponentially folded horns, a very high power amplifier and the introduction of much higher fidelity than had previously been available.

Dr. Hunt attended the technical session at the Los Angeles AES meeting in 1970 when I demonstrated the computation of acoustic gain for the sound system at hand, followed by Acousta-Voicing equalization in real time on the first H.P. Real Time Analyzer, all in 20 minutes. Dr. Hunt’s remark to the audience following the demonstration insured the immediate acceptance of what we had achieved without any questions from the previous doubters. Dr. Hunt took genuine interest in the technology and was generous in his praise of our application of it. He said, “I don’t fully understand how you have done it, but it certainly works.”
broadcasting station and consequently a "clear channel" that Ralph Townsley utilized to modulate 20–20,000 Hz low distortion AM signals. Those of us who had Sargent Rayment TRF tuners had AM signals undistinguishable from FM, except during electrical storms. Any graduating Electrical engineer who could pass Townsley’s basic audio networks test, for a job at WBAA, was indeed an engineer who could think for himself or herself about audio signals.

Great audio over AM radio in the late 1920s and early 1930s ran from the really well-engineered Atwater Kent tuned radio frequency receiver (still the best way to receive AM signals via such classics as the Sargent Rayment TRF tuner) to the absolutely remarkable, for its time, E.H. Scott’s Quaranta (not to be confused with the equally famous H.H. Scott of postwar years).

This was a 48 tube superheterodyne receiver built on six chrome chassis weighing 620 lbs with five loudspeakers (two woofers, midrange, and high frequency units) biamped with 50 W for the low frequencies and 40 W for the high frequencies. My first view of one of these in the late 1930s revealed that wealth could provide a cultural life.

**Edwin Armstrong**

*1890–1954*  
*The Invention of Radio and Fidelity*

The technical history of radio is best realized by the inventor/engineer Edwin Howard Armstrong. Other prominent figures were political and other engineers were dwarfed by comparison to Armstrong.

In the summer of 1912, Armstrong, using the new triode vacuum tube, devised a new regenerative circuit in which part of the signal at the plate was fed back to the grid to strengthen incoming signals. In spite of his youth, Armstrong had his own pass to the famous West Street Bell Labs because of his regenerative circuit work. The regenerative circuit allowed great amplification of the received signal and also was an oscillator, if desired, making continuous wave transmission possible. This single circuit became not only the first radio amplifier, but also the first continuous wave transmitter that is still the heart of all radio operations.

In 1912–1913 Armstrong received his engineering degree from Columbia University, filed for a patent, and then returned to the university as assistant to professor and inventor Michael Pupin. Dr. Pupin was a mentor to Armstrong and a great teacher to generations at Columbia University.

World War I intervened and Armstrong was commissioned as an officer in the U.S. Army Signal Corps and sent to Paris. While there and in the pursuit of weak enemy wireless signals, he designed a complex eight tube receiver called the *superheterodyne circuit*, the circuit still used in 98% of all radio and television receivers.

In 1933 Armstrong invented and demonstrated wide-band frequency modulation that in field tests gave clear reception through the most violent storms and the greatest fidelity yet witnessed. The carrier was constant power while the frequency was modulated over the bandpass chosen.

He had built the entire FM transmitter and receiver on breadboard circuits of Columbia University. After the fact of physical construction, he did the mathematics.

Armstrong, in developing FM, got beyond the equations of the period which in turn laid the foundations for information theory, which quantifies how bandwidth can be exchanged for noise immunity.

In 1922, John R. Carson of AT&T had written an IRE paper that discussed modulation mathematically. He showed that FM could not reduce the station band-
width to less than twice the frequency range of the audio signal, “Since FM could not be used to narrow the transmitted band, it was not useful.”

Edwin Armstrong ignored narrowband FM and moved his experiments to 41 MHz and used a 200 kHz channel for wideband, noiseless reproduction. FM broadcasting allowed the transmitter to operate at full power all the time and used a limiter to strip off all amplitude noise in the receiver. A detector was designed to convert frequency variations into amplitude variations.

Paul Klipsch was a personal friend of Edwin Armstrong: Mr. Klipsch had supplied Klipschorns for the early FM demonstration just after WWII. This was when Armstrong, through Sarnoff’s political manipulation, had been forced to move FM from 44–50 MHz to 88–108 MHz, requiring a complete redesign of all equipment. It was a stark lesson on how the courts, the media, and really big money can destroy genuine genius. Armstrong had literally created radio: the transmitters, the receivers for AM-FM-microwave in their most efficient forms. David Sarnoff made billions out of Armstrong’s inventions, as well as an economic-political empire via the AM radio networks. No court or any politician should ever be allowed to make a technical judgment. Those judgments should be left to the technical societies as the “least worst” choice.

The history of audio is not the forum for discussing the violent political consequences—Sarnoff of RCA totally controlled the powerful AM networks of the time. In 1954 attorneys for RCA and AT&T led to Armstrong’s death by suicide. The current AM programming quality put on FM leaves quality FM radio a rare luxury in some limited areas.

The few, myself included, who heard the live broadcasts of the Boston Symphony Orchestra over the FM transmitter given them by Armstrong and received on the unparalleled, even today, precedent FM receivers know what remarkable transparency can be achieved between art and technology.

Plato said, “God ever geometrizes.” Richard Heyser, the geometer, should feel at ease with God. To those whose minds respond to the visual, Heyser’s measurements shed a bright light on difficult mathematical concepts. The Heyser Spiral displays the concepts of the complex plane in a single visual flash. Heyser was a scientist in the purest sense of the word, employed by NASA, and audio was his hobby. I am quite sure that the great scientists of the past were waiting at the door for him when he past through. His transform has yet to be fully understood. As with Maxwell, we may have to wait a hundred years.

When I first met Richard C. Heyser in the mid-1960s, Richard worked for Jet Propulsion Labs as a senior scientist. He invited me to go to his basement at his home to see his personal laboratory. The first thing he showed me on his Time Delay Spectrometry equipment was the Nyquist plot of a crossover network he was examining. I gave the display a quick look and said, “That looks like a Nyquist plot!”

He replied, “It is.”

“But,” I said, “No one makes a Nyquist analyzer.”

“That’s right,” he replied.

At this point I entered the modern age of audio analysis. Watching Dick tune in the signal delay between his microphone and the loudspeaker he was testing until the correct bandpass filter Nyquist display appeared on the screen was a revelation. Seeing the epicycles caused by resonances in the loudspeaker and the passage of non-minimum phase responses back through all quadrants opened a million questions.

Dick then showed me the Bode plots of both frequency and phase for the same loudspeaker but I was to remain a fan of seeing everything at once via the Nyquist plot.
To put all this in perspective (I worked at Altec at the time) I knew of no manufacturer in audio capable of making any of these measurements. We all had Bruel and Kjaer or General Radio frequency analyzers and good Tektronics oscilloscopes, but zero true acoustic phase measurement capabilities. I do not mean to imply that the technology didn’t exist because Wente calculated the phase response of 555A in the 1920s, but rather that commercial instruments available in audio did not exist until Richard Heyser demonstrated the usefulness of the measurements and Gerald Stanley of Crown International actually built a commercially available device. Heyser’s remarkable work became the Time, Envelope, Frequency (TEF) system, first in the hands of Crown International, and later as a Gold Line instrument.

The early giants of audio computed theoretical phase responses for minimum phase devices. A few pure scientists actually measured phase—Weiner, Ewask, Marivardi and Stroh, but their results had failed to go beyond their laboratories.

From 1966 until today, 42 years later, such analysis can now be embodied in software in fast, large memory computers. Dennis Gabor’s (1900–1979) analytic signal theory appeared in Heyser’s work as amplitude response, phase response, and Envelope Time Curves (ETC). One glance at the Heyser Spiral for impedance reveals Gabor’s analytic signal and the complex numbers as real, imaginary, and Nyquist plot. The correlation of what seems first to be separate components into one component is a revelation to the first time viewer of this display. The unwinding of the Nyquist plot along the frequency axis provides a defining perspective.

Heyser’s work led to loudspeakers with vastly improved spatial response, something totally unrecognized in the amplitude-only days. Arrays became predictable and coherent. Signal alignment entered the thought of designers. The ETC technology resulted in the chance to meaningfully study loudspeaker–room interactions.

Because the most widely taught mathematical tools proceed from impulse responses, Heyser’s transform is perceived “through a glass darkly.” It is left in the hands of practitioners to further the research into the transient behavior of loudspeakers. The decades-long lag of academia will eventually apply the lessons of the Heyser transform to transducer signal delay and signal delay interaction.

I have always held Harry Olson of RCA in high regard because, as editor of the Audio Engineering Society Journal in 1969, he found Richard C. Heyser’s original paper in the waste basket—it had been rejected by means of the idiot system of non-peer review used by the AES Journal.

Calculators and Computers

In the late 1960s, I was invited to Hewlett Packard to view a new calculator they were planning to market. I was working at this time with Arthur C. Davis (not a relative) at Altec, and Art was a friend of William Hewlett. Art had purchased one of the very first RC oscillators made in the fabled HP garage. He had used them for the audio gear that he had designed for the movie—Fantasia.

The 9100 calculator—computer was the first brain-child that Tom Osborne took to HP, after having been turned down by SCM, IBM, Friden and Monroe. (I purchased one; it cost me $5100. I used it to program the first acoustic design programs.) In 1966, a friend introduced Osborne to Barney Oliver at HP. After reviewing the design he asked Osborne to come back the next day to meet Dave and Bill, to which Osborne said, “Who?” After one meeting with “Dave & Bill,” Osborne knew he had found a home for his 9100. Soon Bill Hewlett turned to Tom Osborne, Dave Cochran, and Tom Whitney, who worked under the direction of Barney Oliver, and said, “I want one in a tenth the volume (the 9100 was IBM typewriter size), ten times as fast, and at a tenth of the price.” Later he added that he “wanted it to be a shirt pocket machine.”

The first HP 35 cost $395, was 3.2 × 5.8 × 1.3 inches and weighed 9 oz with batteries. It also fit into Bill Hewlett’s shirt pocket. (Bill Hewlett named the calculator the HP 35 because it had 35 keys.) Art Davis took me to lunch one day with Mr. Hewlett. Because I had been an ardent user of the HP 9100 units, I was selected to preview the HP 35 during its initial tests in Palo Alto.
In my mind, these calculators revolutionized audio education, especially for those without advanced university educations. The ability to quickly and accurately work with logarithm, trigonometric functions, complex numbers, etc., freed us from the tyranny of books of tables, slide rules, and carefully hoarded volumes such as Massa’s acoustic design charts and Vegas’s ten place log tables.

For the multitude of us who had experienced difficulty in engineering courses with misplaced decimal points and slide rule manipulation and extrapolation, the HP 35 released inherent talents we didn’t realize we possessed. The x^y key allowed instant K numbers. The ten-place log tables became historical artifacts.

When I suggested to the then president of Altec that we should negotiate being the one to sell the HP 35s to the electronics industry (Altec then owned Allied Radio,) his reply stunned me, “We are not in the calculator business.” I thought as he said it, “Neither is Hewlett Packard.” His decision made it easy for me to consider leaving Altec.

I soon left Altec and started Synergetic Audio Concepts, teaching seminars in audio education. I gave each person attending a seminar an HP 35 to use during the 3-day seminar. I know that many of those attending immediately purchased an HP calculator, which changed their whole approach to audio system design. As Tom Osborne wrote, “The HP 35 and HP 65 changed the world we live in.”

Since the political demise of the Soviet Union, “Mozarts-without-a-piano” have been freed to express their brilliance. Dr. Wolfgang Ahnert, from former East Germany, was enabled to use his mathematical skills with matching computer tools to dominate the audio-acoustic design market place.

The history of audio and acoustics is the saga of the mathematical understanding of fundamental physical laws. Hearing and seeing are illusionary, restricted by the inadequacy of our physical senses. The science and art of audio and acoustics are essential to our understanding of history inasmuch as art is metaphysical (above the physical). Also art precedes science.

That the human brain processes music and art in a different hemisphere from speech and mathematics suggests the difference between information, that can be mathematically defined and communication that cannot. A message is the flawless transmission of a text. Drama, music, and great oratory cannot be flawlessly transmitted by known physical systems. For example, the spatial integrity of a great orchestra in a remarkable acoustic space is today even with our astounding technological strides only realizable by attending the live performance.

The complexity of the auditory senses defies efforts to record or transmit it faithfully.

The perception of good audio will often flow from the listener’s past experience, i.e., wow and flutter really annoys musicians whereas harmonic distortion, clipping, etc., grate on an engineer’s ear–mind system.

I have not written about today’s highly hyped products as their history belongs to the survivors of the early 21st century. It can be hoped that someday physicists and top engineers will for some magic reason return to the development of holographic audio systems that approach fidelity.

Telecommunication technology, fiber optics, lasers, satellites, etc. have obtained worldwide audiences for both trash and treasure.

The devilish power that telecommunications has provided demagogues is frightening, but shared communication has revealed to a much larger audience the prosperity of certain ideas over others, and one can hope that the metaphysics behind progress will penetrate a majority of the minds out there.

That the audio industry’s history has barely begun is evidenced every time one attends a live performance. We will, one day, look back on the neglect of the metaphysical element, perhaps after we have uncovered the parameters at present easily heard but unmeasurable by our present sciences. History awaits the ability to generate the sound field rather than a sound field. When a computer is finally offered to us that is capable of such generation, the question it must answer is,

“How does it feel?”

2.1 Introduction

Many people get involved in the audio trade prior to experiencing technical training. Those serious about practicing audio dig in to the books later to learn the physical principles underlying their craft. This chapter is devoted to establishing a baseline of information that will prove invaluable to anyone working in the audio field.

Numerous tools exist for those who work on sound systems. The most important are the mathematical tools. Their application is independent of the type of system or its use, plus, they are timeless and not subject to obsolescence like audio products. Of course, one must always balance the mathematical approach with real-world experience to gain an understanding of the shortcomings and limitations of the formulas. Once the basics have been mastered, sound system work becomes largely intuitive.

Audio practitioners must have a general understanding of many subjects. The information in this chapter has been carefully selected to give the reader the big picture of what is important in sound systems. Many of the topics are covered in greater detail in other chapters of this book. In this initial treatment of each subject, the language of mathematics has been kept to a minimum, opting instead for word explanations of the theories and concepts. This provides a solid foundation for further study of any of the subjects. Considering the almost endless number of topics that could be included here, I selected the following based on my own experience as a sound practitioner and instructor. They are:

1. The Decibel and Levels.
2. Frequency and Wavelength.
3. The Principle of Superposition.
4. Ohm’s Law and the Power Equation.
5. Impedance, Resistance, and Reactance.
6. Introduction to Human Hearing.
8. Sound Radiation Principles.

A basic understanding in these areas will provide the foundation for further study in areas that are of particular interest to the reader. Most of the ideas and principles in this chapter have existed for many years. While I haven’t quoted any of the references verbatim, they get full credit for the bulk of the information presented here.

2.2 The Decibel

Perhaps the most useful tool ever created for audio practitioners is the decibel (dB). It allows changes in system parameters such as power, voltage, or distance to be related to level changes heard by a listener. In short, the decibel is a way to express “how much” in a way that is relevant to the human perception of loudness. We will not track its long evolution or specific origins here. Like most audio tools, it has been modified many times to stay current with the technological practices of the day. Excellent resources are available for that information. What follows is a short study on how to use the decibel for general audio work.

Most of us tend to consider physical variables in linear terms. For instance, twice as much of a quantity produces twice the end result. Twice as much sand produces twice as much concrete. Twice as much flour produces twice as much bread. This linear relationship does not hold true for the human sense of hearing. Using that logic, twice the amplifier power should sound twice as loud. Unfortunately, this is not true.

Perceived changes in the loudness and frequency of sound are based on the percentage change from some initial condition. This means that audio people are concerned with ratios. A given ratio always produces the same result. Subjective testing has shown that the power applied to a loudspeaker must be increased by about 26% to produce an audible change. Thus a ratio of 1.26:1 produces the minimum audible change, regardless of the initial power quantity. If the initial amount of power is 1 watt, then an increase to 1.26 watts (W) will produce a “just audible” increase. If the initial quantity is 100 W, then 126 W will be required to produce a just audible increase. A number scale can be linear with values like 1, 2, 3, 4, 5, etc. A number scale can be proportional with values like 1, 10, 100, 1000, etc. A scale that is calibrated proportionally is called a logarithmic scale. In fact, logarithm means “proportional numbers.” For simplicity, base 10 logarithms are used for audio work. Using amplifier power as an example, changes in level are determined by finding the ratio of change in the parameter of interest (e.g. wattage) and taking the base 10 logarithm. The resultant number is the level change between the two wattages expressed in Bels. The base 10 logarithm is determined using a look-up table or scientific calculator. The log conversion accomplishes two things:

1. It puts the ratio on a proportional number scale that better correlates with human hearing.
2. It allows very large numbers to be expressed in a more compact form, Fig. 2-1.

The final step in the decibel conversion is to scale the Bel quantity by a factor of ten. This step converts Bels to decibels and completes the conversion process,
The decibel scale is more resolute than the Bel scale.

The decibel is always a power-related ratio. Electrical and acoustical power changes can be converted exactly in the manner described. Quantities that are not powers must be made proportional to power—a relationship established by the power equation.

\[
W = \frac{E^2}{R}
\]

where,
- \(W\) is power in watts,
- \(E\) is voltage in volts,
- \(R\) is resistance in ohms.

This requires voltage, distance, and pressure to be squared prior to taking the ratio. Some practitioners prefer to omit the squaring of the initial quantities and simply change the log multiplier from ten to twenty. This produces the same end result.

Fig. 2-3 provides a list of some dB changes along with the ratio of voltage, pressure, distance, and power required to produce the indicated dB change. It is a worthwhile endeavor to memorize the changes indicated in bold type and be able to recognize them by listening.

A decibel conversion requires two quantities that are in the same unit, i.e., watts, volts, meters, feet. The unit cancels during the initial division process, leaving the ratio between the two quantities. For this reason, the decibel is without dimension and is therefore technically not a unit in the classical sense. If two arbitrary quantities of the same unit are compared, the result is a relative level change. If a standard reference quantity is used in the denominator of the ratio, the result is an absolute level and the unit is dB relative to the original

### Equations

1. **Compare**
   - \(W_1\) to \(W_2\) in the same unit
   - \(E_1\) to \(E_2\) in the same unit
   - \(R_1\) to \(R_2\) in the same unit

2. **Compress**
   - \(1 = 10^0 = 0\)
   - \(10 = 10^1 = 1\)
   - \(100 = 10^2 = 2\)
   - \(1,000 = 10^3 = 3\)
   - \(10,000 = 10^4 = 4\)
   - \(100,000 = 10^5 = 5\)
   - \(1,000,000 = 10^6 = 6\)

3. **Scale**
   - \(dB = 10 \log \left( \frac{W_1}{W_2} \right)\)
   - \(dB = 20 \log \left( \frac{E_1}{E_2} \right)\)

**Figure 2-1.** A logarithmic scale has its increments marked by a fixed ratio, in this case 10 to 1, forming a more compact representation than a linear scale. Courtesy Syn-Aud-Con.

**Figure 2-2.** The steps to performing a decibel conversion are outlined. Courtesy Syn-Aud-Con.
and is dependent on the voltage change only, not the resistance that it is developed across or the power transfer. Since open-circuit conditions exist almost universally in modern analog systems, the practice of using the decibel with a voltage reference is widespread and well-accepted.

Figure 2-4. Some common decibel references used by the audio industry.

One of the major utilities of the decibel is that it provides a common denominator when considering level changes that occur due to voltage changes at various points in the signal chain. By using the decibel, changes in sound level at a listener position can be determined from changes in the output voltage of any device ahead of the loudspeaker. For instance, a doubling of the microphone output voltage produces a 6 dB increase in output level from the microphone, mixer, signal processor, power amplifier, and ultimately the sound level at the listener. This relationship assumes linear operating conditions in each device. The 6 dB increase in level from the microphone could be caused by the talker speaking 6 dB louder or by simply reducing the miking distance by one-half (a 2:1 distance ratio). The level controls on audio devices are normally calibrated in relative dB. Moving a fader by 6 dB causes the output voltage of the device (and system) to increase by a factor of 2 and the output power from the device (and system) to be increased by a factor of four.

Absolute levels are useful for rating audio equipment. A power amplifier that can produce 100 watts of continuous power is rated at

$$L_{out} = 10 \log W$$
$$= 10 \log 100$$
$$= 20 \text{ dBW}$$
This means that the amplifier can be 20 dB louder than a 1 watt amplifier. A mixer that can output 10 volts prior to clipping can be rated at

\[
L_{out} = 20 \log E \\
= 20 \log 10 \\
= 20 \text{ dBV}
\]  

(2-3)

If the same mixer outputs 1 volt rms at meter zero, then the mixer has 20 dB of peak room above meter zero.

If a loudspeaker can produce a sound level at 1 meter of 90 dB ref. 20 \(\mu\)Pa (micro-Pascals), then at 10 meters its level will be

\[
L_p = 90 + 20 \log \frac{1}{10} \\
= 90 + (-20) \\
= 70 \text{ dB}
\]  

(2-4)

In short, the decibel says, “The level difference caused by changing a quantity will depend upon the initial value of the quantity and the percentage that it is changed.”

The applications of the decibel are endless, and the utility of the decibel is self-evident. It forms a bridge between the amount of change of a physical parameter and the loudness change that is perceived by the human listener. The decibel is the language of audio, Fig. 2-5.

2.3 Loudness and Level

The perceived loudness of a sound event is related to its acoustical level, which is in turn related to the electrical level driving the loudspeaker. Levels are electrical or acoustical pressures or powers expressed in decibels. In its linear range of operation, the human hearing system will perceive an increase in level as an increase in loudness. Since the eardrum is a pressure sensitive mechanism, there exists a threshold below which the signal is distinguishable from the noise floor. This threshold is about 20 \(\mu\)Pa of pressure deviation from ambient at midrange frequencies. Using this number as a reference and converting to decibels yields

\[
L_p = 20 \log \frac{0.00002}{0.00002} \\
= 20 \log 1 \\
= 0 \text{ dB (or 0 dB SPL)}
\]  

(2-5)

This is widely accepted as the threshold of hearing for humans at mid-frequencies. Acoustic pressure levels are always stated in dB ref. 0.00002 Pa. Acoustic power levels are always stated in dB ref. 1 pW (picowatt or \(10^{-12} \text{ W}\)). Since it is usually the pressure level that is of interest, we must square the Pascals term in the decibel conversion to make it proportional to power. Sound pressure levels are measured using sound level meters with appropriate ballistics and weighting to emulate human hearing. Fig. 2-6 shows some typical sound pressure levels that are of interest to audio practitioners.

2.4 Frequency

Audio practitioners are in the wave business. A wave is produced when a medium is disturbed. The medium can be air, water, steel, the earth, etc. The disturbance produces a fluctuation in the ambient condition of the medium that propagates as a wave that radiates outward from the source of the disturbance. If one second is used as a reference time span, the number of fluctuations above and below the ambient condition per second is the frequency of the event, and is expressed in cycles per second, or Hertz. Humans can hear frequencies as low as 20 Hz and as high as 20,000 Hz (20 kHz). In an audio circuit the quantity of interest is usually the electrical voltage. In an acoustical circuit it is the air pressure deviation from ambient atmospheric pressure. When the air pressure fluctuations have a frequency between 20 Hz and 20 kHz they are audible to humans.

As stated in the decibel section, humans are sensitive to proportional changes in power, voltage, pressure, and distance. This is also true for frequency. If we start at

---

**Figure 2-5.** Summary of decibel formulas for general audio work. Courtesy Syn-Aud-Con.
The lowest audible frequency of 20 Hz and increase it by a 2:1 ratio, the result is 40 Hz, an interval of one octave. Doubling 40 Hz yields 80 Hz. This is also a one-octave span, yet it contains twice the frequencies of the previous octave. Each successive frequency doubling yields another octave increase and each higher octave will have twice the spectral content of the one below it. This makes the logarithmic scale suitable for displaying frequency. Figs. 2-7 and 2-8 show a logarithmic frequency scale and some useful divisions. The perceived midpoint of the spectrum for a human listener is about 1 kHz. Some key frequency ratios exist:

- 10:1 ratio—decade.
- 2:1 ratio—octave.

The spectral or frequency response of a system describes the frequencies that can pass through that system. It must always be stated with an appropriate tolerance, such as ±3 dB. This range of frequencies is the bandwidth of the system. All system components have a finite bandwidth. Sound systems are usually bandwidth limited for reasons of stability and loudspeaker protection. A spectrum analyzer can be used to observe the spectral response of a system or system component.

2.5 Wavelength

If the frequency $f$ of a vibration is known, the time period $T$ for one cycle of vibration can be found by the simple relationship

$$T = \frac{1}{f} \quad (2-6)$$

The time period $T$ is the inverse of the frequency of vibration. The period of a waveform is the time length of one complete cycle, Fig. 2-9. Since most waves propagate or travel, if the period of the wave is known, its physical size can be determined with the following equation if the speed of propagation is known:

$$\lambda = Tc \quad (2-7)$$

$$\lambda = \frac{c}{f} \quad (2-8)$$

Waves propagate at a speed that is dependent on the nature of the wave and the medium that it is passing through. The speed of the wave determines the physical size of the wave, called its wavelength. The speed of light in a vacuum is approximately 300,000,000 meters per second (m/s). The speed of an electromagnetic wave in copper wire is somewhat less, usually 90% to 95% of the speed of light. The fast propagation speed of electromagnetic waves makes their wavelengths extremely long at audio frequencies, Fig. 2-10.
At the higher radio frequencies (VHF and UHF), the wavelengths become very short—1 meter or less. Antennas to receive such waves must be of comparable physical size, usually one-quarter to one-half wavelength. When waves become too short for practical antennae, concave dishes can be used to collect the waves. It should be pointed out that the highest frequency that humans can hear (about 20 kHz) is a very low frequency when considering the entire electromagnetic spectrum.

An acoustic wave is one that is propagating by means of vibrating a medium such as steel, water, or air. The propagation speeds through these media are relatively slow, resulting in waves that are long in length compared to an electromagnetic wave of the same frequency. The wavelengths of audio frequencies in air range from about 17 m (20 Hz) to 17 mm (20 kHz). The wavelength of 1 kHz in air is about 0.334 m (about 1.13 ft).

When physically short acoustic waves are radiated into large rooms, there can be adverse effects from reflections. Acoustic reflections occur when a wave encounters a change in acoustic impedance, usually from a rigid surface, the edge of a surface or some other obstruction. The reflection angle equals the incidence angle in the ideal case. Architectural acoustics is the study of the behavior of sound waves in enclosed spaces. Acousticians specialize in creating spaces with reflected sound fields that enhance rather than detract from the listening experience.

When sound encounters a room surface, a complex interaction takes place. If the surface is much larger than the wavelength, a reflection occurs and an acoustic shadow is formed behind the boundary.
If the obstruction is smaller than the wavelength of the wave striking it, the wave diffracts around the obstruction and continues to propagate. Both effects are complex and frequency (wavelength) dependent, making them difficult to calculate, Fig. 2-11. The reflected wave will be strong if the surface is large and has low absorption. As absorption is increased, the level of the reflection is reduced. If the surface is random, the wave can be scattered depending on the size relationship between the wave and the surface relief. Commercially available diffusors can be used to achieve uniform scattering in critical listening spaces, Fig. 2-12.

### 2.6 Surface Shapes

The geometry of a boundary can have a profound affect on the behavior of the sound that strikes it. From a sound reinforcement perspective, it is usually better to scatter sound than to focus it. A concave room boundary should be avoided for this reason, Fig. 2-13. Many auditoriums have concave rear walls and balcony faces that require extensive acoustical treatment for reflection control. A convex surface is more desirable, since it scatters sound waves whose wavelengths are small relative to the radius of curvature. Room corners can provide useful directivity control at low frequencies, but at high frequencies can produce problematic reflections.

Electrical reflections can occur when an electromagnetic wave encounters a change in impedance. For such waves traveling down a wire, the reflection is back towards the source of the wave. Such reflections are not usually a problem for analog waves unless there is a phase offset between the outgoing and reflected waves. Note that an audio cable would need to be very long for its length to cause a significant time offset between the...

incident and reflected wave (many thousands of meters). At radio frequencies, reflected waves pose a huge problem, and cables are normally terminated (operated into a matched impedance) to absorb the incident wave at the receiving device and reduce the level of the reflection. The same is true for digital signals due to their very high frequency content.

Figure 2-10. Acoustic wavelengths are relatively short and interact dramatically with their environment. Audio wavelengths are extremely long, and phase interaction on audio cables is not usually of concern. Courtesy Syn-Aud-Con.

The same is true for digital signals due to their very high frequency content.

2.7 Superposition

Sine waves and cosine waves are periodic and singular in frequency. These simple waveforms are the building blocks of the complex waveforms that we listen to every day. The amplitude of a sine wave can be displayed as a function of time or as a function of phase rotation, Fig. 2-14. The sine wave will serve as an example for the following discussion about superposition. Once the size (wavelength) of a wave is known, it is useful to subdivide it into smaller increments for the purpose of tracking its progression through a cycle or comparing its progression with that of another wave. Since the sine wave describes a cyclic (circular) event, one full cycle is represented by 360°, at which point the wave repeats.

When multiple sound pressure waves pass by a point of observation, their responses sum to form a composite wave. The composite wave is the complex combination of two or more individual waves. The amplitude of the
summation is determined by the relative phase of the individual waves. Let’s consider how two waves might combine at a point of observation. This point might be a listener seat or microphone position. Two extremes exist. If there is no phase offset between two waves of the same amplitude and frequency, the result is a coherent summation that is twice the amplitude of either individual wave (+6 dB). The other extreme is a 180° phase offset between the waves. This results in the complete cancellation of the pressure response at the point of observation. An infinite number of intermediate conditions occur between these two extremes. The phase interaction of waves is not a severe problem for analog audio signals in the electromagnetic domain for sound systems, where the wavelengths at audio frequencies are typically much longer than the interconnect cables. Waves reflected from receiver to source are in phase and no cancellation occurs. This is not the case for video, radio frequency, and digital signals. The shorter wavelengths of these signals can be dramatically affected by wave superposition on interconnect cables. As such, great attention must be given to the length and terminating impedance of the interconnect cables to assure efficient signal transfer between source and receiver. The practice of impedance matching between source, cable, and load is usually employed.

In sound reinforcement systems, phase interactions are typically more problematic for acoustical waves than electromagnetic waves. Phase summations and cancellations are the source of many acoustical problems experienced in auditoriums. Acoustic wavelengths are often short relative to the room size (at least at high frequency), so the waves tend to bounce around the room before decaying to inaudibility. At a listener position, the reflected waves “superpose” to form a complex waveform that is heard by the listener. The sound radiated from multiple loudspeakers will interact in the same manner, producing severe modifications in the radiated sound pattern and frequency response. Antenna designers have historically paid more attention to these interactions than loudspeaker designers, since there are laws that govern the control of radio frequency emissions. Unlike antennas, loudspeakers are usually broadband devices that cover one decade or more of the audible spectrum. For this reason, phase interactions between multiple loudspeakers never result in the complete cancellation of sound pressure, but rather cancellation at some frequencies and coherent summation at others. The subjective result is tonal coloration and image shift of the sound source heard by the listener. The significance of this phenomenon is application-dependent. People having dinner in a restaurant

![Corners return sound to its source](image1.jpg)

**Figure 2-13.** Some surfaces produce focused reflections. Courtesy Syn-Aud-Con.

![Concave surfaces focus sound](image2.jpg)

![Convex surfaces scatter sound](image3.jpg)

**Figure 2-14.** Simple harmonic motion can be represented with a sine or cosine wave. Both are viewpoints of the same event from different angles. Courtesy Syn-Aud-Con.
would not be concerned with the effects of such interactions since they came for the food and not the music. Concert-goers or church attendees would be more concerned, because their seat might be in a dead spot, and the interactions disrupt their listening experience, possibly to the point of reducing the information conveyed via the sound system. A venue owner may make a significant investment in good quality loudspeakers, only to have their response impaired by such interactions with an adjacent loudspeaker or room surface, Fig. 2-16.

Phase interactions are most disruptive in critical listening environments, such as recording studio control rooms or high quality home entertainment systems. Users of these types of systems often make a large investment to maintain sonic accuracy by purchasing phase coherent loudspeakers and appropriate acoustical treatments for the listening space. The tonal coloration caused by wave interference may be unacceptable for a recording studio control room but may be artistically pleasing in a home audio system.

Loudspeaker designers can use wave interaction to their advantage by choosing loudspeaker spacings that form useful radiation patterns. Almost all pattern control in the low frequency decade is achieved in this manner. Uninformed system designers create undesirable radiation patterns by accident in the way that they place and stack loudspeakers. The results are poor coverage and reduced acoustic gain.

The proper way to view the loudspeaker and room are as filters that the sound energy must pass through en route to the listener. Some aspects of these filters can be compensated with electronic filters—a process known as equalization. Other aspects cannot, and electronic equalization merely aggravates or masks the problem.

2.8 Ohm’s Law

In acoustics, the sound that we hear is nature restoring an equilibrium condition after an atmospheric disturbance. The disturbance produces waves that cause the atmospheric pressure to oscillate above and below ambient pressure as they propagate past a point of observation. The air always settles to its ambient state upon cessation of the disturbance.

In an electrical circuit, a potential difference in electrical pressure between two points causes current to flow. Electrical current results from electrons flowing to a point of lower potential. The electrical potential difference is called an electromotive force (EMF) and the unit is the volt (V). The rate of electron flow is called current and the unit is the ampere (A). The ratio between voltage and current is called the resistance and the unit is the ohm (Ω). The product of voltage and current is the apparent power, W, that is produced by the source and consumed by the load. Power is the rate of doing work and power ratings must always include a reference to time. A power source can produce a rated voltage at a rated flow of current into a specified load for a specified period of time. The ratio of voltage to current can be manipulated to optimize a source for a specific task. For instance, current flow can be sacrificed to maximize voltage transfer. When a device is called upon to deliver appreciable current, it is said to be operating under load. The load on an automobile increases when it must maintain speed on an uphill grade, and greater power transfer between the engine and drive train is required. Care must be taken when loading audio components to prevent distortion or even damage. Ohm’s Law describes the ratios that exist between voltage, current, and resistance in an electrical circuit.

\[
R = \frac{E}{I} \tag{2-9}
\]

\[
E = IR \tag{2-10}
\]

\[
I = \frac{E}{R} \tag{2-11}
\]

where,

- \( E \) is in volts,
- \( I \) is in amperes,
- \( R \) is in ohms.
Direct current (dc) flows in one direction only. In ac (alternating current) the direction of current flow is alternating at the frequency of the waveform. Voltage and current are not always in sync so the phase relationship between them must be considered. Power flow is reduced when they are not in relative phase (synchronization). Voltage and current are in phase in resistive circuits. Phase shifts between voltage and current are produced by reactive elements in a circuit. Reactance reduces the power transferred to the load by storing energy and reflecting it back to the source. Loudspeakers and transformers are examples of sound system components that can have significant reactive characteristics. The combined opposition to current flow caused by resistance and reactance is termed the impedance ($Z$) of the circuit. The unit for impedance is also the ohm ($\Omega$). An impedance can be purely resistive, purely reactive, or most often some combination of the two. This is referred to as a complex impedance. Impedance is a function of frequency, and impedance measurements must state the frequency at which the measurement was made. Sound system technicians should be able to measure impedance to verify proper component loading, such as at the amplifier/loudspeaker interface.

$$Z = \sqrt{R^2 + (X_T)^2}$$

(2-12)

where,

$Z$ is the impedance in ohms,

$R$ is the resistance in ohms,

$X_T$ is the total reactance in ohms.

Reactance comes in two forms. Capacitive reactance causes the voltage to lag the current in phase. Inductive reactance causes the current to lag the voltage in phase. The total reactance is the sum of the inductive and capacitive reactance. Since they are different in sign one can cancel the other, and the resultant phase angle between voltage and current will be determined by the dominant reactance.

In mechanics, a spring is a good analogy for capacitive reactance. It stores energy when it is compressed and returns it to the source. In an electrical circuit, a capacitor opposes changes in the applied voltage. Capacitors are often used as filters for passing or rejecting certain frequencies or smoothing ripples in power supply voltages. Parasitic capacitances can occur when conductors are placed in close proximity.

$$X_C = \frac{1}{2\pi f C}$$

(2-13)

where,

$f$ is frequency in hertz,

$C$ is capacitance in farads,

$X_C$ is the capacitive reactance in ohms.

In mechanics, a moving mass is analogous to an inductive reactance in an electrical circuit. The mass tends to keep moving when the driving force is removed. It has therefore stored some of the applied energy. In electrical circuits, an inductor opposes a change in the current flowing through it. As with capacitors, this property can be used to create useful filters in audio systems. Parasitic inductances can occur due to the ways that wires are constructed and routed.

$$X_L = 2\pi f L$$

(2-14)

where,

$X_L$ is the inductive reactance in ohms.

Inductive and capacitive reactance produce the opposite effect, so one can be used to compensate for the other. The total reactance $X_T$ is the sum of the inductive and capacitive reactance.

$$X_T = X_L - X_C$$

(2-15)

Note that the equations for capacitive and inductive reactance both include a frequency term. Impedance is therefore frequency dependent, meaning that it changes with frequency. Loudspeaker manufacturers often publish impedance plots of their loudspeakers. The impedance of interest from this plot is usually the nominal or rated impedance. Several standards exist for determining the rated impedance from the impedance plot, Fig. 2-16.

![Figure 2-16. An impedance magnitude plot displays impedance as a function of the applied frequency. Courtesy Syn-Aud-Con.](image-url)
An impedance phase plot often accompanies an impedance magnitude plot to show whether the loudspeaker load is resistive, capacitive, or inductive at a given frequency. A resistive load will convert the applied power into heat. A reactive load will store and reflect the applied power. Complex loads, such as loudspeakers, do both. When considering the power delivered to the loudspeaker, the impedance $Z$ is used in the power equation. When considering the power dissipated by the load, the resistive portion of the impedance must be used in the power equation. The power factor describes the reduction in power transfer caused by the phase angle between voltage and current in a reactive load. Some definitions are useful.

\[
\text{Apparent Power (Total Power)} = \frac{E^2}{Z} \tag{2-16}
\]

\[
\text{Active Power (Absorbed Power)} = \frac{E^2}{R} \tag{2-17}
\]

\[
\text{Reactive Power (Reflected Power)} = \frac{E^2}{Z \cos \theta} \tag{2-18}
\]

where,

$\theta$ is the phase angle between the voltage and current.

Ohm’s Law and the power equation in its various forms are foundation stones of the audio field. One can use these important tools for a lifetime and not exhaust their application to the electrical and acoustical aspects of the sound reinforcement system.

### 2.9 Human Hearing

It is beneficial for sound practitioners to have a basic understanding of the way that people hear and perceive sound. The human auditory system is an amazing device, and it is quite complex. Its job is to transduce fluctuations in the ambient atmospheric pressure into electrical signals that will be processed by the brain and perceived as sound by the listener. We will look at a few characteristics of the human auditory system that are of significance to audio practitioners.

The dynamic range of a system describes the difference between the highest level that can pass through the system and its noise floor. The threshold of human hearing is about 0.00002 Pascals (Pa) at mid frequencies. The human auditory system can withstand peaks of up to 200 Pa at these same frequencies. This makes the dynamic range of the human auditory system approximately

\[
DR = 20 \log \frac{200}{0.00002} = 140 \text{ dB}
\]

The hearing system can not take much exposure at this level before damage occurs. Speech systems are often designed for 80 dB ref. 20 $\mu$Pa and music systems about 90 dB ref. 20 $\mu$Pa for the mid-range part of the spectrum.

Audio practitioners give much attention to achieving a flat spectral response. The human auditory system is not flat and its response varies with level. At low levels, its sensitivity to low frequencies is much less than its sensitivity to mid-frequencies. As level increases, the difference between low- and mid-frequency sensitivity is less, producing a more uniform spectral response. The classic equal loudness contours, Fig. 2-17, describe this phenomenon and have given us the weighting curves, Fig. 2-18, used to measure sound levels.

Modern sound systems are capable of producing very high sound pressure levels over large distances. Great care must be taken to avoid damaging the hearing of the audience.

The time response of the hearing system is slow compared to the number of audible events that can occur in a given time span. As such, our hearing system integrates closely spaced sound arrivals (within about 35 ms) with regard to level. This is what makes sound indoors appear louder than sound outdoors. While reflected sound increases the perceived level of a sound source, it also adds colorations. This is the heart of how we perceive acoustic instruments and auditoriums. A good recording studio or concert hall produces a musically pleasing reflected sound field to a listener position. In general, secondary energy arrivals pose problems if they arrive earlier than 10 ms (severe tonal coloration) after the first arrival or later than 50 ms (potential echo), Fig. 2-19.

The integration properties of the hearing system make it less sensitive to impulsive sound events with regard to level. Peaks in audio program material are often 20 dB or more higher in level than the perceived loudness of the signal. Program material that measures 90 dBA (slow response) may contain short term events at 110 dBA or more, so care must be taken when exposing musicians and audiences to high powered sound systems.

The eardrum is a pressure sensitive diaphragm that responds to fluctuations in the ambient atmospheric pressure. Like a loudspeaker and microphone, it has an overload point at which it distorts and can be damaged.
The Occupational Safety and Health Administration (OSHA) is responsible for assuring that public spaces remain in compliance regarding sound exposure. Sound systems are a major source of high level sounds and should work within OSHA guidelines. Tinnitus, or ringing in the ears, is one symptom of excessive sound exposure.

2.10 Monitoring Audio Program Material

The complex nature of the audio waveform necessitates specialized instrumentation for visual monitoring. Typical voltimeters are not suitable for anything but the simplest waveforms, such as sine waves. There are two aspects of the audio signal that are of interest to the system operator. The peaks of the program material
must not exceed the peak output capability of any component in the system. Ironically the peaks have little to do with the perceived loudness of the signal or the electrical or acoustic power generated by it. Both of these parameters are more closely tied to the rms (root-mean-square) value of the signal. Measurement of the true rms value of a waveform requires specialized equipment that integrates energy over a time span, much like the hearing system does. This integrated data will better correlate with the perceived loudness of the sound event. So audio practitioners need to monitor at least two aspects of the audio signal—its relative loudness (related to the rms level) and peak levels. Due to the complexity of true rms monitoring, most meters display an average value that is an approximation of the rms value of the program material.

Many audio processors have instrumentation to monitor either peak or average levels, but few can track both simultaneously. Most mixers have a VI (volume indicator) meter that reads in VU (volume units). Such meters are designed with ballistic properties that emulate the human hearing system and are useful for tracking the perceived loudness of the signal. Meters of this type all but ignore the peaks in the program material, making them unable to display the available headroom in the system or clipping in a component. Signal processors usually have a peak LED that responds fast enough to indicate peaks that are at or near the component’s clipping point. Many recording systems have PPM (peak program meters) that track the peaks but reveal little about the relative loudness of the waveform.

Fig. 2-20 shows an instrument that monitors both peak and relative loudness of the audio program material. Both values are displayed in relative dB, and the difference between them is the approximate crest factor of the program material. Meters of this type yield a more complete picture of the audio event, allowing both loudness and available headroom to be observed simultaneously.

![Figure 2-20. A meter that can display both average and peak levels simultaneously. Courtesy Dorrough Electronics.](image)

### 2.11 Sound Propagation

Sound waves are emitted from acoustic sources—devices that move to modulate the ambient atmospheric pressure. Loudspeakers become intentional acoustic sources when they are driven with waveforms that cause them to vibrate at frequencies within the bandwidth of the human listener. A point source is a device that radiates sound from one point in space. A true point source is an abstract idea and is not physically realizable, as it would be of infinitesimal size. This does not prevent the use of the concept to describe the characteristics of devices that are physically realizable.

Let us consider the properties of some idealized acoustic sources—not ideal in that they would be desirable for sound reinforcement use, but ideal in respect to their behavior as predictable radiators of acoustic energy.

#### 2.11.1 The Point Source

A point source with 100% efficiency would produce 1 watt of acoustical power from one watt of applied electrical power. No heat would result, since all of the electrical power is converted. The energy radiated from the source would travel equally in all directions from the source. Directional energy radiation is accomplished by interfering with the emerging wave. Since interference would require a finite size, a true infinitesimal point source would be omnidirectional. We will introduce the effects of interference later.

Using 1 pW (picowatt) as a power reference, the sound power level produced by 1 acoustic watt will be

\[
L_W = 10 \log \frac{1 \text{W}}{10^{-12} \text{W}} = 120 \text{ dB}
\]

(2-20)

Note that the sound power is not dependent on the distance from the source. A sound power level of \(L_W = 120 \text{ dB}\) would represent the highest continuous sound power level that could result from 1 W of continuous electrical power. All real-world devices will fall short of this ideal, requiring that they be rated for efficiency and power dissipation.

Let us now select an observation point at a distance 0.282 m from the sound source. As the sound energy propagates, it forms a spherical wave front. At 0.282 m this wave front will have a surface area of one square meter. As such, the one watt of radiated sound power is passing through a surface area of 1 m².
This is the sound intensity level \( L_I \) of the source and represents the amount of power flowing through the surface of a sphere of 1 square meter. Again, this is the highest intensity level that could be achieved by an omnidirectional device of 100% efficiency. \( L_I \) can be manipulated by confining the radiated energy to a smaller area. The level benefit gained at a point of observation by doing such is called the \textit{directivity index} (DI) and is expressed in decibels. All loudspeakers suitable for sound reinforcement should exploit the benefits of directivity control.

For the ideal device described, the sound pressure level \( L_P \) (or commonly \( \text{SPL} \)) at the surface of the sphere will be numerically the same as the \( L_W \) and \( L_I \) \((L_P = 120 \text{ dB})\) since the sound pressure produced by 1 W will be 20 Pa. This \( L_P \) is only for one point on the sphere, but since the source is omnidirectional, all points on the sphere will be the same. To summarize, at a distance of 0.282 m from a point source, the sound power level, sound intensity level, and sound pressure level will be numerically the same. This important relationship is useful for converting between these quantities, Fig. 2-21.

\[
L_I = 10 \log \frac{1 \text{W/m}^2}{10^{-12} \text{W/m}^2} = 120 \text{ dB}
\]

This behavior is known as the inverse-square law (ISL), Fig. 2-22. The ISL describes the level attenuation versus distance for a point source radiator due to the spherical spreading of the emerging waves. Frequency dependent losses will be incurred from atmospheric absorption, but those will not be considered here. Most loudspeakers will roughly follow the inverse square law level change with distance at points remote from the source, Fig. 2-23.

\[
\Delta L_P = 20 \log \frac{0.564}{0.282} = 6 \text{ dB}
\]

\[\text{Figure 2-22.} \text{ When the distance to the source is doubled, the radiated sound energy will be spread over twice the area. Both } L_I \text{ and } L_P \text{ will drop by } 6 \text{ dB}. \text{ Courtesy Syn-Aud-Con.}\]

\[\text{Figure 2-23.} \text{ The ISL is also true for directional devices in their far field (remote locations from the device).} \text{ Courtesy Syn-Aud-Con.}\]

\section*{2.11.2 The Line Source}

Successful sound radiators have been constructed that radiate sound from a line rather than a point. The infinite line source emits a wave that is approximately cylindrical in shape. Since the diverging wave is not
expanding in two dimensions, the level change with increasing distance is half that of the point source radiator. The sound level from an ideal line source will decrease at 3 dB per distance doubling rather than 6 dB, Fig. 2-24. It should be pointed out that these relationships are both frequency and line length dependent, and what is being described here is the ideal case. Few commercially available line arrays exhibit this cylindrical behavior over their full bandwidth. Even so, it is useful to allow a mental image of the characteristics of such a device to be formed.

If the line source is finite in length (as all real-world sources will be), then there will be a phase differential between the sound radiated from different points on the source to a specific point in space. All of the points will be the most in phase on a plane perpendicular from the array and equidistant from the end points of the array. As the point of observation moves away from the midpoint, phase interaction will produce lobes in the radiated energy pattern. The lobes can be suppressed by clever design, allowing the wave front to be confined to a very narrow vertical angle, yet with wide horizontal coverage. Such a radiation pattern is ideal for some applications, such as a broad, flat audience plane that must be covered from ear height. Digital signal processing has produced well-behaved line arrays that can project sound to great distances. Some incorporate an adjustable delay for each element to allow steering of the radiation lobe. Useful designs for auditoriums are at least 2 meters in vertical length.

While it is possible to construct a continuous line source using ribbon drivers, etc., most commercially available designs are made up of closely spaced discrete loudspeakers or loudspeaker systems and are more properly referred to as line arrays, Fig. 2-25.

### 2.12 Conclusion

The material in this chapter was carefully selected to expose the reader to a broad spectrum of principles regarding sound reinforcement systems. As a colleague once put it, “Sound theory is like an onion. Every time you peel off a layer another lies beneath it!” Each of these topics can be taken to higher levels, and many have been by other authors within this textbook. The reader is encouraged to use this information as a springboard into a life-long study of audio and acoustics. We are called upon to spend much of our time learning about new technologies. It must be remembered that new methods come from the mature body of principles and practices that have been handed down by those who came before us. Looking backward can have some huge rewards.

*If I can see farther than those who came before me, it is because I am standing on their shoulders.*

3.1 Psychoacoustics and Subjective Quantities

Unlike other senses, it is surprising how limited our vocabulary is when talking about hearing. Especially in the audio industry, we do not often discriminate between subjective and objective quantities. For instance, the quantities of frequency, level, spectrum, etc. are all objective, in a sense that they can be measured with a meter or an electronic device; whereas the concepts of pitch, loudness, timbre, etc. are subjective, and they are auditory perceptions in our heads. Psychoacoustics investigates these subjective quantities (i.e., our perception of hearing), and their relationship with the objective quantities in acoustics. Psychoacoustics got its name from a field within psychology—i.e., recognition science—which deals with all kinds of human perceptions, and it is an interdisciplinary field of many areas, including psychology, acoustics, electronic engineering, physics, biology, physiology, computer science, etc.

Although there are clear and strong relationships between certain subjective and objective quantities—e.g., pitch versus frequency—other objective quantities also have influences. For example, changes in sound level can affect pitch perception. Furthermore, because no two persons are identical, when dealing with perceptions as in psychoacoustics, there are large individual differences, which can be critical in areas such as sound localization. In psychoacoustics, researchers have to consider both average performances among population and individual variations. Therefore, psychophysical experiments and statistical methods are widely used in this field.

Compared with other fields in acoustics, psychoacoustics is relatively new, and has been developing greatly. Although many of the effects have been known for some time (e.g., Hass effect), new discoveries have been found continuously. To account for these effects, models have been proposed. New experimental findings might invalidate or modify old models or make certain models more or less popular. This process is just one representation of how we develop our knowledge. For the purpose of this handbook, we will focus on summarizing the known psychoacoustic effects rather than discussing the developing models.

3.2 Ear Anatomy and Function

Before discussing various psychoacoustic effects, it is necessary to introduce the physiological bases of those effects, namely the structure and function of our auditory system. The human ear is commonly considered in three parts: the outer ear, the middle ear, and the inner ear. The sound is gathered (and as we shall see later, modified) by the external ear called the pinna and directed down the ear canal (auditory meatus). This canal is terminated by the tympanic membrane (eardrum). These parts constitute the outer ear, as shown in Figs. 3-1 and 3-2. The other side of the eardrum faces the middle ear. The middle ear is air filled, and pressure equalization takes place through the eustachian tube opening into the pharynx so normal atmospheric pressure is maintained on both sides of the eardrum. Fastened to the eardrum is one of the three ossicles, the malleus which, in turn, is connected to the incus and stapes. Through the rocking action of these three tiny bones the vibrations of the eardrum are transmitted to the oval window of the cochlea with admirable efficiency. The sound pressure in the liquid of the cochlea is increased some 30–40 dB over the air pressure acting on the eardrum through the mechanical action of this remarkable middle ear system. The clear liquid filling the cochlea is incompressible, like water. The round window is a relatively flexible pressure release allowing sound energy to be transmitted to the fluid of the cochlea via the oval window. In the inner ear the traveling waves set up on the basilar membrane by vibrations of the oval window stimulate hair cells that send nerve impulses to the brain.

3.2.1 Pinna

The pinna, or the human auricle, is the most lateral (i.e., outside) portion of our auditory system. The beauty of these flaps on either side of our head may be questioned, but not the importance of the acoustical function they serve. Fig. 3-3 shows an illustration of various parts of the human pinna. The entrance to the ear canal, or concha, is most important acoustically for filtering because it contains the largest air volume in a pinna. Let
us assume for the moment that we have no pinnae, just holes in the head, which is actually a simplest model for human hearing, called the spherical head model. Cupping our hands around the holes would make sounds louder as more sound energy is directed into the opening. How much does the pinna help in directing sound energy into the ear canal? We can get some idea of this by measuring the sound pressure at the opening of the ear canal with and without the hand behind the ear. Weiner and Ross did this and found a gain of 3 to 5 dB at most frequencies, but a peak of about 20 dB in the vicinity of 1500 Hz. Fig. 3-4 shows the transfer function measured by Shaw, and the curves numbered 3 and 4 are for concha and pinna flange, respectively. The irregular and asymmetric shape of a pinna is not just for aesthetic reasons. In Section 3.11, we will see that it is actually important for our ability to localize sounds and to aid in spatial-filtering of unwanted conversations.

### 3.2.2 Temporal Bones

On each of the left and right sides of our skull, behind the pinna, there is a thin, fanlike bone—namely, the temporal bone—covering the entire human ear, except for the pinna. This bone can be further divided into four portions—i.e., the squamous, mastoid, tympanic and petrous portions. The obvious function for the temporal bone is to protect our auditory system. Other than cochlear implant patients, whose temporal bone has to be partly removed during a surgery, people might not pay much attention to it, especially regarding acoustics. However the sound energy that propagates through the bone into our inner ear, as opposed to through the ear canal and middle ear, is actually fairly significant. For patients with conductive hearing loss—e.g., damage of middle ear—there are currently commercially available devices, which look something like headphones and are placed on the temporal bone. People with normal hearing can test it by plugging their ears while wearing the device. Although the timbres sound quite different from normal hearing, the filtered speech is clear enough to understand. Also because of this bone conduction, along with other effects such as acoustic reflex, which will be discussed in Section 3.2.4.1, one hears his or her own
voice differently from how other people hear the voice. While not receiving much attention in everyday life, it might be sometimes very important. For example, an experienced voice teacher often asks a student singer to record his or her own singing and playback with an audio system. The recording will sound unnatural to the singer but will be a more accurate representation of what the audience hears.

### 3.2.3 Ear Canal

The ear canal has a diameter about 5 to 9 mm and is about 2.5 cm long. It is open to the outside environment at the concha, and is closed at the tympanic membrane. Acoustically, it can be considered as a closed pipe whose cross-sectional shape and area vary along its length. Although being bended and irregular in shape, the ear canal does demonstrate the modal characteristic of a closed pipe. It has a fundamental frequency of about 3 kHz, corresponding to a quarter wavelength close to the length of the ear canal. Because of this resonant frequency, our hearing is most sensitive to a frequency band around 3 kHz, which is, not just by coincidence, the most important frequency band of human speech. On Fig. 3-4, the number 5 curve shows the effect of the ear canal, taking the eardrum into account as well. As can be seen, there is an approximately 11 dB of gain at around 2.5 kHz. After combining all the effects of head, torso and neck, pinna, ear canal and eardrum, the total transfer function is the curve marked with a letter T on Fig. 3-4. It is relatively broadly tuned between 2 and 7 kHz, with as much as 20 dB of gain. Unfortunately, because of this resonance, in very loud noisy environments with broadband sound, hearing damage usually first happens around 4 kHz.

### 3.2.4 Middle Ear

The outer ear, including the pinna and the ear canal, ends at the eardrum. It is an air environment with low impedance. On the other hand, the inner ear, where the sensory cells are, is a fluid environment with high impedance. When sound (or any wave) travels from one medium to another, if the impedances of the two media do not match, much of the energy would be reflected at the surface, without propagating into the second medium. For the same reason, we use microphones to record in the air and hydrophones to record under water. To make our auditory system efficient, the most important function of the middle ear is to match the impedances of outer and inner ears. Without the middle ear, we would suffer a hearing loss of about 30 dB (by mechanical analysis and experiments on cats).

A healthy middle ear (without middle ear infection) is an air-filled space. When swallowing, the eustachian tube is open to balance the air pressure inside the middle ear and that of the outside world. Most of the time, however, the middle ear is sealed from the outside environment. The main components of the middle ear are the three ossicles, which are the smallest bones in our body: the malleus, incus, and stapes. These ossicles form an ossicular chain, which is firmly fixed on the eardrum and the oval window on each side. Through mostly three types of mechanical motions—namely piston motion, lever motion and buckling motion—the acoustic energy is transferred into the inner ear effectively. The middle ear can be damaged temporarily by middle ear infection, or permanently by genetic disease. Fortunately, with current technology, doctors can rebuild the ossicles with titanium, the result being a total recovering of hearing. Alternatively one can use devices that rely on bone conduction.

### 3.2.4.1 Acoustic Reflex

There are two muscles in the middle ear: the tensor tympani that is attached to the malleus, and the stapedius muscle that is attached to the stapes. Unlike other muscles in our bodies, these muscles form an angle with respect to the bone, instead of along the bone, which makes them very ineffective for motion. Actually the function of these muscles is for changing the stiffness of the ossicular chain. When we hear a very loud sound—i.e., at least 75 dB higher than the hearing threshold—when we talk or sing, when the head is touched, or when the body moves, these middle ear muscles will contract to increase the stiffness of the ossicular chain, which makes it less effective, so that our inner ear is protected from exposure to the loud sound. However, because this process involves a higher stage of signal processing, and because of the filtering features, this protection works only for slow onset and low-frequency sound (up to 1.2 kHz) and is not effective for noises such as an impulse or noise with high frequencies (e.g., most of the music recordings today).

### 3.2.5 Inner Ear

The inner ear, or the labyrinth, is composed of two systems: the vestibular system, which is critical to our sense of balance, and the auditory system which is used for hearing. The two systems share fluid, which is separated from the air-filled space in the middle ear by
the oval window and the round window. The auditory portion of the inner ear is the snail-shaped cochlea. It is a mechanical-to-electrical transducer and a frequency-selective analyzer, sending coded nerve impulses to the brain. This is represented crudely in Fig. 3-5. A rough sketch of the cross section of the cochlea is shown in Fig. 3-6. The cochlea, throughout its length (about 35 mm if stretched out straight), is divided by Reissner’s membrane and the basilar membrane into three separate compartments—namely, the scala vestibuli, the scala media, and the scala tympani. The scala vestibuli and the scala tympani share the same fluid, perilymph, through a small hole, the helicotrema, at the apex; while the scala media contains another fluid, endolymph, which contains higher density of potassium ions facilitating the function of the hair cells. The basilar membrane supports the Organ of Corti, which contains the hair cells that convert the relative motion between the basilar membrane and the tectorial membrane into nerve pulses to the auditory nerve.

When an incident sound arrives at the inner ear, the vibration of the stapes is transported into the scala vestibuli through the oval window. Because the cochlear fluid is incompressible, the round window connected to the scala tympani vibrates accordingly. Thus, the vibration starts from the base of the cochlea, travels along the scala vestibuli, all the way to the apex, and then through the helicotrema into the scala tympani, back to the base, and eventually ends at the round window. This establishes a traveling wave on the basilar membrane for frequency analysis. Each location at the basilar membrane is most sensitive to a particular frequency—i.e., the characteristic frequency—although it also responds to a relatively broad frequency band at smaller amplitude. The basilar membrane is narrower (0.04 mm) and stiffer near the base, and wider (0.5 mm) and looser near the apex. (By contrast, when observed from outside, the cochlea is wider at the base and smaller at the apex.) Therefore, the characteristic frequency decreases gradually and monotonically from the base to the apex, as indicated in Fig. 3-5. The traveling-wave phenomenon illustrated in Figs. 3-7 and 3-8 shows the vibration patterns—i.e., amplitude versus location—for incident pure tones of different frequencies. An interesting point in Fig. 3-8 is that the vibration pattern is asymmetric, with a slow tail close to the base (for high frequencies) and a steep edge close to the apex (for low frequencies). Because of this asymmetry, it is easier for the low frequencies to mask the high frequencies than vice versa.

Within the Organ of Corti on the basilar membrane, there are a row of inner hair cells (IHC), and three to five rows of outer hair cells (OHC), depending on location. There are about 1500 IHCs and about 3500 OHCs. Each hair cell contains stereociliae (hairs) that vibrate corresponding to the mechanical vibration in the fluid around them. Because each location on the basilar membrane is most sensitive to its own characteristic frequency, the hair cells at the location also respond most to its characteristic frequency. The IHCs are sensory cells, like microphones, which convert mechanical vibration into electrical signal—i.e., neural firings. The OHCs, on the other hand, change their shapes according to the control signal received from efferent nerves. Their function is to give an extra gain or attenuation, so that the output of the IHC is tuned to the characteristic frequency much more sharply than the IHC itself. Fig. 3-9 shows the tuning curve (output level vs. frequency) for a particular location on the basilar membrane with and without functioning OHCs. The tuning curve is much broader with poor frequency selectivity when the OHCs do not function. The OHCs make our auditory system an active device, instead of a passive microphone. Because the OHCs are active and
consume a lot of energy and nutrition, they are usually damaged first due to loud sound or ototoxic medicines (i.e., medicine that is harmful to the auditory system). Not only does this kind of hearing loss make our hearing less sensitive, it also makes our hearing less sharp. Thus, as is easily confirmed with hearing-loss patients, simply adding an extra gain with hearing aids would not totally solve the problem.

### 3.3 Frequency Selectivity

#### 3.3.1 Frequency Tuning

As discussed in Section 3.2.5, the inner hair cells are sharply tuned to the characteristic frequencies with help from the outer hair cells. This tuning character is also conserved by the auditory neurons connecting to the inner hair cells. However, this tuning feature varies with level. Fig. 3-10 shows a characteristic diagram of tuning curves from a particular location on the basilar membrane at various levels. As can be seen in this graph, as level increases, the tuning curve becomes broader, indicating less frequency selectivity. Thus, in order to hear music more sharply, one should play back at a relatively low level. Moreover, above 60 dB, as level increases, the characteristic frequency decreases. Therefore when one hears a tone at a high level, a neuron that is normally tuned at a higher characteristic frequency is now best tuned to the tone. Because eventually the brain perceives pitch based on neuron input, at high levels, without knowing that the characteristic frequency has decreased, the brain hears the pitch to be sharp.

Armed with this knowledge, one would think that someone who was engaged in critical listening—a recording engineer, for example—would choose to listen at moderate to low levels. Why then do so many...
Chapter 3

audio professionals choose to monitor at very high levels? There could be many reasons. Loud levels may be more exciting. It may simply be a matter of habit. For instance, an audio engineer normally turns the volume to his or her customary level fairly accurately. Moreover, because frequency selectivity is different at different levels, an audio engineer might choose to make a recording while listening at a “realistic” or “performance” level rather than monitoring at a level that is demonstratedly more accurate. Finally, of course, there are some audio professionals who have lost some hearing already, and in order to pick up certain frequency bands they keep on boosting the level, which unfortunately further damages their hearing.

3.3.2 Masking and Its Application in Audio Encoding

Suppose a listener can barely hear a given acoustical signal under quiet conditions. When the signal is playing in presence of another sound (called “a masker”), the signal usually has to be stronger so that the listener can hear it. The masker does not have to include the frequency components of the original signal for the masking effect to take place, and a masked signal can already be heard when it is still weaker than the masker.

Masking can happen when a signal and a masker are played simultaneously (simultaneous masking), but it can also happen when a masker starts and ends before a signal is played. This is known as forward masking. Although it is hard to believe, masking can also happen when a masker starts after a signal stops playing! In general, the effect of this backward masking is much weaker than forward masking. Forward masking can happen even when the signal starts more than 100 ms after the masker stops, but backward masking disappears when the masker starts 20 ms after the signal.

The masking effect has been widely used in psychoacoustical research. For example, Fig. 3-10 shows the tuning curve for a chinchilla. For safety reasons, performing such experiments on human subjects is not permitted. However, with masking effect, one can vary the level of a masker, measure the threshold (i.e., the minimum sound that the listener can hear), and create a diagram of a psychophysical tuning curve that reveals similar features.

Besides scientific research, masking effects are also widely used in areas such as audio encoding. Now, with distribution of digital recordings, it is desirable to reduce the sizes of audio files. There are lossless encoders, which is an algorithm to encode the audio file into a smaller file that can be completely reconstructed with another algorithm (decoder). However, the file sizes of the lossless encoders are still relatively large. To further reduce the size, some less important information has to be eliminated. For example, one might eliminate high frequencies, which is not too bad for speech communication. However, for music, some important quality might be lost. Fortunately, because of the masking effect, one can eliminate some weak sounds that are masked so that listeners hardly notice the difference. This technique has been widely used in audio encoders, such as MP3.
3.3.3 Auditory Filters and Critical Bands

Experiments show that our ability to detect a signal depends on the bandwidth of the signal. Fletcher (1940)\(^{18}\) found that, when playing a tone in the presence of a bandpass masker, as the masker bandwidth was increased while keeping the overall level of the masker unchanged, the threshold increased as bandwidth increased up to a certain limit, beyond which the threshold remained constant. One can easily confirm that, when listening to a bandpass noise with broadening bandwidth and constant overall level, the loudness is unchanged, until a certain bandwidth is reached, and beyond that bandwidth the loudness increases as bandwidth increases, although the reading of an SPL meter is constant. An explanation to account for these effects is the concept of auditory filters. Fletcher proposed that, instead of directly listening to each hair cell, we hear through a set of auditory filters, whose center frequencies can vary or overlap, and whose bandwidth is varying according to the center frequency. These bands are referred to as critical bands (CB). Since then, the shape and bandwidth of the auditory filters have been carefully studied. Because the shape of the auditory filters is not simply rectangular, it is more convenient to use the equivalent rectangular bandwidth (ERB), which is the bandwidth of a rectangular filter that gives the same transmission power as the actual auditory filter. Recent study by Glasberg and Moore (1990) gives a formula for ERB for young listeners with normal hearing under moderate sound pressure levels\(^{21}\):

\[
ERB = 24.7(4.37F + 1)
\]

where,

the center frequency of the filter \(F\) is in kHz,

\(ERB\) is in Hz.

Sometimes, it is more convenient to use an ERB number as in Eq. 3-1,\(^{21}\) similar to the Bark scale proposed by Zwicker et al.\(^{22}\):

\[
ERB \text{ Number} = 21.4 \log(4.37F + 1) \quad (3-1)
\]

where,

the center frequency of the filter \(F\) is in kHz.

Table 3-1 shows the ERB and Bark scale as a function of the center frequency of the auditory filter. The Bark scale is also listed as a percentage of center frequency, which can then be compared to filters commonly used in acoustical measurements: octave (70.7%), half octave (34.8%), one-third octave (23.2%), and one-sixth octave (11.6%) filters. The ERB is shown in Fig. 3-11 as a function of frequency. One-third octave filters which are popular in audio and have been widely used in acoustical measurements ultimately have their roots in the study of human auditory response. However, as Fig. 3-11 shows, the ERB is wider than \(1/3\) octave for frequencies below 200 Hz; is smaller than \(1/3\) octave for frequencies above 200 Hz; and, above 1 kHz, it approaches \(1/6\) octave.

3.4 Nonlinearity of the Ear

When a set of frequencies are input into a linear system, the output will contain only the same set of frequencies, although the relative amplitudes and phases can be adjusted due to filtering. However, for a nonlinear system, the output will include new frequencies that are not present in the input. Because our auditory system has developed mechanisms such as acoustic reflex in the middle ear and the active processes in the inner ear, it is nonlinear. There are two types of nonlinear-
Chapter 3

3.5 Perception of Phase

The complete description of a given sound includes both an amplitude spectrum and a phase spectrum. People normally pay a lot of attention to the amplitude spectrum, while caring less for the phase spectrum. Yet academic researchers, hi-fi enthusiasts, and audio engineers all have asked, “Is the ear able to detect phase differences?” About the middle of the last century, G. S. Ohm wrote, “Aural perception depends only on the amplitude spectrum of a sound and is independent of the phase angles of the various components contained in the spectrum.” Many apparent confirmations of Ohm’s law of acoustics have later been traced to crude measuring techniques and equipment.

Actually, the phase spectrum sometimes can be very important for the perception of timbre. For example, an impulse and white noise sound quite different, but they have identical amplitude spectrum. The only difference occurs in the phase spectrum. Another common example is speech: if one scrambles the relative phases in the spectrum of a speech signal, it will not be intelligible. Now, with experimental evidence, we can confirm that our ear is capable of detecting phase information. For example, the neural firing of the auditory nerve happens at a certain phase, which is called the phase-locking, up to about 5 kHz. The phase-locking is important for pitch perception. In the brainstem, the information from left and right ears is integrated, and the interaural phase difference can be detected, which is important for spatial hearing. These phenomena will be discussed in more detail in Sections 3.9 and 3.11.

3.6 Auditory Area and Thresholds

The auditory area depicted in Fig. 3-12 describes, in a technical sense, the limits of our aural perception. This area is bounded at low sound levels by our threshold of hearing. The softest sounds that can be heard fall on the threshold of hearing curve. Above this line the air molecule movement is sufficient to elicit a response. If, at any given frequency, the sound pressure level is increased sufficiently, a point is reached at which a ticking sensation is felt in the ears. If the level is increased substantially above this threshold of feeling, it becomes painful. These are the lower and upper boundaries of the auditory area. There are also frequency limitations below about 20 Hz and above about 16 kHz, limitations that (like the two thresholds) vary considerably from individual to individual. We are less concerned here about specific numbers than we are about principles. On the auditory area of Fig. 3-12, all the sounds of life are...
played out—low frequency or high, very soft or very intense. Speech does not utilize the entire auditory area. Its dynamic range and frequency range are quite limited. Music has both a greater dynamic range than speech and a greater frequency range. But even music does not utilize the entire auditory area.

3.7 Hearing Over Time

If our ear was like an ideal Fourier analyzer, in order to translate a waveform into a spectrum, the ear would have to integrate over the entire time domain, which is not practical and, of course, not the case. Actually, our ear only integrates over a limited time window (i.e., a filter on the time axis), and thus we can hear changes of pitch, timbre, and dynamics over time, which can be shown on a spectrogram instead of a simple spectrum. Mathematically, it is a wavelet analysis instead of a Fourier analysis. Experiments on gap detection between tones at different frequencies indicate that our temporal resolution is on the order of 100 ms, which is a good estimate of the time window of our auditory system. For many perspectives (e.g., perceptions on loudness, pitch, timbre), our auditory system integrates acoustical information within this time window.

3.8 Loudness

Unlike level or intensity, which are physical or objective quantities, loudness is a listener’s subjective perception. As the example in Section 3.3, even if the SPL meter reads the same level, a sound with a wider bandwidth might sound much louder than a sound with a smaller bandwidth. Even for a pure tone, although loudness follows somewhat with level, it is actually a quite complicated function, depending on frequency. A tone at 40 dB SPL is not necessarily twice as loud as another sound at 20 dB SPL. Furthermore, loudness also varies among listeners. For example, a listener who has lost some sensitivity in a certain critical band will perceive any signal in that band to be at a lower level relative to someone with normal hearing.

Although there is no meter to directly measure a subjective quantity such as loudness, psycho-physical scaling can be used to investigate loudness across subjects. Subjects can be given matching tasks, where they are asked to adjust the level of signals until they match, or comparative tasks, where they are asked to compare two signals and estimate the scales for loudness.

3.8.1 Equal Loudness Contours and Loudness Level

By conducting experiments using pure tones with a large population, Fletcher and Munson at Bell Labs (1933) derived equal loudness contours, also known as the Fletcher-Munson curves. Fig. 3-13 shows the equal loudness contours later refined by Robinson and Dadson, which have been recognized as an international standard. On the figure, the points on each curve correspond to pure tones, giving the same loudness to an average listener. For example, a pure tone at 50 Hz at 60 dB SPL is on the same curve as a tone at 1 kHz at 30 dB. This means that these two tones have identical loudness to an average listener. Obviously, the level for the 50 Hz tone is 30 dB higher than the level of the 60 Hz tone, which means that we are much less sensitive to the 50 Hz tone. Based on the equal loudness contours, loudness level, in phons, is introduced. It is always referenced to a pure tone at 1 kHz. The loudness level of a pure tone (at any frequency) is defined as the level of a 1 kHz tone that has identical loudness to the given tone for an average listener. For the above example, the loudness of the 50 Hz pure tone is 30 phons, which means it is as loud as a 30 dB pure tone at 1 kHz. The lowest curve marked with “minimum audible” is the hearing threshold. Although many normal listeners can hear tones weaker than this threshold at some fre-
quencies, on average, it is a good estimate of a minimum audible limit. The tones louder than the curve of 120 phons will cause pain and hearing damage.

The equal loudness contours also show that human hearing is most sensitive around 4 kHz (which is where the hearing damage due to loud sounds first happens), less sensitive to high frequencies, and much less sensitive for very low frequencies (which is why a subwoofer has to be very powerful to produce strong bass, the price of which is the masking of mid-and high-frequencies and potential hearing damage). A study of this family of curves tells us why treble and bass frequencies seem to be missing or down in level when favorite recordings are played back at low levels.\(^{26}\)

One might notice that for high frequencies above 10 kHz, the curves are nonmonotonic for low levels. This is due to the second resonant mode of the ear canal. Moreover, at low frequencies below 100 Hz, the curves are close to each other, and the change of a few dB can give you the feeling of more than 10 dB of dynamic change at 1 kHz. Furthermore, the curves are much flatter at high levels, which unfortunately encouraged many to listen to reproduced music at abnormally high levels, again causing hearing damage. Actually, even if one wanted to have flat or linear hearing, listening at abnormally high levels might not be wise, because the frequency selectivity of our auditory system will be much poorer, leading to much greater interaction between various frequencies. Of course, one limitation of listening at a lower level is that, if some frequency components fall below the hearing threshold, then they are not audible. This problem is especially important for people who have already lost some acuity at a certain frequency, where his or her hearing threshold is much higher than normal. However, in order to avoid further damage of hearing, and in order to avoid unnecessary masking effect, one still might consider listening at moderate levels.

The loudness level considers the frequency response of our auditory system, and therefore is a better scale than the sound pressure level to account for loudness. However, just like the sound pressure level is not a scale for loudness, the loudness level does not directly represent loudness, either. It simply references the sound pressure level of pure tones at other frequencies to that of a 1 kHz pure tone. Moreover, the equal loudness contours were achieved with pure tones only, without consideration of the interaction between frequency components — e.g., the compression within each auditory filter. One should be aware of this limit when dealing with broadband signals, such as music.

### 3.8.2 Level Measurements with A-, B-, and C-Weightings

Although psychoacoustical experiments give better results on loudness, practically, level measurement is more convenient. Because the equal loudness contours are flatter at high levels, in order to make level measurements somewhat representing our loudness perception, it is necessary to weight frequencies differently for measurements at different levels. Fig. 3-14 shows the three widely used weighting functions.\(^{27}\) The A-weighting level is similar to our hearing at 40 dB, and is used at low levels; the B-weighting level represents our hearing at about 70 dB; and the C-weighting level is more flat, representing our hearing at 100 dB, and thus is used at high levels. For concerns on hearing loss, the A-weighting level is a good indicator, although hearing loss often happens at high levels.

### 3.8.3 Loudness in Sones

Our hearing for loudness is definitely a compressed function (less sensitive for higher levels), giving us both sensitivity for weak sounds and large dynamic range for loud sounds. However, unlike the logarithmic scale (dB) that is widely used in sound pressure level, experimental evidence shows that loudness is actually a power law function of intensity and pressure as shown in Eq. 3-3.
where, $k$ and $k'$ are constants accounting for individuality of listeners,

$I$ is the sound intensity,

$p$ is the sound pressure,

$\alpha$ varies with level and frequency.

The unit for loudness is **sones**. By definition, one sone is the loudness of a 1 kHz tone at a loudness level of 40 phons, the only point where phons and SPL meet. If another sound sounds twice as loud as the 1 kHz tone at 40 phons, it is classified as 2 sones, etc. The loudness of pure tones in sones is compared with the SPL in dB in Fig. 3-15. The figure shows that above 40 dB, the curve is a straight line, corresponding to an exponent of about 0.3 for sound intensity and an exponent of 0.6 for sound pressure as in Eq. 3-3. The exponent is much greater for levels below 40 dB, and for frequencies below 200 Hz (which can be confirmed by the fact that the equal loudness contours are compact for frequencies below 200 Hz on Fig. 3-13).

One should note that Eq. 3-3 holds for not only pure tones, but also bandpass signals within an auditory filter (critical band). The exponent of 0.3 ($<1$) indicates compression within the filter. However, for a broadband signal that is wider than one critical bandwidth, Eq. 3-3 holds for each critical band, and the total loudness is simply the sum of loudness in each band (with no compression across critical bands).

### 3.8.4 Loudness versus Bandwidth

Due to less compression across critical bands, broadband sounds, such as a rocket launching or a jet aircraft taking off, seem to be much louder than pure tones or narrow bands of noise of the same sound pressure level. In fact, as in the example in Section 3.3.3, increasing the bandwidth does not increase loudness until the critical bandwidth is exceeded. Beyond that point multiple critical bands are excited, and the loudness increases markedly with increase in bandwidth because of less compression across critical bands. For this reason, the computation of loudness for a wide band sound must be based on spectral distribution of energy. Filters no narrower than critical bands are required and $\frac{1}{3}$ octave filters are commonly used.

### 3.8.5 Loudness of Impulses

Life is filled with impulse-type sounds: snaps, pops, crackles, bangs, bumps, and rattles. For impulses or tone bursts with duration greater than 100 ms, loudness is independent of pulse width. The effect on loudness for pulses shorter than 200 ms is shown in Fig. 3-16. This curve shows how much higher the level of short pulses of noise and pure tones must be to sound as loud as continuous noise or pure tones. Pulses longer than 200 ms are perceived to be as loud as continuous noise or pure tones. Pulses longer than 200 ms are perceived to be as loud as continuous noise or pure tones of the same level. For the shorter pulses, the pulse level must be increased to maintain the same loudness as for the longer pulses. Noise and tonal pulses are similar in the level of increase required to maintain the same loudness. Fig. 3-16 indicates that the ear has a time constant of about 200 ms, confirming the time window on the order of 100 ms, as discussed in Section 3.7. This means that band levels should be measured.
with RMS detectors having integration times of about 200 ms. This corresponds to the FAST setting on a sound level meter while the SLOW setting corresponds to an integration time of 500 ms.

3.8.6 Perception of Dynamic Changes

How sensitive is our hearing of dynamic changes? In other words, how much intensity or level change will lead to a perception of change of loudness? To discuss this kind of problem, we need the concept of just-noticeable difference (JND), which is defined as the minimum change that can be detected. Weber’s Law states that the JND in intensity, in general and not necessarily for hearing, is proportional to the overall intensity. If Weber’s Law holds, the Weber fraction in dB as defined in Eq. 3-4 would be a constant, independent of the overall intensity and the overall level.

$$\text{Weber fraction in dB} = 10\log\left(\frac{\Delta I}{I}\right) = \text{constant} \quad (3-4)$$

where,

$I$ is the intensity,

$\Delta I$ is the JND of intensity.

Please note that the Weber fraction in dB is not the JND of SPL ($\Delta L$), which can be calculated according to Eq. 3-5.

$$\Delta L = 10\log\left(1 + \frac{\Delta I}{I}\right) \quad (3-5)$$

If $\Delta I$ is much smaller than $I$, Eq. 3-5 is approximately

$$\Delta L = 4.35\left(1 + \frac{\Delta I}{I}\right) \quad (3-6)$$

Fig. 3-17 shows the measurement of the Weber fraction for broadband signals up to 110 dB SPL.39 Above 30 dB, the Weber fraction in dB is indeed a constant of about −10 dB, corresponding to a JND ($\Delta L$) of 0.4 dB. However, for weak sounds below 30 dB, the Weber fraction in dB is higher, and can be as high as 0 dB, corresponding to a JND ($\Delta L$) of 3 dB. In other words, our hearing is less sensitive (in level) for dynamic changes of sounds weaker than 30 dB. Interestingly, when measuring with pure tones, it was found that the Weber fraction is slightly different from the broadband signals.30 This phenomenon is known as the near-miss Weber’s Law. Fig. 3-17 includes a more recent measurement for pure tones,31 which demonstrates that the Weber fraction gradually decreases up to 85 dB SPL and can be lower than −12 dB, corresponding to a JND ($\Delta L$) less than 0.3 dB. The near-miss Weber’s Law for pure tones is believed to be associated with the broad excitation patterns across frequency at high levels.32

3.9 Pitch

Pitch seems to be a very clear concept, and yet it is very hard to give an accurate definition. The definition by the American National Standards Institute (ANSI) is as follows: “Pitch is that attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from low to high.”33 Like loudness, pitch is a subjective quantity. The ANSI standard also states: “Pitch depends mainly on the frequency content of the sound stimulus, but it also depends on the sound pressure and the waveform of the stimulus.”33

Roughly speaking, the sounds we perceive as pitch are musical tones produced by a musical instrument (except for percussion instruments) and human voice. It is either a pure tone at a certain frequency, or a complex tone with certain fundamentals and a series of harmonics whose frequencies are multiples of the
fundamental frequency. For example, when a violin is playing a tone of concert A (440 Hz), the spectrum includes not only the frequency of 440 Hz but also the frequencies of 880 (2 × 440) Hz, 1320 (3 × 440) Hz, and 1760 (4 × 440) Hz, etc.

To perceive a pitch, the sound must be able to match with a pure tone, i.e., a listener must be able to adjust the frequency of a pure tone to produce an identical pitch as the given sound. An opposite example is as follows. When one hits a small drum, it might sound higher than a bigger drum. However, normally one cannot match the sound that a drum produces with a pure tone. The exception, of course, would be a tympani or a steel drum. Therefore, the sound that most drums make does not result in the perception of pitch. Another attribute of pitch is that, if a sound has pitch, one can use it to make a melody. One could use a frequency generator to produce a pure tone at a frequency of 10 kHz, and one could match it with another tone by listening to the beats. However, it would not be perceived as a tone, and it could not be used as part of a melody; therefore it would not be thought of as having pitch.34 This will be discussed further in Section 3.9.3.

3.9.1 The Unit of Pitch

The unit of *mel* is proposed as a measure of the subjective quantity of pitch.35 It is always referenced to a pure tone at 1 kHz at 40 dB above a listener’s threshold, which is defined as 1000 mels. If another sound produces a pitch that sounds two times as high as this reference, it is considered to be 2000 mels, etc. Fig. 3-18 shows the relationship between pitch in mels and frequency in Hz. The frequency axis in Fig. 3-18 is in logarithmic scale. However, the curve is not a straight line, indicating that our pitch perception is not an ideal logarithmic scale with respect to frequency in Hz. This relationship is probably more important for melodic intervals (when notes are played sequentially) than for chords (when notes are played simultaneously). In a chord, in order to produce a clean harmony, the notes have to coincide with the harmonics of the root note; otherwise, beats will occur, sounding out of tune. In the music and audio industry, it is much more convenient to use frequency in Hz or the unit of *cent* based on the objective quantity of frequency.

Because our hearing is approximately a logarithmic scale on frequency—e.g., doubling frequency transposes a musical note to an octave higher—musical intervals between two tones can be described objectively in the unit of cent as defined by Eq. 3-7.

\[
\text{Musical Interval in cents} = 1200 \log_{10} \left( \frac{f_2}{f_1} \right)
\]

(3-7)

where, \( f_1 \) and \( f_2 \) are the fundamental frequencies of the two tones.

Thus, a semi-tone on a piano (equal temperament) is 100 cents, and an interval of an octave is 1200 cents. Using the unit of cent, one can easily describe the differences among various temperaments (e.g., equal temperament, Pythagorean scale, Just-tuning, etc.).

3.9.2 Perception of Pure and Complex Tones

How does our brain perceive pitch? The basilar membrane in the inner ear functions as a frequency analyzer: pure tones at various frequencies will excite specific locations on the basilar membrane. This would seem to suggest that the location of the maximum excitation on the basilar membrane determines the pitch. Actually, the process is much more complicated: besides the place coding, there is also temporal coding, which accounts for the time interval between two adjacent neural spikes. The temporal coding is necessary for perceiving the pitch of complex tones, the virtual pitch with missing fundamentals, etc.36,37 The theories based on place coding and temporal coding have been proposed to explain the origin of perception of pure and complex pitches. For either the place theory or the temporal theory, there is experimental evidence supporting and dis-
favoring it. As we develop our knowledge, we will probably understand more about when each coding takes place.

When hearing a complex tone, we are tolerant with harmonics slightly mistuned. For instance, if three frequencies of 800, 1000, and 1200 Hz (i.e., the 4th, 5th and 6th harmonics of a fundamental of 200 Hz) are combined and presented to a listener, the pitch perceived is 200 Hz. If all of them are shifted upward by 30 Hz—i.e., 830, 1030, and 1230 Hz—the fundamental, theoretically, is now 10 Hz, and those three components are now the 83rd, 103rd, and 123rd harmonics of the fundamental of 10 Hz. However, when playing this mistuned complex tone, listeners can hear a clear pitch at 206 Hz, which matches the middle frequency—i.e., 1030 Hz—the 4th harmonic of the fundamental. Although the other two frequencies are slightly mistuned (in opposite directions) as harmonics, the pitch is very strong.

It is worth mentioning that pitch recognition is an integrated process between the two ears, in other words, it is a binaural process. When two harmonics of the same fundamental are presented to each ear independently, the listener will hear the pitch at the fundamental frequency, not as two pitches, one in each ear.

3.9.3 Phase-Locking and the Range of Pitch Sensation

What is the range of the fundamental frequency that produces a pitch? Is it the same as the audible range from 20 Hz to 20 kHz? The lowest key in a piano is 27.5 Hz, not too far from the lowest limit. However, for the high limit, it is only about 5 kHz. Because the pitch perception requires temporal coding, the auditory neurons have to fire at a certain phase of each cycle, which is called phase-locking. Unfortunately, the auditory system is not able to phase-lock to frequencies above 5 kHz. This is why the highest note on a piccolo, which is the highest pitch in an orchestra, is 4.5 kHz, slightly lower than 5 kHz. Notes with fundamentals higher than 5 kHz are not perceived as having pitch and cannot be used for musical melodies. One can easily confirm this statement by transposing a familiar melody by octaves: when the fundamental is above 5 kHz, although one can hear something changing, the melody cannot be recognized any more.

3.9.4 Frequency Difference Limen

The frequency difference limen is another way of saying “the just-noticeable difference in frequency.” It is the smallest frequency difference that a listener can discriminate. Experiments with pure tones of duration of 500 ms show that, for levels higher than 10 dB above threshold, between 200 Hz and 5 kHz, the frequency difference limen is less than 0.5% of the given frequency, corresponding to 9 cents (about \(\frac{1}{10}\) of a semi-tone).

3.9.5 Dependence of Pitch on Level

Pitch can be affected by level, however, the influence is not universal across frequency. At frequencies below 1 kHz, the pitch decreases as level increases; whereas at frequencies above 3 kHz, the pitch increases with increasing level; and at frequencies between 1 and 3 kHz, varying the level has little effect on pitch. This is known as Stevens rule. Terhardt et al. summarized several studies of level dependence of pure tones and came up with the following equation for an average listener:

\[
100 \times \frac{p - f}{f} = 0.02 \left( L - 60 \right) \left( \frac{f}{1000} - 2 \right)
\]

where,

- \(f\) is the frequency in Hz of a pure tone at a sound pressure level of \(L\) in dB,
- \(p\) is the frequency of a pure tone at 60 dB SPL that matches the pitch of the given tone \(f\).

3.9.6 Perfect Pitch

Some people, especially some musicians, develop perfect pitch, also known as absolute pitch. They can identify the pitch of a musical tone without help from an external reference like a tuner—i.e., they have established an absolute scale of pitch in their heads. Some of them describe the feeling of certain note analogous to a certain color. Some believe that one can establish a sensation of perfect pitch if he or she has a lot of experience listening to music on certain keys (which is normally due to musical training) before the age of 4. It is fair to state that having perfect pitch is not a requirement for a fine musician. Other than the advantage of tuning musical instruments or singing without a tuning device, there is no evidence that a person with perfect pitch would sing more accurately in tune. With the help of a tuner or accompaniment, a good musician without perfect pitch would do just as well. There is, however, a disadvantage due to age effect. For senior persons (especially those above the age of 65), the pitch scales are often shifted so that they would hear music that is being played normally to sound out of tune. This might
not be noticeable for a person without perfect pitch. However, for a senior musician with perfect pitch, he or she might find it to be annoying when perceiving everyone else in the orchestra playing out of tune. He or she has to live with it, because he or she might be the only one in the orchestra playing out of tune.

3.9.7 Other Pitch Effects

Pitch is mostly dependent on the fundamental frequency, and normally the fundamental frequency is one of the strongest harmonics. However, the fundamental of a complex tone can be missing or masked with a narrowband noise, while still producing a clear pitch. The pitch produced without fundamental is called virtual pitch, and it is evidence favoring the temporal theory over the place theory. The waveform of a virtual pitch bears identical period as a normal complex tone including the fundamental at the same frequency.

When listening to a broadband signal with a certain interaural phase relationship, although listening with one ear does not produce a pitch, when listening with both ears, one can hear a pitch on top of the background noise. These kind of pitches are called “binaural pitches”.

3.10 Timbre

Timbre is our perception of sound color. It is that subjective dimension that allows us to distinguish between the sound of a violin and a piano playing the same note. The definition by the American Standards Association states that the timbre is “that attribute of sensation in terms of which a listener can judge that two sounds having the same loudness and pitch are dissimilar,” and “timbre depends primarily upon the spectrum of the stimulus, but it also depends upon the waveform, the sound pressure, the frequency location of the spectrum, and the temporal characteristics of the stimulus.” Each sound has its unique spectrum. For musical instruments, the spectrum might be quite different for different notes, although they all sound like tones produced by the same instrument. The timbre of a sound produced in a concert hall may even vary with listener position because of the effects of air absorption and because of the frequency-dependent absorption characteristics of room surfaces.

It is worth noting that, in order to more completely describe timbre, both amplitude and phase spectra are necessary. As the example in Section 3.5 shows, although a white noise and an impulse have identical amplitude spectra, they sound quite differently due to the difference in the phase spectra. Sometimes the onset and offset of a tone might be important for timbre (e.g., the decay of a piano tone). Thus, along with the consideration of the time window of human hearing (on the order of 100 ms), the most accurate description of a timbre would be a spectrogram (i.e., the spectrum developing with time), as shown in Fig. 3-19.

3.11 Binaural and Spatial Hearing

What is the advantage of having two ears? One obvious advantage is a backup: if one ear is somehow damaged, there is another one to use, a similar reason to having two kidneys. This explanation is definitely incomplete. In hearing, having two ears gives us many more advantages. Because of having two ears, we can localize sound sources, discriminate sounds originated from different locations, hear conversations much more clearly, and be more immune to background noises.

3.11.1 Localization Cues for Left and Right

When a sound source is on the left with respect to a listener, it is closer to the left ear than to the right ear. Therefore the sound level is greater at the left ear than that at the right ear, leading to an interaural level difference (ILD). Sometimes, people also use the interaural intensity difference (IID) to describe the same quantity. Moreover, because the sound wave reaches the left ear earlier than the right ear, there is an interaural time difference (ITD) between the two ears. However, the auditory neurons do not directly compare ITD, and instead, they compare the interaural phase difference (IPD). For
a pure tone, ITD and IPD are linearly related. The ITD and IPD are also referred to as the *interaural temporal difference*. In summary, for localization of left and right, there are two cues—i.e., the ILD and ITD cues.

Adjusting either the ILD or the ITD cues can affect sound localization of left and right. In reality, both of those cues vary. There are limits for both cues. In order to better localize using the ILD cues, the interaural differences should be greater. Because of diffraction around the head, at frequencies below 1 kHz, the levels at both ears are similar, leading to small ILD cues. Therefore ILD cues are utilized at high frequencies, when the head shadow has a big effect blocking the contralateral ear (the one not pointing at the source). On the other hand, there is a limit for the ITD cues as well. At frequencies above 700 Hz, the IPD of a source at extreme left or right would exceed 180°. For a pure tone, this would lead to confusion: a tone far to the right might sound to the left, Fig. 3-20. Since we care most about the sound sources in front of us, this limit of 700 Hz can be extended upward a little bit. Furthermore, with complex signal with broad bandwidth, we can also use the time delay (or phase difference) of the low-frequency modulation. In general, the frequency of 1.2 kHz, (or a frequency range between 1 and 1.5 kHz) is a good estimate for a boundary, below which ITD cues are important, and above which ILD cues are dominant.

![Diagram](image)

**Figure 3-20.** Confusion of interaural phase difference (IPD) cues at high frequencies. The dashed curve for the left ear is lagging the solid curve for the right ear by 270°, but it is confused as the left ear is leading the right ear by 90°.

In recording, adjusting the *ILD* cues is easily achieved by panning between the left and right channels. Although adjusting ITD cues also move the sound image through headphones, when listening through loudspeakers, the ILD cues are more reliable than ITD cues with respect to the loudspeaker positions.

### 3.11.2 Localization on Sagittal Planes

Consider two sound sources, one directly in front of and one directly behind the head. Due to symmetry, the ILD and ITD are both zero for those sources. Thus, it would seem that, by using only ILD and ITD cues, a listener would not be able to discriminate front and back sources. If we consider the head to be a sphere with two holes at the ear-positions (the spherical head model), the sources producing a given ITD all locate on the surface of a cone as shown in Fig. 3-21. This cone is called the cone of confusion.\(^{46}\) If only ITD cues are available for a listener with a spherical head, he or she would not be able to discriminate sound sources on a cone of confusion. Of course, the shape of a real head with pinnae is different from the spherical head, which changes the shape of the cone of confusion, but the general conclusion still holds. When the ILD cues are also available, due to diffraction of the head (i.e., the head shadow), the listener can further limit the confusion into a certain cross-section of the cone (i.e., the dark “donut” in Fig. 3-21). That is the best one can do with ILD and ITD cues. However, in reality, most people can easily localize sound sources in front, in the back, and above the head, etc, even with eyes closed. We can localize sources in a *sagittal plane* (a vertical plane separating the body into, not necessarily equal, left and right parts) with contribution of the asymmetrical shape of our pinnae, head, and torso of our upper body. The pinnae are asymmetrical when looked at from any direction. The primary role of the pinna is to filter or create spectral cues that are virtually unique for every angle of incidence. Different locations on the cone of confusion will be filtered differently, producing spectral cues unique to each location.

The common way of describing the spectral cue for localization is the *head-related transfer function* (HRTF), an example of which is shown in Fig. 3-22. It is the transfer function (gain versus frequency), illustrating the filtering feature of the outer ear, for each location in space (or, more often, for each angle of incidence). Nowadays, with probe microphones inserted close to the eardrum, HRTF can be measured with high accuracy. Once it is obtained for a given listener, when listening to a recording made in an anechoic chamber convolved with the proper HRTF, one can “cheat” the auditory system and make the listener believe that the recording is being played from the location corresponding to the HRTF.
There are two challenges when using spectral cues. The first is discriminating between the filtering feature and the spectrum of the source. For instance, if one hears a notch around 9 kHz, it might be due to an HRTF, or the original source spectrum might have a notch around 9 kHz. Unfortunately there is no simple way to discriminate between them. However, for a familiar sound (voice, instruments, etc.) with a spectrum known to the auditory system, it is easier to figure out the HRTFs and thus easier to localize the source than an unknown sound. Instead of forgetting either the new or the old ears, the subject actually memorizes both sets of ears, and becomes in a sense bilingual, and is able to switch between the two sets of ears.

3.11.3 Externalization

Many listeners prefer listening to music through loudspeakers instead of through headphones. One of the reasons is that when listening through headphones, the pinnae are effectively bypassed, and the auditory system is not receiving any of the cues that the pinnae produce. Over headphones, the instruments and singers’ voices are all perceived or localized inside the head. When listening through loudspeakers, although the localization cues are not perfect, the sounds are externalized if not localized, somewhat more naturally. If, however, music playing through the headphones includes the HRTFs of the listener, he or she should be able to externalize the sound perfectly. Algorithms are available to simulate 3D sound sources at any location in free field and in a regular room with reverberation. The simulation is accurate to up to 16 kHz, and listeners cannot discriminate between the real source and the virtual (simulated) sound. An inconvenience nevertheless is that the system has to be calibrated to each listener and each room. In 1985, Jones et al. devised a test for stereo imagery utilizing a reverberator developed at the Northwestern University Computer Music Studio. The reverberator utilized HRTFs to create very compelling simulations of 3D space and moving sound sources within 3D space. The test by Jones et al. called LEDR (Listening Environment Diagnostic Recording) NU™, contained sound examples that moved in very specific sound paths. When played over loudspeaker systems that were free from phase or temporal distortions and in environments free from early reflections, the paths were perceived as they were intended. In the presence of early reflection or misaligned crossovers or drivers, the paths are audibly corrupted.
3.11.4 Precedence (Hass) Effect

When two clicks are presented simultaneously to a listener, one on the left and one on the right, the listener would perceive a click in front—i.e., average the localization cues of the two clicks. However, if one of the clicks is delayed (up to 5 ms) compared to the other, the listener still perceives them as one fused click but will localize the fused image with cues of the first click only and ignore the localization cue of the later one. For delays longer than 5 ms, the listener will hear two distinct clicks instead of one fused click. For speech, music or other complex signals, this upper limit can be increased to about 40 ms. This phenomenon that the auditory system localizes on the first arrival is called precedence effect, or Haas effect.54,55

The precedence effect has very practical uses in audio. For example, in a large church, it may not be possible or practical to cover the entire church from one loudspeaker location. One solution is to place a primary loudspeaker in the front of the church, with secondary loudspeakers along the side walls. Because of the precedence effect, if the signal to the loudspeakers along the walls is delayed so that the direct sound from the front arrives at a listener first, the listener will localize the front loudspeaker as the source of the sound, even though most of the content will actually be coming from the loudspeaker to the side, which is much closer to the listener, and may even be operating at a higher level. When such systems are correctly set up, it will sound as though the secondary loudspeakers are not even turned on. Actually turning them off demonstrates exactly how important they are, as without them the sound is unacceptable, and speech may even be unintelligible.

3.11.5 Franssen Effect

The Franssen Effect56 can be a very impressive demonstration in a live room. A pure tone is played through two loudspeakers at two different locations. One loudspeaker plays the tone first and is immediately faded, while the same pure tone is boosted at the other loudspeaker, so that the overall level is not changed significantly, Fig. 3-23. Although the original loudspeaker is not playing at all, most of the audience will still believe that the sound is coming from the first loudspeaker. This effect can last for a couple minutes. One can make this demonstration more effectively by disconnecting the cable to the first loudspeaker, and the audience will still localize the sound to that loudspeaker. The Franssen effect reveals the level of our auditory memory of source locations in a live room.

Figure 3-23. Franssen effect (Reference 56). The figure shows the level of two loudspeakers at two different locations in a live room. Loudspeaker One plays a pure tone first, and is immediately faded. Meanwhile, the same tone played by Loudspeaker Two is boosted, so that the overall level in the room is not changed significantly. After Loudspeaker One stops playing, listeners will still perceive the sound originated from Loudspeaker One, up to a couple minutes.

3.11.6 Cocktail Party Effect and Improvement of Signal Detection

In a noisy environment, such as a cocktail party, many people are talking simultaneously. However, most people have the ability to listen to one conversation at a time, while ignoring other conversations going on around them. One can even do this without turning his or her head to the loudspeaker. As we mentioned earlier, one benefit of binaural hearing is the ability to spatially filter. Because the talkers are spatially separated, our auditory system can filter out unwanted sound spatially. Patients with hearing difficulties usually suffer greatly in a noisy environment because they are unable to pick up an individual’s conversation out of the background.

Because the background noise is normally in phase between the two ears, in electronic communication, one can reverse the phase of a signal in one ear and make it out of phase between the ears. Then signal detection is much better due to spatial filtering. So, in general, binaural hearing not only gives us localization ability, but also improves our ability to detect an acoustical signal, especially in a noisy or reverberant environment.

3.11.7 Distance Perception

Distance cues are fairly difficult to replicate. In free field conditions, the sound pressure level will decrease 6 dB with every doubling of the distance between a point source and an observer. Thus reducing the volume should make us feel the source is farther away. In practice, however, we tend to underestimate the distance: the level has to be attenuated by 20 dB in order to give us the perception of a doubled distance.57 Of course if we do not know how loud the original source is, we do not have an absolute scale based on level.
When a sound source is very far, because the air absorbs high-frequencies more than the low-frequencies, the perceived sound would contain more low-frequency energy, with a darker timbre. This is why thunder far away is just rumble whereas thunder nearby has a crack to it. However, this is a very weak effect\(^5\) and therefore is relatively insignificant for events nearby, which is mostly the case in everyday life.

A more compelling cue for replicating and perceiving distance is adjusting the ratio of the direct to reverberant sound. In real spaces, a sound nearby will not only be louder but also will have a relatively high direct-to-reverberant ratio. As the sound moves away, it gets quieter, and the direct-to-reverberant ratio reduces until critical distance is reached. At critical distance the direct and reverberant levels are equal. Moving a sound source beyond critical distance will not result in an increased sense of distance.

Further Reading

Textbooks on psychoacoustics and auditory physiology are available for various audiences. One might find some of the following books to be helpful:

This page intentionally left blank
The field of room acoustics divides easily into two broad categories: noise control and subjective acoustics. These two branches of acoustics actually have rather little in common. Noise control, to a great extent, must be designed into a project. It is very difficult, if not impossible to retroactively improve the isolation of a room. However, it is often possible to change the way a room sounds subjectively by simply modifying the wall treatment. It is important to keep in mind that noise is a subjective categorization. Sound pressure, sound intensity, and sound transmission can all be measured. Noise is unwanted sound. It is much more difficult to measure and quantify the extent to which any given sound annoys any given individual. To the Harley rider driving his Fat Boy™ past your studio, the exhaust is music to his ears but noise to you. Your music is noise to the therapist trying to conduct a session of a very different sort next door. The music in studio A is noise to the band trying to record in studio B down the hall.

Throughout this chapter, the term sound room will be used to designate any room that requires some measure of quiet in order for the room to serve its purpose.

4.1 Noise Criteria

When specifying permissible noise levels, it is customary to use some form of the noise criteria (NC). The beauty of the NC contours is that a spectrum specification is inherent in a single NC number. The NC contours of Fig. 4-1 are helpful in setting a background noise goal for a sound room.1 Other families of NC contours have been suggested such as the PNC,2 Fig. 4-2 which adds an additional octave to the low end of the scale, and NR (noise rating), Fig. 4-3, used in Europe. In 1989 Beranek proposed the NCB or Balanced Noise Criteria.3 The NCB adds the 16 Hz octave band and the slopes of the curves are somewhat modified relative to the NC or PNC curves, Fig. 4-4.

Beranek also proposed NCB limits for various applications as shown in Table 4-2.

Considering the spectrum of noise is far superior to using a single, wideband noise level. However, if desired, each NC contour can be expressed as an overall decibel level by adding the sound power in each octave band as in Table 4-1. These overall levels are convenient for rough appraisal of noise levels from a single sound level meter (SLM) reading. For example, if the SLM reads 29 dB on the A-weighting scale for the background noise of a studio, it could be estimated that the NC of that room is close to NC-15 on the assumption that the noise spectrum of that room matched the corresponding NC contour, and that there are no dominant pure tone components.

It is helpful to see recommended NC ranges for recording studios and other rooms compared to criteria applicable to spaces used for other purposes, Table 4-2. The NC goals for concert halls and halls for opera,
musicals, and plays are low to assure maximum dynamic range for music and greatest intelligibility for speech. This same reasoning applies to high-quality listening rooms such as control rooms. For recording studios, stringent NC goals are required to minimize noise pickup by the microphone. Levels below NC-30 are generally considered "quiet," but there are different degrees of quietness. An NC-25 is at the low end of what is expected of an urban residence. This means that

if an NC-25 were met in an urban residence, it is likely that the occupants would perceive it as being quiet. That same NC-25 represents the upper limit of what is acceptable for a recording studio. Most recording studios, especially those that record material with wide dynamic content, will require NC-20 or even 15. Levels lower than NC-15 require expensive construction and are difficult to achieve in urban settings.

4.2 Site Selection

Part of meeting a noise goal is the careful selection of a building site, a site that is appropriate for the application and where the NC is achievable and affordable. It is one thing to build a room meeting an NC-15 in a cornfield in central Iowa. It is another thing altogether to build an NC-15 room in downtown Manhattan. When surveying a site, watch for busy roads, especially freeways; elevated, ground level, or underground railroads, busy intersections, airports, and fire stations. When economic or other factors make such a location imperative, allowance must be made for the extra cost of the structure to provide the requisite protection from such noise. When considering space in an existing building, inspect all neighboring spaces and be wary of adjacent spaces that are vacant unless the owner of the sound-sensitive space also controls the vacant space.

Remember that buildings can be very noisy spaces. Sources of noise include elevator doors and motors, heating, ventilating, and air-conditioning equipment; heel taps on hard floors, plumbing, and business machines.

If selecting a plot of land, a limited amount of protection can be achieved by erecting earthen embankments or masonry walls between the structure and the noise source. These are reasonably effective at high frequencies, but low-frequency components of noise whose wavelengths are large relative to the size of the embankment tend to diffract over the top. A stand of dense shrubbery might yield as much as 10 dB of overall attenuation. Physical separation of the proposed structure from the noise source is helpful but limited by the inverse-square law. The 6 dB per distance double rule applies only to point sources in free-field conditions but it is useful for rough estimation. Going from 50 ft to 100 ft (a change of 50 ft) from the source yields the same reduction of noise level as going from 100 ft to 200 ft (a change of 100 ft). Clearly, increasing separation counts most when close to the source. At any given location sites, locating the sound-sensitive rooms on the face of the building away from a troublesome noise source is favorable, especially if no reflective structures are there to reduce the barrier effect.

There are two ways that noise travels from the source to the observer. It is either transmitted through the air—airborne noise—or carried through the structure or the earth—structure borne noise. A highway carrying heavy truck traffic or an overhead or subway railroad, may literally shake the earth to such an extent that large amplitude, low-frequency vibrations of the ground may be conducted to the foundation of the structure and carried to all points within that structure. Even if such vibrations are subsonic, they have been known to shake microphones with good low-frequency response so as to overload low level electronic circuits. Vibration, both subsonic and sonic, is carried with amazing efficiency throughout a reinforced concrete structure. The speed of sound in air is 344 m/s whereas the speed of sound in reinforced concrete, for example, is on the order of 3700 m/s. A large-area masonry wall within a structure, when vibrated at high amplitude, can radiate significant levels of sound into the air by diaphragmatic action. It is possible by using a combination of vibration-measuring equipment and calculations (outside the scope of this treatment) to estimate the sound pressure level radiated into a room via such a structure-borne path. In most cases noise is transmitted to the observer by both air and structure.

4.2.1 Site Noise Survey

A site survey gives the designer a good idea of the noise levels present at the proposed building site. It is important to know how much noise exists in the immediate environment so that appropriate measures can be taken to reduce it to acceptable levels.

Ambient noise is very complex, a fluctuating mixture of traffic and other noises produced by a variety of human and natural sources. The site noise should be documented with the appropriate test equipment. Subjective approaches are unsatisfactory. Even a modest investment in a studio suite or a listening room justifies the effort and expense of a noise survey of the site which provides the basis for designing walls, floor, and ceiling to achieve the low background noise goals.

One approach to a noise survey of the immediate vicinity of a proposed sound room is to contract with an acoustical consultant to do the work and submit a report. If technically oriented persons are available, they may be able to turn in a credible job if supplied with the right equipment and given some guidance.

The easy way to survey a proposed site is to use one of the more sophisticated microprocessor-based
recording noise analyzers available today. There are a number of fine units that are capable of producing reliable and very useful site surveys. Fig. 4-5 is an example of a 24 hour site survey made with the Gold Line TEF 25 running Noise Level Analysis™ software. One can also use a handheld sound level meter (SLM) if outfitted with the appropriate options. Some real-time frequency analyzers such as the Brüel and Kjaer 2143 are also appropriate. It is also acceptable to use a dosimeter such as the Quest Technologies model 300, Fig. 4-6.

No matter which analyzer is used, the system must be calibrated using a microphone calibrator. The weather conditions, especially temperature and relative humidity, should be noted at the time of calibration. The measuring microphone may be mounted in a weatherproof housing at the desired location with the microphone cable running to the equipment indoors. There are a number of terms which will appear on any display of a noise survey. There will be a series of \( L_n \) levels indicated, see Table 4-3. These are called exceedance or percentile levels. \( L_{10} \) refers to the noise level exceeded 10% of the time, \( L_{50} \) the level exceeded 50% of the time, \( L_{90} \) the level exceeded 90% of the time and so forth. In the United States \( L_{10} \) is considered to indicate the average maximum level and \( L_{90} \) the average minimum or background level. Since many noise levels vary dramatically over time, it is useful to have a number which represents the equivalent constant decibel level. The \( L_{eq} \). This is the steady continuous level that would yield the same energy over a given period of time as the measured levels. \( L_{dn} \) indicates a 24 hour \( L_{eq} \) with 10 dB added to the levels accumulated between 2200 and 0700 h to account for the increased annoyance potential during the nighttime hours. The Community Noise Equivalent Level (CNEL) also is used to document noise levels over a 24 hour period. It differs from the \( L_{dn} \) as weighting factors for the evening period between 1900 to 2200 h are included. The \( L_{eq} \) for evening hours is increased by 5 dB while the \( L_{eq} \) for the nighttime hours is increased by 10 dB.

Table 4-3. Common Level Designations in Noise Surveys

| \( L_{10} \) | Noise level exceeded 10% of the time |
| \( L_{50} \) | Noise level exceeded 50% of the time |
| \( L_{90} \) | Noise level exceeded 90% of the time |
| \( L_{dn} \) | 24 hour \( L_{eq} \) |
| \( l_{mean} \) | Arithmetic mean of measured levels |

The \( l_{mean} \) is the arithmetic mean of the measured levels. \( L_{min} \) and \( L_{max} \) refer to the lowest and highest measured instantaneous levels, respectively.

Ideally, the site survey should take place over a minimum of 24 hours. A 24 hour observation captures
diurnal variations; observations on selected days of the week capture especially noisy events varying from day to day or occurring at certain times during the week.

All of these analyzers, with the exception of the Brüel and Kjaer 2143, will capture only the sound pressure levels over time. The 2143 will also capture the spectrum of the noise as well. If an analyzer such as the 2143 is not available, it is advisable to make a number of measurements of the spectrum as well as the time-stamped level record.

The data collected from the site survey should be combined with projections of the levels anticipated in the sound room and what will be tolerated in adjacent spaces.

4.2.2 Transmission Loss

Once the noise load is known and the desired NC is determined, attention must be given to the design of systems that will provide enough isolation to achieve the goal. Transmission loss is the loss that occurs when a sound goes through a partition or barrier. A higher $TL$ number means more loss, i.e., less acoustic energy gets through. If the desired NC or noise limit is known, and the noise load is known, a designer must then design barriers or partitions that have appropriate $TL$ to meet the design goal.

$$TL = 10\log\left(\frac{P_{\text{incident}}}{P_{\text{transmitted}}}\right)$$  \hspace{1cm} (4-1)

4.2.3 Sound Barriers

The purpose of a sound barrier is to attenuate sound. To be effective, the barrier must deal with airborne as well as structure-borne noise. Each barrier acts as a diaphragm, vibrating under the influence of the sound impinging upon it. As the barrier vibrates, some of the energy is absorbed, and some is reradiated. The simplest type of barrier is the limp panel or a barrier without any structural stiffness. Approached theoretically, a limp panel should give a transmission loss increase of 6 dB for each doubling of its mass.

$$TL = 14.5\log(Mf) - 16$$  \hspace{1cm} (4-3)

where,

$f$ is the frequency in hertz.

Transmission loss also varies with frequency, even though Eq. 4-1 has no frequency term in it. With a few reasonable assumptions, the following expression can be derived, which does include frequency:

$$TL = 14.5\log(Mf) + 23$$  \hspace{1cm} (4-2)

where,

$TL$ is the transmission loss in decibels,

$M$ is the surface density of the barrier in pounds per square foot.

Fig. 4-7 is plotted from the empirical mass law stated in Eq. 4-3, which is applicable to any surface density and any frequency, as long as the mass law is operating free from other effects.

From Fig. 4-7 several general conclusions can be drawn. One is that at any particular frequency, the heavier the barrier, the higher the transmission loss. A concrete wall 12 in (30 cm) thick with a surface density of 150 lb/ft$^2$ (732 kg/m$^2$) gives a higher transmission loss than a ¼ in (6 mm) glass plate with a surface density of 3 lb/ft$^2$ (14.6 kg/m$^2$). Another conclusion is that for a given barrier the higher the frequency, the higher the transmission loss.

The straight lines of Fig. 4-7 give only a partial picture since barrier effects other than limp mass dominate. Fig. 4-8 shows four different regions in the frequency domain of a barrier. At extremely low frequencies, stiffness of the barrier dominates. At somewhat higher frequencies, resonance effects control as the barrier vibrates like a diaphragm. Above a critical frequency, a coincidence effect controls the transmission loss of the barrier. The mass law is an important effect in determining barrier performance, but resonance and coincidence cause significant deviations.
The low-frequency resonance effect is due to the mechanical resonance of the barrier. For heavier barriers, the resonant-frequency is usually below the audible limit. As the panel vibrates at resonance, there is virtually no transmission loss. At frequencies above resonance, the mass law is in effect, and the function stays fairly linear until the coincidence effect. The coincidence effect occurs when the wavelength of the incident sound coincides with the wavelength of the bending waves in the panel. For a certain frequency and a certain angle of incidence, the bending oscillations of the panel will be amplified, and the sound energy will be transmitted through the panel with reduced attenuation. The incident sound covers a wide range of frequencies and arrives at all angles, but the overall result is that the coincidence effect creates an “acoustical hole” over a narrow range of frequencies giving rise to what is called the coincidence dip in the transmission loss curve. This dip occurs above a critical frequency, which is a complex function of the properties of the material. Table 4-4 lists the critical frequency for some common building materials.

4.2.4 Sound Transmission Class (STC)

The noise criterion approach is convenient and valuable because it defines a permissible noise level and spectrum by a single NC number. It is just as convenient and valuable to be able to classify the transmission loss of a barrier versus frequency curve by a single number. The STC or sound transmission class, is a single number method of rating partitions. A typical standard contour is defined by the values in Table 4-5. A plot of the data in Table 4-5 is shown in Fig. 4-5. Only the STC-40 contour is shown in Fig. 4-9, but all other contours have exactly the same shape. It is important to note that the STC is not a field measurement. The field STC, or FSTC, is provided for in ASTM E336-97 annex a1. The FSTC is often 5 dB or so worse than the laboratory STC rating. Therefore a door rated at STC-50 can be expected to perform around STC-45 when installed.

![Figure 4-8](image)

Figure 4-8. The performance of a barrier is divided into four regions controlled by stiffness, resonance, mass, and coincidence.

![Figure 4-9](image)

Figure 4-9. The standard shape used in determining the sound transmission class (STC) of a partition (ASTM E413-87).

Nonetheless, the STC provides a standardized way to compare products made by competing manufacturers.

Assume that a TL versus frequency plot of a given partition is at hand and that we want to rate that partition with an STC number. The first step is to prepare a transparent overlay on a piece of tracing paper of the standard STC contour (the STC-40 contour of Table 4-5 and Fig. 4-9) to the same frequency and TL scales as the TL graph. This overlay is then shifted vertically until some of the measured TL values are below the contour and the following conditions are fulfilled:

1. The sum of the deficiencies (i.e., the deviations below the contour) shall not be greater than 32 dB.
2. The maximum deficiency at any single test point shall not exceed 8 dB.

When the contour is adjusted to the highest value that meets these two requirements, the sound transmission class of that partition is the TL value corresponding to the intersection of the contour and the 500 Hz ordinate. An example of the use of STC is given in Fig. 4-10. To determine the STC rating for the
measured TL curve shown in Fig. 4-10, the STC overlay is first aligned to 500 Hz and adjusted vertically to read some estimated value, say, STC-44. The difference between the measured TL level and the STC curve is recorded at each of the \( \frac{1}{3} \) octave points. These data are added together. The total, 47 dB, is more than the 32 dB allowed. The STC overlay is next lowered to an estimated STC-42, and a total of 37 dB results. Lowering the overlay to STC-41 yields a total of 29 dB, which fixes the STC-41 contour as the rating for the TL curve of Fig. 4-10.

Figure 4-10. The method of determining the single-number STC rating of a barrier from its measured TL graph.

The final illustration of STC methods is given in Fig. 4-11. In this case, a pronounced coincidence dip appears at 2500 Hz. This illustrates the second STC requirement, “the maximum deficiency at any single test point shall not exceed 8 dB.” This 8 dB requirement fixes the overlay at STC-39, although it might have been considerably higher if only the 32 dB sum requirement applied.

The shape of the standard STC contour may be very different from the measured TL curve. For precise work, using measured, or even expertly estimated, TL curves may be desirable rather than relying on STC single number ratings. Convenience usually dictates use of the STC shorthand system, but it is, at best, a rather crude approximation to the real-world TL curves.

Assume that a goal of NC-20 has been chosen for a sound room. The noise survey indicates a noise level and spectrum as shown in Fig. 4-12. What wall construction will bring the noise of Fig. 4-12 down to the NC-20 goal we have set for the interior? Fig. 4-13 shows that a wall having a rating of STC-55 is required. The next step is to explore the multitude of possible wall configurations to meet the STC-55 requirement as well as other needs.

If the NC curve in Fig. 4-12 is subtracted from the measured noise curve, this will indicate the raw data that indicates the amount of loss needed to achieve the desired NC. This is plotted in Fig. 4-13. The standard STC template is laid over the graph and the needed STC is read opposite the 500 Hz mark.
4.3 Isolation Systems

Isolation systems must be dealt with holistically. One must consider walls, ceilings, floors, windows, doors, etc. as parts of a whole isolation system. Vibration takes every path possible when traveling from one spot to another. For example, if one intends to build a sound room directly below a bedroom of another tenant in a building, one might assume that special attention must be paid to the ceiling. Of course this is correct. However, there are often paths that would permit the vibration to bypass the ceiling. All these flanking paths must be accounted for if isolation between two spaces is desired.

It should be noted that in some parts of the country (most notably California) building codes require seismic engineering. Make sure that the isolation systems that are under consideration do not violate any local seismic codes or require additional seismic restraints. Mason Industries has published a bulletin that is quite instructive in seismic engineering.11

4.3.1 Wall Construction

Acoustic partitions are complex entities. As was previously noted, walls exhibit different degrees of isolation in different segments of the spectrum. It is therefore imperative that you know what frequencies you are isolating. (Refer to Fig. 4-8.) The more massive the wall and the more highly damped the material, the fewer the problems introduced by diaphragmatic resonance. In comparing the relative effectiveness of various wall configurations, the mass law offers the most easily accessible rough approximation. However, most practical acoustical partitions actually perform better—that is, they achieve more loss—than what is predicted by the mass law. To assist in the computation of isolation based on mass, the densities of various common building materials are listed in Table 4-6. If an air space is added as in double wall construction, this introduces an element other than mass and generally leads to higher transmission loss.

4.3.2 High-Loss Frame Walls

The literature describing high TL walls is extensive. Presented here is a dependable, highly simplified overview of the data with an emphasis on practical solutions for sound room walls. Jones’s summary shown in Table 4-7 describes eight frame constructions including the STC performance of each.7 In each of these constructions Gypsum wallboard is used because it provides an inexpensive and convenient way to get necessary wall mass and as fire retardant properties. Two lightweight concrete block walls, systems 9 and 10, fall in the

general STC range of the gypsum wallboard walls 1 to 8, inclusive.

The three papers by Green and Sherry report measurements on many wall configurations utilizing gypsum wallboard. Fig. 4-14 describes three of them yielding STCs from 56 to 62.

An expression of the empirical mass law stated as an STC rating rather than transmission loss is shown in Fig. 4-15. This makes it easy to evaluate the partitions of Table 4-7 and Fig. 4-14 with respect to partition surface weight. The numbered STC shaded ranges of Fig. 4-15 correspond to the same numbered partitions of Table 4-7, and the A, B, and C points refer to the A, B, and C constructions of Fig. 4-14. From Fig. 4-15 it can be seen that the performance of wall types 1 and 9 can be predicted from the mass law. The other wall types perform better than what the mass law curve predicts. This better performance results primarily from decoupling one leaf of a structure from the other.

In recent years there have been new developments in wallboard. QuietRock™ is an internally damped wallboard. Although it is considerably more expensive than standard gypsum board, it far outperforms conventional drywall, and for a given STC because less material is needed when using QuietRock, the cost can be offset.

Following are ten points to remember concerning frame walls for highest STC ratings:

1. It is theoretically desirable to avoid having the coincidence dip associated with one leaf of a wall at the same frequency as that of the other leaf. Making the two leaves different with coincidence dips appearing at different frequencies should render their combined effect more favorable. However, Green and Sherry found this effect negligible when partitions having equivalent surface weights were compared.

2. The two leaves of a wall can be made different by utilizing gypsum board of different thickness, mounting a soft fiber (sound-deadening) board under one gypsum board face and/or mounting gypsum board on resilient channels on one side.

3. Resilient channels are more effective on wood studs than on steel studs.

1*QuietRock copyright Quiet Solution, 125 Elko Dr., Sunnyvale, CA, 94089.
4. Steel stud partitions usually have an STC from two to ten points higher than the equivalent wood stud partition. The flange of the common C-shaped steel stud is relatively flexible and transmits somewhat less sound energy from face to face.

5. If multiple layers of gypsum board are used, mounting the second layer with adhesive rather than screws can affect an STC increase by as much as six points. This is especially helpful with higher density walls.

6. A fiberglass cavity filler (such as R-7) may increase STC by five to eight points. It is more effective in multilayer partitions if the second layer is attached with adhesive.

7. A slight increase in STC results from increasing stud spacing from 16 inches to 24 inches on center.

8. Increasing stud size from 2 inches to 3 inches does not significantly increase either transmission loss or STC in steel-stud partitions with filler in the cavity.

9. Additional layers of gypsum wallboard increase STC and TL, but the greatest improvement is with lighter walls. Adding layers increases stiffness, which tends to shift the coincidence dip to a lower frequency.

10. Attaching the first wallboard layer to studs with adhesive actually reduces STC.

### 4.3.3 Concrete Block Walls

Concrete block walls behave much like solid walls of the same surface weight and bending stiffness. In Table 4-7, wall system 9 is a lightweight, hollow, concrete block wall with both sides sealed with latex paint. In Fig. 4-15 we see that the performance of this specific wall falls close to pure mass operation. The STC-46 is matched or exceeded by many frame walls listed before it in Table 4-7. Wall system 10 in Table 4-7 is the same as 9, except wall system 10 has a new leaf, is furred out, and has mineral fiber added to one side in the cavity. These additions increase the STC from 46 to 57. It should be noted that there are less expensive frame structures that perform just as well. The performance of concrete walls can be improved by increasing the thickness of the wall, by plastering one or both faces, or by filling the voids with sand or well-rodded concrete, all of which increase wall mass. The STC performance of such walls can be estimated from Fig. 4-15 when the pounds-per-square-foot surface density is calculated. To further improve the performance one must add a furred-out facing (such as 10) or adding a second block wall with an air space.

### 4.3.4 Concrete Walls

The empirical mass law line in Fig. 4-15 goes to 100 lb/ft² (488 kg/m²), just far enough to describe an 8 inch concrete wall of 150 lb/ft³ density (surface density 100 lb/ft² or 732 kg/m²). This wall gives a rating close to STC-54. By extending the line we would find that a 12 inch wall would give STC-57, and a concrete wall 24 inches thick, about STC-61. The conclusion is inescapable. This brute-force approach to sound TL is not the cheapest solution. High TL concrete walls can be improved by introducing air space—e.g., two 8 inch walls spaced a foot or so apart. Such a wall requires specialized engineering talent to study damping of the individual leaves of the double wall, the coupling of the two leaves by the air cavity, the critical frequencies involved, the resonances of the air cavity, and so on.

### 4.3.5 Wall Caulking

There is continual movement of all building components due to wind, temperature expansion and contraction, hygroscopic changes, and deflections due to creep and loading. These movements can open up tiny cracks that are anything but tiny in their ability to negate the effects of a high-loss partition. An acoustical sealant is required to caulk all joints of a partition if the highest TL is to be attained. This type of sealant is a specialty product with nonstaining, nonhardening properties that provides a good seal for many years. Fig. 4-16 calls attention to the importance of bedding steel runners and wood plates in caulking to defeat the irregularities always present on concrete surfaces. A bead of sealant should also be run under the inner layer of gypsum board. The need for such sealing is as important at the juncture of wall-to-wall and wall-to-ceiling as it is at the floor line. The idea is to seal the room hermetically. Fig. 4-17 is a nomograph that illustrates what happens if there is leakage in a partition. The X axis represents a partition that is not compromised by any leaks. The family of curves are gaps or holes expressed as percentages of the whole surface area of the partition. This nomograph shows that a partition rated at a TL of 45 with no penetrations would perform as a TL-30 wall if only 0.1% of the wall were open. Consider what this means in real terms. A partition has a surface area of 10 m², 0.1% of 10 m² amounts to an opening with an area of a square centimeter (cm²). This could be a gap in the wall/ floor junction where the caulking was omitted, or it could be the area left open by the installation of an electrical box in a partition. This small gap will reduce the performance of the wall by a significant amount. All
of the engineering and calculations that have been discussed so far can be rendered meaningless if sufficient care is not taken to seal all holes in a partition.

4.3.6 Floor and Ceiling Construction

Building high TL walls around a sound room is futile unless similar attention is given to both the floor/ceiling system above the room and to the floor of the sound room itself. Heel and other impact noise on the floor above the room is readily transmitted through the ceiling structure and radiated into the sound room unless precautions are taken. The floor and ceiling structure of Fig. 4-18A is the type common in most existing frame buildings. Impact noise produced on the floor above is transmitted through the joists to the ceiling diaphragm below and radiated with little loss into the room below. Carpet on the floor above softens heel taps, but is low mass, and therefore has little effect on transmission of structure-borne sounds. Some decoupling of the floor membrane from the ceiling membrane is introduced in Fig. 4-18B in the form of resilient mounting of the ceiling gypsum board. Placing absorbent material in the cavity is also of modest benefit. In Table 4-8 four floor and ceiling structures are described along with STC ratings for each, as determined from field TL measurements.
Another means of decoupling the floor above from the sound room ceiling involves suspending the entire ceiling by a resilient suspension, such as in Fig. 4-19. Mason Industries, Inc. reports one test that demonstrates the efficacy of this approach. They started with a 3 inch concrete floor that alone gave STC-41. With a 12 inch air gap, a ⅝ inch gypsum board ceiling was supported on W30N spring and neoprene hangers, resulting in STC-50. By adding a second layer of ⅝ inch gypsum board and a sound-absorbent material in the air space, an estimated STC-55 was realized. The W30N hanger uses both a spring and neoprene. This combination is effective over a wide frequency range. The spring is effective at low frequencies and the neoprene at higher frequencies.

4.3.7 Floor Construction

Many variables must be considered when designing isolated floors. These variables include cost, load limits of the existing structure, the desired isolation, and the spectrum of the noise. Every successful system uses a combination of mass and resilient support designed to work above the resonance point of the system, and thus achieve isolation. There are three general approaches to floating or isolated floors; the continuous underlayment, the resilient mount, and the raised slab, Fig. 4-20.

Floating Floors. Once again, simply increasing mass is often the least productive way to make significant gains in STC. For example, a 6 inch solid concrete floor has an STC of 54, and doubling the thickness to 12 inches...
raises it only to STC-59. There are many recording studios and other sound-sensitive rooms that require floors greater than STC-54. The answer is in dividing available mass and placing an air space between. The results of an actual test, sponsored by Mason Industries, Inc., are given in Fig. 4-21.\textsuperscript{12} The TL of basic T sections (4 inch floor thickness) with 2 inches of poured concrete gives a total thickness of 6 inches and the STC-54 mentioned previously. Adding a 4 inch concrete floor on top of the same structural floor with 1 inch of air gap gives a healthy STC-76, which should be adequate for all but the most critical applications. A 4 inch slab added to the 6 inch floor without an air space gives only STC-57. A 19 dB improvement can be attributed directly to the air space.

**Continuous Underlayment.** The continuous underlayment is the simplest and easiest form of floating floor to construct. It is most often used for residential and light commercial applications where surface loads are relatively light. The technique consists of laying down some sort of vibration-absorbing mat and then constructing a floor on top of the mat, taking care not to penetrate the mat with any fasteners. The perimeter is surrounded with a perimeter isolation product and sealed with a nonhardening acoustical sealant. Maxxon offers a number of products including Acou-Mat 3, Acousti-MatII-Green, and Enkasonic\textsuperscript{®}. These are all underlayments that form a resilient layer upon which a wood floor can be constructed, Fig. 4-22, or can be part of a poured concrete system.

![Figure 4-21. Four methods used in floating floors for increasing transmission loss.](image1)

![Figure 4-22. Enkasonic floor system.](image2)

**Isolation Mount Systems.** If heavier loads are anticipated and greater isolation is needed, an isolation mount system should be considered. Various manufacturers build systems for isolating either wood floors or concrete slabs. Wood floors can be isolated as shown in Fig. 4-23. This system offered by Kinetics utilizes encapsulated fiberglass pads, imbedded in a roll of low-frequency fiberglass designed to fill the air space.

![Figure 4-23. Kinetics Floating Wood Floor. Courtesy Kinetics Corp.](image3)
Another approach by Mason Industries is to build a grid supported on neoprene mounts or, if greater isolation is needed, on combination spring and neoprene as shown in Fig. 4-24. A wood floor is then built on the substructure.

In some situations a floating concrete slab is indicated in Fig. 4-25, concrete slab is supported by the model RIM mat. The roll-out mat is ordered with the pad spacing based on the expected load. When the mat is unrolled (1) the plywood panels are then put in place, (2) the plastic sheet laid over the plywood, and (3) the concrete poured, Fig. 4-25. A perimeter board isolates the floating floor from the walls. The plastic film protects the plywood and helps to avoid bridges.

**Raised-Slab or Jack-Up System.** This system is for heavy duty applications where high STC ratings are needed. In Fig. 4-26 the individual isolators are housed in metal canisters, Fig. 4-27, that are placed typically on 36 inch to 48 inch centers each dimension. The metal canisters are arranged to tie into the steel reinforcing grid and are cast directly in the concrete slab. After sufficient curing time (about 28 days), it is lifted by judicious turning of all the screws one-quarter or

---

**Figure 4-27.** Kinetics FLM isolation mount. Courtesy Kinetics Corp.
one-half turn at a time. This is continued until an air space of at least 1 inch is achieved. Fig. 4-28 shows an alternative raised slab system utilizing springs instead of neoprene or fiberglass mounts. After the slab is raised to the desired height, the screw holes are filled with grout and smoothed. Fig. 4-29 further describes the elements of the raised-slab system. Turning the screws in the load-bearing isolation mounts raises the cured slab, producing an air space of the required height. This system requires heavier reinforcement rods in the concrete than the system of Fig. 4-25.

4.3.8 Summary of Floating Floor Systems

Loading must be calculated for each type of floating floor systems discussed. If the resilient system is too stiff, vibration will travel through the isolator rendering it ineffective. Likewise if the springs are too soft, they will collapse under the weight of the structure and also be ineffective.

Each floating floor system has its advocates. No one type of floor will suit all situations. The designer is urged to consider all the variables before making a decision. For example, there are pros and cons concerning use of neoprene versus the compressed, bonded, and encased units of glass fiber. Most of the arguments have to do with deterioration of isolating ability with age and freedom from oxidation, moisture penetration, and so on.

Fig. 4-30 combines several features that have been discussed in a “room within a room.” The walls are supported on the floating floor and stabilized with sway braces properly isolated. The ceiling is supported from the structure with isolation hangers. This type of hanger incorporates both a spring, which is particularly good for isolation from low-frequency vibration, and a Neoprene or a fiberglass element in series, which provides good isolation from higher-frequency components. An important factor is the application of a non-hardening type of acoustical sealant at the points marked “S.” An even better approach would be to support the ceiling from the walls by using joists or trusses spanning the room. Such a room should provide adequate protection from structure-borne vibrations originating within the building as well as from those vibrations transmitted through the ground to the building from nearby truck, surface railroad, or subway sources.
The design of rooms to achieve maximum isolation from airborne and structure-borne sounds is a highly specialized undertaking, ordinarily entrusted to consultants expert in that branch of acoustics. However, a sound engineer, charged with the responsibility of working with a consultant or doing the design personally, is advised to become familiar with the sometimes conflicting claims of suppliers and the literature on the subject.

### 4.3.9 Acoustical Doors

Every part of an acoustical door is critical to its performance. Special metal acoustical doors are available with special cores, heavy hinges, including special sealing and latching hardware. Their acoustical performance is excellent and their higher cost must be evaluated against high labor costs in constructing an alternative. There are two design elements required in considering what kind of door to utilize. There is the transmission loss of the door itself and there is the sealing system. The sealing system is more critical of the two. Whatever system is used, it must hold up over time and withstand the wear and tear of use. Doors and their seals are difficult to build and are often the weak point of a sound room. There is good reason to design sound room access and egress in such a way that excessively high performance is not required of a single door. Use of a sound lock corridor principle places two widely spaced doors in series, relieving the acoustical requirements of each, Fig. 4-31.

#### Homemade Acoustical Doors

An inexpensive door, satisfactory for less demanding applications, can be built from void-free plywood or high density particle board. It is also possible to start with a core material of particle board and laminate it with gypsum board if sufficient care is taken to protect the fragile edges of the gypsum board. Doors for acoustical isolation must have a solid and void-free core and be as massive as practical. Most residential grade doors are hollow and approach acoustical transparency. Some commercially available solid core doors are made of laminated wood; others, of particle board with composition board facing. The latter has the greater surface density. The 5.2 lb/ft² of the particle-board type gives an STC value of about 35. An STC-35 does not do justice to, say, STC-55 walls. Nevertheless, for doors separated as they are in the case of a sound lock, the TL of one door comes close to adding arithmetically to the loss of the other door. Two doors, well separated, approach doubling the effect of one.

All this implies a perfect seal around the periphery of the door attained only by nailing the door shut and applying a generous bead of acoustical sealant on the crack. A practical operative door must utilize some form of weatherstripping or other means for its seal. Fig. 4-32 illustrates different approaches to sealing a door. Many of these, especially the wiping type, require constant maintenance and frequent replacement. One of the more satisfactory types is the magnetic seal, similar to those on most household refrigerator doors. Zero International manufactures a system of door seals specifically designed for acoustical applications, Fig. 4-33. This type of commercially available acoustical door seal is a good way to get results from a homemade door that approaches the performance of a proprietary door at a fraction of the cost.

#### Proprietary Acoustical Doors

By far the more satisfactory doors for acoustical isolation in sound rooms are those manufactured especially for the purpose. Such doors offer measured and guaranteed performance over the life of the door with only occasional adjustment of seals. This is in stark contrast to the need for constant seal maintenance in the homemade door shown in Fig. 4-32. Each manufacturer has its own strengths. Some doors like the Overly and the IAC use cam lift hinges, which actually lift the door as it opens.

Manufacturers of building elements that need to be rated for sound transmission use ASTM standards in measuring their products. ASTM e-90 is the appropriate standard for sound transmission measurements. Copies of the standards are available at www.ASTM.com. Most manufacturers build a range of doors to suit specific needs. IAC builds doors ranging from an STC-43 to an impressive STC-64, Fig. 4-34.
4.3.10 Windows

Occasionally sound rooms require windows. The observation window between control room and studio is an example. It can very easily have a weakening effect on the overall TL of the partition between the two rooms. (See Section 3.3.11.) A wall with a rating of STC-60 alone might very well be reduced to STC-50 with even one of the more carefully designed and built windows installed. Just how much the window degrades the overall TL depends on the original loss of the partition, the TL of the window alone, the relative areas of the two, and of course, the care with which the window is installed. To understand the factors going into the design of an effective observation window, a good place to start is to study the effectiveness of glass as a barrier.\textsuperscript{15}

**Transmission Loss of Single Glass Plates.** The measured transmission loss of \(\frac{1}{4}\) in, \(\frac{1}{2}\) inch, and \(\frac{3}{4}\) inch single-glass plates (or float) 52 inch \(\times\) 76 inch is shown in Fig. 4-35. As expected, the thicker the glass plate, the higher the general TL except for a coincidence dip in

---

**Figure 4-32.** Numerous types of weather stripping can be used for sealing doors to audio rooms. Courtesy Tab Books, Inc.

**Figure 4-33.** Sealing systems from Zero Mfg.
each graph. Although the heavy \( \frac{3}{4} \) inch plate attains a TL of 40 dB or more above 2 kHz. It is inappropriate for use in an STC-50 or STC-55 wall. Considering this general lack of sufficient TL and the complication of the coincidence dip, the single-glass approach is insufficient for most observation window needs. Laminated glass is more of a *limp mass* than glass plate of the same thickness and, hence, has certain acoustical advantages in observation windows. The characteristics of \( \frac{1}{4} \) inch, \( \frac{1}{2} \) inch, and \( \frac{3}{4} \) inch laminated single-glass plates are shown in Fig. 4-36.

**Transmission Loss of Spaced Glass Plates.** Fig. 4-37 shows the effect of three different spacings. In all cases the same \( \frac{3}{4} \) inch and \( \frac{1}{2} \) inch glass plates are used, but the air space is varied from 2 inches to 6 inches. The effect of spacing the glass plates is greatest below 1500 Hz. There is practically no increase in transmission loss by spacing the two glass plates above 1500 Hz. In general, the 2 inch increase from 2 inches to 4 inches is less effective than the same 2 inch spacing increase from 4 inches to 6 inches. Many observation windows in recording studios utilize spacings of 12 inches or more to maximize the spacing effect.

When two glass plates are separated only a small amount, such as glass widely used for heat insulation, the sound TL is essentially the same as the glass alone from which it is fabricated. There is practically no acoustical advantage using this type of glass in observation windows. This is one of the few cases where thermal insulation does not correspond to acoustic isolation. The single case of using laminated glass for one of
Chapter 4

Managing Cavity Resonance. The TL measurements in Fig. 4-37 were made with no absorbing material around the periphery of the space between the two glass plates. By lining this periphery with absorbent material, the natural cavity resonance of the space is reduced. An average 5 dB increase in TL can be achieved by installing a minimum of 1 inch absorbent on these reveals. The use of 4 inches of absorbing material, covered with, perhaps, perforated metal, further improves low-frequency transmission loss.

The practice of using glass plates of different thickness is substantiated by shallower coincidence dips in Fig. 4-37 as compared to Fig. 4-35. Resonance associated with the plates or the cavity tend toward the creation of acoustical holes, or the reduction of TL at the resonance frequencies. Hence, distributing these resonance frequencies by the staggering of plate thickness and use of laminated glass is important.

Homemade Acoustical Windows. The essential constructional features of two types of observation windows are shown in Fig. 4-38. Fig. 4-38A is typical of the high TL type commensurate with walls designed for high loss. The high TL of the window is achieved by using heavy laminated glass, maximum practical spacing of the glass plates, absorbent reveals between the glass plates, and other important details such as a generous application of acoustical sealant. It is very important to note that the windowsill and other elements of the frame do not bridge the gap between the two walls and thereby compromise the double wall construction. Bridging the double wall construction at the window is a very common error that must be avoided if the STC of the partition is to be maintained.

Fig. 4-38B shows a window for a single stud wall, a more modest TL. The same general demands are placed on this window as on the one in Fig. 4-38A, except that scaled down glass thickness and spacing are appropriate.

Inclining one of the plates, as shown in Fig. 4-38, has advantages and disadvantages. Slanting one pane reduces the average spacing, which slightly reduces the TL. However, slanting one window as shown especially in a studio (as distinct from a control room) will have the beneficial effect of preventing a discrete reflection right back at a performer standing in front of the window. The principal benefit of such plate inclination is really the control of light reflections that interfere with visual contact between the rooms.

Proprietary Acoustical Windows. Many of the same companies that build proprietary acoustical doors also build acoustical windows. IAC builds a line of windows ranging from STC-35 to STC-58. The STC-53 window from IAC is shown in Fig. 4-39 and Fig. 4-40. It should be noted that the same warning about bridging a double wall construction applies to proprietary windows as well as to home-made ones.

Figure 4-37. Spacing two dissimilar glass plates improves transmission loss. Glass of ½ and ⅛ inch thickness used in all cases.

the plates with 6 inch separation is included in Fig. 4-37. The superior performance of laminated glass comes with a higher cost.
4.3.11 Transmission Loss of a Compound Barrier

We are using the term compound to refer to those partitions that are not homogeneous—e.g. those partitions that include areas with differing TL ratings. For example, when an observation window having one TL is set in a wall having another TL, the overall TL is obviously something else, but what is it? It most certainly cannot be obtained by simple manipulation of TLs or STC values. The problem must be referred to as the basics of sound power transmission. Fig. 4-41 illustrates the case of a 4.4 ft × 6.4 ft window set in a 10 ft × 15 ft partition between control room and studio. The way the transmission loss of the window and the wall affect each other is given by the expression:

\[
TL = -10 \log \left( \frac{S_1}{10^{TL_1/10}} + \frac{S_2}{10^{TL_2/10}} \right)
\]

where,
- \(TL\) is the overall transmission loss,
- \(S_1\) is the fractional wall surface,
- \(TL_1\) is the wall transmission loss in decibels,
- \(S_2\) is the fractional window surface,
- \(TL_2\) is the window transmission loss in decibels.

As an example let us say that for a given frequency the wall \(TL_1 = 50\) dB and the window \(TL_2 = 40\) dB. From Fig. 4-40 we see that \(S_1 = 0.812\) and \(S_2 = 0.188\). The overall TL is

\[
TL = -10 \log \left( \frac{0.812}{10^{50/10}} + \frac{0.188}{10^{40/10}} \right) = 45.7 dB
\]

The 40 dB window has reduced the 50 dB wall to a 45.7 dB overall effectiveness as a barrier. This is for a given frequency. Fig. 4-42 solves Eq. 4-4 in a graphical form using the following steps:

1. Figure the ratio of glass area to total wall area, and find the number on the X axis.
2. Subtract window TL from wall TL, and find the intersection of this value with the area ratio on the X axis.
3. From the intersection, find the reduction of the wall TL from the left scale.
4. Subtract this figure from the original wall TL.

Using the graph of Fig. 4-42, find the effect of the window on the compound wall. The ratio of the window area to the wall area is 0.23. Locate 0.23 along the bottom axis. The difference in TL between the two is 10 dB. Find the intersection between the 10 dB line and the ratio of the areas. A reduction of slightly less than 5 dB is read off the left scale. Subtracting 5 dB from the
Figure 4-39. Noise-Lock™ window by IAC is rated at STC 53. Courtesy IAC.

Figure 4-40. Head and sill requirements for IAC Noise-Lock™ windows. Courtesy IAC.
50 dB wall TL gives the overall TL with a window of 45 dB. (Calculated from Eq. 4-4 gives 45.7 dB.)

It is usually easier and more economical to get high TL in wall construction than in window construction. The possibility arises of compensating for a deficient window by overdesigning the wall. For example, recognizing that an STC-70 masonry wall is possible, how far will it lift an STC-45 window? Using Eq. 4-4 again, we find the overall STC to be 52.2 dB, an increase of over 7 dB over the STC-45 window. Actually, using Eq. 4-4 with STC values is a gross oversimplification embracing all the inaccuracies of fitting measured TL values with a single-number STC rating. Making the calculations from measured values of TL at each frequency point is much preferred. Of course, all this assumes an airtight seal has been achieved.

Everything that bridges the isolation system is a potential short circuit for noise. Such bridges include, HVAC ducts, electrical conduit, sprinkler systems, plumbing, raceways, and the like.

Now we have the formula for empirically looking at the effect of a crack in the wall (Fig. 4-17 was plotted using Eq. 4-4). Let us assume that an observation window and wall combination have a calculated composite TL of 50 dB. The window, installed with less than ideal craftsmanship, developed a ¼ inch (0.125 in) crack around the window frame as the mortar dried and pulled from the frame. Since this is the window of Fig. 4-41, the length of the crack is 21.6 ft, giving a crack area of 0.225 ft². What effect will this crack have on the otherwise 50 dB wall? Substituting into Eq. 4-4, we find the new TL of the wall with the crack to be 28 dB. This is similar to leaving off an entire pane of glass or a layer of gypsum board. If the crack were only ⅛ inch wide, the TL of the wall would be reduced from 50 dB to 31.2 dB. A crack only 0.001 inch wide would reduce the TL of 50 dB to 40.3 dB. Let the builder beware!

### 4.3.12 Isolation Systems Summary

Noise migrates from one area to another in two ways. It travels through the air and it travels through the structure. To reduce or eliminate airborne noise, one must eliminate all air paths between the spaces. To reduce structure-borne noise one must create isolation systems that eliminate mechanical connections between spaces. It is a rather simple matter to make these statements. Implementing the solutions is obviously much more difficult. The following points should be kept in mind:

- Make seams airtight.
- Analyze all possible flanking paths that noise will take and realize that all must be controlled if significant isolation is desired.
- A room built entirely on a floating slab with the ceiling supported entirely by the walls will always be superior to any other method.

### 4.4 Heating, Ventilating, and Air Conditioning (HVAC) Systems for Low Noise

So far in this chapter we have considered systems that keep unwanted sound out. When we consider HVAC systems we are dealing with systems that (a) breach the acoustical shell designed to keep noise out, (b) introduce considerable noise of their own, and (c) provide a pathway for sound (noise) to easily migrate from one space to another. HVAC systems can sometimes undermine all the efforts of isolation. Often the cheapest solution to providing HVAC to sound sensitive spaces is to
use window units that get shut off when quiet is needed! If this solution is not acceptable, and central distributed systems must be used, the designer must understand that success will require significant expense and engineering. The design of HVAC systems is best left to professional mechanical engineers. No better preparation for this responsibility can be obtained than from carefully studying the American Society of Heating, Refrigeration, and Air-Conditioning Engineers (ASHRAE) publications.\textsuperscript{16,17,18}

It is important to understand that HVAC systems found in most residences or even in light commercial or office spaces are totally inadequate for use in noise critical spaces. Unlike residential systems that often use high efficiency systems that deliver low volumes of cold air at high velocities, low noise systems require high volume, low velocity delivery. Many commercial systems utilize supply ducts and the return relies on leakage under doors or common ceiling plenums. In order to achieve low noise, both the supply and return must be individually ducted to each room.

### 4.4.1 Location of HVAC Equipment

From the standpoint of sound room noise, the best location for the HVAC equipment is in the next county. Short of this, a spot should be selected that isolates the inevitable vibration of such equipment from the sound-sensitive area. A good situation is to have the equipment mounted on a concrete pad completely isolated from the structure. In this way, the noise problem is reduced to handling the noise coming through the ducts, a much simpler task than fighting structure-borne vibration.

### 4.4.2 Identification of HVAC Noise Producers

The various types and paths of HVAC noise producers are identified in Fig. 4-43. This figure provides an interesting study in flanking paths. It is important to remember that there will be relatively little noise reduction unless all of the paths are controlled. A represents the sound room. B represents the room containing the HVAC system. Looking at the noise sources as numbered, 1 and 2 represent the noise produced by the diffusors themselves. The noise is produced by the air turbulence that is created as the air moves through the diffusor. Many diffusors have a noise rating at a given air flow, and the only element of control in this case is selecting the design with the best rating. Don’t forget that this applies to the return grille as well as the supply diffusor. Arrows 3 and 4 represent essentially fan noise, which travels to the room via both supply and return ducts and is quite capable of traveling upstream or downstream. The delivery of fan noise over these two paths can be reduced by silencers and/or duct linings. Sizing the ductwork properly is also a means of combating fan noise since sound power output of a fan is fixed largely by air volume and pressure. Arrow 5 represents a good example of a flanking path that is often missed. Depending on how the ceiling in both of the rooms is constructed, the sound from the HVAC unit can travel up through the ceiling in the HVAC room and comes down into room A. Of course the way to control path 5 is to make sure that the ceilings in both rooms are well built, massive enough to control low frequency vibrations, and of course, airtight. Arrow 6 represents that path where the sound can travel through gaps or holes inadvertently left in the partition. This has already been discussed in Section 4.3.11 and in Fig. 4-17. Number 7 represents the sound that can travel straight through a poorly built wall. Numbers 8, 9, and 10 represents the paths that the structure-borne vibrations can take through the structure. We will deal with isolation issues in the next section. Finally, 11 and 12 represent what is called break-in noise. This is what happens when sound enters or breaks into a duct and travels down it, radiating into the room.

### 4.4.3 Vibration Isolation

The general rule is first to do all that can reasonably be done at the source of vibration. The simple act of mounting an HVAC equipment unit on four vibration mounts may help reduce transmitted vibration, may be of no effect at all, or may actually amplify the vibrations, depending on the suitability of the mounts for the job. Of course, if it is successful it would drastically reduce or eliminate paths 8, 9, and 10 in Fig. 4-43. The isolation efficiency is purely a function of the relationship between the frequency of the disturbing source $f_d$ to isolator natural frequency $f_n$, as shown by Fig. 4-44. If $f_d = f_n$, a resonance condition exists, and maximum vibration is transmitted. Isolation begins to occur when $f_d/f_n$ is equal to or greater than 2. Once in this isolation range, each time $f_d/f_n$ is doubled, the vibration transmission decreases 4–6 dB. It is beyond the scope of this treatment to go further than to identify the heart of both the problem and the solution, leaving the rest to experts in the field.
4.4.4  Attenuation of Noise in Ducts

Metal ducts with no linings attenuate fan noise to a certain extent. As the duct branches, part of the fan noise energy is guided into each branch. Duct wall vibration absorbs some of the energy, and any discontinuity (such as a bend) reflects some energy back toward the source. A very large discontinuity, such as the outlet of the duct flush with the wall, reflects substantial energy back toward the source. This results in attenuation of noise entering the room, as shown in Fig. 4-45. Unlike many other systems in acoustics this is one attenuation that is greater at low frequencies than at the highs.

Lining a duct increases attenuation primarily in the higher audio frequency range. Fig. 4-46 shows measured duct attenuation with 1 inch duct lining on all four sides. The dimensions shown are for the free area inside the duct. This wall effect attenuation is greatest
for the smaller ducts. For midband frequencies, a 10 ft length of ducting can account for 40 dB or 50 dB attenuation for ducts 12 inches × 24 inches or smaller. There is a trade-off, however, as decreasing the cross section of the duct increases the velocity of the air moving through it. Higher air velocities produce greater turbulence noise at the grille/diffuser. Great stress is commonly placed on attenuation contributed by right-angle bends that are lined with duct liner. Fig. 4-47 evaluates attenuation of sound in lined bends. Only lining on the sides is effective, which is the way the elbows of Fig. 4-47 are lined. Here again, attenuation is greater at higher audio frequencies. The indicated duct widths are clear measurements inside the lining. The lining thickness is 10% of the width of the duct and extends two duct widths ahead and two duct widths after the bend. It is apparent that the lining contributes much to attenuation of noise coming down the duct, but less so at lower frequencies. Here too, there is a trade-off. Every bend, lined or not, increases the turbulence and therefore the noise.

in Fig. 4-48A. The comparable characteristic of a reactive muffler is also shown in Fig. 4-48B.

![Figure 4-46](image1.jpg)

**Figure 4-46.** Measured noise attenuation in rectangular ducts. (After ASHRAE, Reference 18, which attributes Owens-Corning Fiberglas Corp. Lab Report 32433 and Kodaras Acoustical Laboratories Report KAL-1422-1 submitted to Thermal Insulation Manufacturer’s Association.)

**4.4.5 Tuned Stub Noise Attenuators**

Fan blades can produce line spectra or tonal noise at a blade frequency of

\[ \text{Blade frequency} = \frac{\text{RPM} \times \text{Number of blades}}{60 \text{ Hz}} \] (4-5)

Usually this noise is kept to a minimum when the HVAC engineer selects the right fan. If such tones continue to be a problem, an effective treatment is to install a tuned stub filter someplace along the duct. These can be very effective in reducing fan tones. A typical stub and its attenuation characteristic are shown

in Fig. 4-48A. The comparable characteristic of a reactive muffler is also shown in Fig. 4-48B.

![Figure 4-47](image2.jpg)

**Figure 4-47.** Noise attenuation in HVAC square-duct elbows without turning vanes. (After ASHRAE Reference 18.)

![Figure 4-48](image3.jpg)

**Figure 4-48.** The tuned stub and reactive muffler used to attenuate tonal components of noise.

**4.4.6 Plenum Noise Attenuators**

As previously stated, a most effective procedure in noise reduction is to reduce the noise at, or very close to, the source. If a system produces a noise level that is too high at the sound room end, one possibility is to install a plenum in the supply and another in the return line. Such a plenum is simply a large cavity lined with absorbing material, as shown in Fig. 4-49. Sometimes a nearby room or attic space can be made into a noise-attenuating plenum, usually at the source. The attenuation realized from a plenum can be estimated from the following expression: 19
where,

- $a$ is the absorption coefficient of the lining,
- $S_e$ is the plenum exit area in square feet,
- $S_w$ is the plenum wall area in square feet,
- $d$ is the distance between the entrance and exit in feet,
- $\theta$ is the angle of incidence at the exit (i.e., the angle that the direction $d$ makes with the axis of exit) in degrees.

For those high frequencies where the wavelength is smaller than plenum dimensions, accuracy is within 3 dB. At lower frequencies Eq. 4-5 is conservative, and the actual attenuation can be 5 dB to 10 dB higher than the value it gives.

For those high frequencies where the wavelength is smaller than plenum dimensions, accuracy is within 3 dB. At lower frequencies Eq. 4-5 is conservative, and the actual attenuation can be 5 dB to 10 dB higher than the value it gives.

**4.4.7 Proprietary Silencers**

When space is at a premium and short runs of duct are necessary, proprietary sound-absorbing units can be installed in the ducts at critical points. There are a number of configurations available, and many attenuation characteristics can be expected. The extra cost of such units may be offset by economies their use would bring in other ways. The user should also be aware that silencers produce a small amount of self-noise and care must be taken to allow the air to return to a laminar flow downstream of the silencer.

The general rule is that the air will require a length equal to 10 times the diameter of the duct to regain a laminar flow.

**4.4.8 HVAC Systems Conclusion**

The intent of this HVAC section is to emphasize the importance of adequate attention to the design and installation of the heating, ventilating, and air-conditioning system in the construction of studios, control rooms, and listening rooms. HVAC noises commonly dominate in such sound rooms and are often the focus of great disappointment as a beautiful new room is placed into service. The problem is often associated with the lack of appreciation by the architect and the HVAC contractor of the special demands of sound rooms. It is imperative that an NC clause be written into every mechanical (HVAC) contract for sound-sensitive rooms.

Residential HVAC systems commonly employ small ducts and high velocity air delivery systems. Air turbulence noise increases as the sixth power of the velocity; hence, high velocity HVAC systems can easily be the source of excessive turbulence noise at grilles and diffusers. Keeping air velocity below 400 ft/min for studios and other professional sound rooms is a basic first requirement. Air flow noise is generated at tees, elbows, and dampers; and it takes from 5 to 10 duct diameters for such turbulence to be smoothed out. This suggests that duct fittings should be spaced adequately. Air flow noise inside a duct causes duct walls to vibrate, tending to radiate into the space outside. Thermal duct wrapping (lagging) helps to dampen such vibrations, but even covered, such ducts should not be exposed in sound-sensitive rooms. This oversimplified treatment of HVAC design is meant to underscore the importance of employing expert design and installation talent, not to create instant experts. The overall HVAC project, however, needs the involvement of the audio engineer at each step.17,18

5.1 Acoustical Treatment Overview

It is possible that there is no area in professional audio where there is more confusion, folklore, and just plain misinformation than in the area of acoustical treatment. Everyone, it seems, is an acoustical expert. Of course, like most disciplines, much of acoustics is logical and intuitive if one understands the fundamentals. As Don Davis wrote, “In audio and acoustics the fundamentals are not difficult; the physics are.” The most fundamental of all rules in acoustics is that nothing is large or small. Everything is large or small relative to the wavelength of the sound under consideration. This is one of the realities that makes the greater field of audio so fascinating. Human ears respond to a range of wavelengths covering approximately 10 octaves, as compared to eyes, which respond to a range of frequencies spanning about one octave. Even though the bandwidth of visible light is obviously much larger than that of audible sound because of the much higher frequencies involved, the range of the wavelengths in this 10 octave bandwidth poses some unique challenges to the acoustician. We must be able to deal with sounds whose wavelengths are 17 m (56 ft) and sounds whose wavelengths are 1.7 cm (0.6 in).

Getting rooms to sound good is an art as much as it is a science. In some situations, concert halls, for example, there is a reasonable agreement as to what makes for a good hall. In other applications, such as home theaters, recording studios, or houses of worship, there is little agreement among the users, let alone the consultants, as to how these rooms should sound. Considerable research must be done before we are able to trace all of the subjective aspects of room acoustics back to physical parameters. However, some fundamental rules and principles can be noted. The acoustician has very few tools. In fact, there are only two things one can do to sound. It can either be absorbed or redirected. Every room treatment, from a humble personal listening room to the most elaborate concert hall, is made up of materials that either absorb or redirect sound. Room acoustics boils down to the management of reflections. In some situations, reflections are problems that must be removed. In other situations, reflections are purposely created to enhance the experience.

This chapter will address general issues of modifying the way rooms sound. Absorption and absorbers will be covered in detail, as well as diffusion and diffusers, and other forms of sound redirection. Additionally, some discussion on the controversial topic of electroacoustical treatments, and brief sections that touch on life safety and the environment as they pertain to acoustical treatments are provided. The information will be thorough, but not exhaustive. There are, after all, entire books dedicated to the subject of acoustical treatments. The intention here is to be able to provide a solid understanding of the fundamentals involved. Specific applications will be dealt with in subsequent chapters.

5.2 Acoustical Absorption

Absorption is the act of turning acoustical energy into some other form of energy, usually heat. The unit of acoustical absorption is the sabin, named after W.C. Sabine (1868–1919), the man considered the father of modern architectural acoustics. It is beyond the scope of this treatment to tell the story of Sabine’s early work on room acoustics, but it should be required reading for any serious student of acoustics. Theoretically, 1.0 sabin equates to one square meter (m²) of complete absorption. Sabine’s original work involved determining the sound absorbing power of a material. He posited that comparing the performance of a certain area of material to the same area of open window would yield its absorbing power relative to the ideal. For example, if 1.0 m² of a material yielded the same absorbing power as 0.4 m² of open window, the relative absorbing power—what we now call the absorption coefficient—would be equal to 0.4.

How absorption is used depends on the application and the desired outcome. Most of the time, absorption is used to make rooms feel less live or reverberant. Absorber performance varies with frequency, with most working well only over a relatively narrow range of frequencies. In addition, absorber performance is not necessarily linear over the effective frequency range.

Measuring or classifying absorbers is not as straightforward as it may seem. There are two main laboratory methods: the impedance tube method and the reverberation chamber method, both of which will be discussed in detail below. Field measurement of absorption will also be discussed below. Absorber performance can also be determined theoretically; discussions of those methods are beyond the scope of this chapter. (The reader is referred to the Bibliography at the end of this chapter for advanced absorber theory texts.)

There are three broad classifications of absorbers: porous, discrete, and resonant. While it is not uncommon for people to design and build their own absorbers (indeed, there has been something of a resurgence in do-it-yourself absorber construction in recent years as a result of the proliferation of how-to guides and Internet discussion forums—this information may or may not be reliable, depending on the reliability of the online resource and the relative expertise of the “experts”
offering guidance), many excellent porous and resonant absorbers are available commercially. Fundamental information about the design of absorbers is included here for two reasons: there may be those who want to build their own absorbers, and more importantly, these absorbers are sometimes inadvertently constructed in the process of building rooms. This is especially true of resonant absorbers.

5.2.1 Absorption Testing

Standardized testing of absorption began with Sabine and continues to be developed and improved upon in the present day. As mentioned above, the two standardized methods for measuring absorption are the reverberation chamber method and the impedance tube method. One can also measure absorption in the field by using either the standardized methods or the other techniques discussed below.

5.2.1.1 Reverberation Chamber Method

The work of Sabine during the late 19th and early 20th centuries is echoed in the present-day standard methods for measuring absorption in a reverberation chamber: ASTM C423 and ISO 354. In both methods, the general technique involves placing a sample of the material to be tested in a reverberation chamber. This is a chamber that has no absorption whatsoever. The rate of sound decay of the room is measured with the sample in place and compared to the rate of sound decay of the empty room. The absorption of the sample is then calculated.

The method of mounting the sample in the test chamber has an effect on the resulting absorption. Thus, standardized methods for mounting are provided. The most common mounting methods employed are Types A, B, and E. Type A simply involves placing the test sample—usually a board-type wall or ceiling absorber—flat against the predefined test area in the chamber (typically on the floor). Type B mounting is

![Figure 5-1. Comparison of absorption reflection and diffusion.](image)
typically encountered with acoustical materials that are spray or trowel applied. The material is first applied to a solid backing board and then tested by placing the treated boards over the predefined test area in the chamber. Type E mounting is the standard method employed for absorbers such as acoustical ceiling tiles. This mounting includes a sealed air space of a defined depth behind the absorbers to mimic the real-world installation of acoustical ceiling tiles with an air plenum above. The depth is defined in millimeters and is denoted as a suffix. For example, a test of acoustical ceiling tiles in an E400 mounting means that the tiles were tested over sealed air space that was 400 mm (16 in) deep.

It should be noted that Type A mounting for board-type wall and ceiling absorbers is so often used as the default method that any mention of mounting method is often carelessly omitted in manufacturer literature. Regardless, it is important to verify the mounting method used when evaluating acoustical performance data. If there is any uncertainty, a complete, independent laboratory test report should be requested and evaluated. Details of the mounting method must be included in the lab report to fulfill the requirements of the test standards.

ASTM C423 is generally used in certified North American laboratories; ISO 354 is generally the adopted standard in European countries. The methods are very similar, but there are some noteworthy differences that can yield different testing results. A main difference that is a frequent subject of criticism is the different minimum sample sizes. The minimum area of material when testing board-type materials in accordance with ASTM C423 is 5.6 m² (60 ft²)[5] (the recommended test area is 6.7 m² [72 ft²]) and that of ISO 354 is 10 m² (107.6 ft²)[6]. In general, this difference in sample size can result in a material having slightly lower absorption coefficients when tested in accordance with ISO 354 relative to the same material tested in accordance with ASTM C423. The ISO method is generally regarded as a more realistic approach when the test results are being applied to spaces that are larger than the test chamber, as is often the case. Nonetheless, ASTM test results have been widely and successfully used in architectural acoustic room design applications for many decades.

The reverberation chamber methods can also be applied to discrete absorbers, such as auditorium seating, highway barriers, office partitions, and even people. The main difference between testing the discrete absorbers and testing panel-type absorbers is how the results are reported. If a material occupies a commensurable area of a test chamber surface, absorption coefficients can be calculated. By contrast, the results of a test of some number of discrete absorbers are generally reported in sabins/unit. (Sometimes referred to as Type J mounting in the literature, provided the test met the standard requirements for that mounting). For example, the absorption of acoustical baffles—the type that might be hung from a factory or gymnasium ceiling—is typically reported in sabins/baffle.

When calculating absorption coefficients for board-type absorbers, the number of sabins in each frequency band is divided by the surface area of the test chamber covered by the sample material. The resulting quantity is the Sabine absorption coefficient, abbreviated \( \alpha_{\text{SAB}} \). The vast majority of absorption coefficients reported in the literature is Sabine absorption coefficients. Since the material is tested in a reverberant space, the Sabine absorption coefficients are useful for predetermining the acoustical properties of a space, provided that the product is intended for use in a similarly reverberant space (i.e., a space where sound can be considered to be impinging equally on a surface from all angles of incidence).

The frequency range of reverberation chamber measurements is limited. At low frequencies, modal effects can dominate the test chamber, thus making accurate measurements of sound decay difficult. At high frequencies, the chambers are large enough that the absorption of air will start to affect the measurement results. Therefore, the frequency range for a reverberation chamber test is typically limited to the \( \frac{1}{2} \) octave bands between 100 and 5000 Hz. This is sufficient for most materials and applications as it spans a full six octaves over what is commonly referred to as the speech range of frequencies—i.e., the range of frequencies that are important to address design issues related to speech communication.

When acoustical treatments are specifically designed to absorb low frequencies, the reverberation chamber method can fall short. However, D’Antonio has implemented a special application of the ASTM C423 method that utilizes fixed microphone positions (vs, the more typical rotating microphone) that measure the decay of the actual modal frequencies of the room. Using this method, D’Antonio has been able to measure low frequency absorption down to the 63 Hz octave band.[8,9] The impedance tube method (discussed below) can also be used to measure low frequency absorption, but a large tube with heavy walls (such as poured concrete) is required.
5.2.1.2 Impedance Tube Testing Methods

The laboratory methods generally involve the use of an impedance tube to measure absorption of normally incident sound—i.e., sound arriving perpendicular to the sample. There are two standard methods to measure absorption in an impedance tube: the single-microphone, standing wave method; and a two-microphone, transfer function method. In general, impedance tube measurements are relatively inexpensive, relatively simple to perform, and can be very useful in research and development of absorber performance. In the standing wave method, for example, the normal absorption coefficient ($\alpha_n$) can be calculated from

$$\alpha_n = \frac{I_i - I_r}{I_i}$$  \hspace{1cm} (5-1)

where,

$I_i$ is the incident sound intensity,

$I_r$ is the reflected sound intensity.

While the cost and time saving benefits of the impedance tube method are obvious, care should be taken since the normal absorption coefficients are not equivalent to the Sabine absorption coefficients discussed in the previous section. In fact, unlike $\alpha_{SAB}$, $\alpha_n$ can never be greater than 1.0. In one set of experiments, $\alpha_{SAB}$ was as little as 1.2 times and as much as almost 5.0 times greater than $\alpha_n$. Regardless, there is no established empirical relationship between $\alpha_{SAB}$ and $\alpha_n$. Normal absorption coefficients should not be used to calculate the properties of a space using standard reverberation time equations.

One main advantage offered by normal absorption coefficients is that they offer an easy way to compare the performance of two absorbers. Reverberation chambers have inherent reproducibility issues (explained in more detail below). The impedance tube can overcome this to some extent. One limitation of the impedance tube is frequency range; large tubes are needed to test low frequencies. Another is that tests of resonant absorbers tend not to produce accurate results, because of the small sample size.

5.2.1.3 Other Absorption Testing Methods

Many methods can be employed for the measurement of sound absorption outside the confines of a laboratory test chamber or impedance tube. Of course, both the reverberation chamber method and the impedance tube methods can be adopted for use in the field. In fact, Appendix X2 of ASTM C423 provides guidelines for carrying out the reverberation method in the field.

When the sound impinging on an absorber is not totally random—as is the case, more often than not—there may be better methods for describing its performance. One of these methods, described by Brad Nelson, involves the analysis of a single reflection by means of signal processing techniques. Although Nelson’s method describes the measurement of absorption at normal incidence, his method can be extended to determine the in situ absorption coefficients of a material at various angles of incidence, which can be particularly useful for the analysis of absorbers that are being used for reflective control in small rooms. Nelson’s method was employed by the author to determine the in situ angular absorption coefficients ($\alpha_\theta$) of two different porous absorbers, the results of which are shown graphically in Fig. 5-2 for reflections in the 2000 Hz band. The results at least partly confirm what has often been observed in recording studios: sculpted acoustical foam tends to be more consistent in its control of reflections at oblique angles of incidence relative to flat, fabric-covered, glass fiber panels of higher density. Or, to put it another way, the glass fiber panel offers more off-axis reflections than the acoustical foam panel. Of course, the relative merits of one acoustical treatment over the other are subjective. The important point is that the differences are quantifiable.

![Figure 5-2. Angular absorption coefficients ($\alpha_\theta$) of two absorbers for the 2000 Hz 1/3-octave band.](image-url)
5.2.1.4 Absorption Ratings

There are three single number ratings associated with absorption, all of which are calculated using the Sabine absorption coefficients. The first and most common is the Noise Reduction Coefficient (NRC). The NRC is the arithmetic average of the 250, 500, 1000, and 2000 Hz octave-band Sabine absorption coefficients, rounded to the nearest 0.05.5 The NRC was originally intended to be a single number rating that gave some indication of the performance of a material in the frequency bands most critical to speech.

To partly address some of the limitations of the NRC, the Sound Absorption Average (SAA) was developed.5 Similar to NRC, the SAA is an arithmetic average, but instead of being limited to four octave bands, the Sabine absorption coefficients of the twelve 1/3 octave bands from 200 through 2500 Hz are averaged and rounded to the nearest 0.01. Table 5-1 provides an example calculation of both NRC and SAA for a set of absorption coefficients.

Finally, ISO 11654 provides a single number rating for materials tested in accordance with ISO 354 called the weighted sound absorption coefficient ($\alpha_w$).12 A curve matching process is involved to derive the $\alpha_w$ of a material. Additionally, shape indicators can be included in parentheses following the $\alpha_w$ value to indicate areas where absorption has significantly exceeded the reference curve. Table 5-1 shows the $\alpha_w$ for the set of absorption coefficients, with the LM indicating that there may be excess low and mid-frequency absorption offered that is not otherwise apparent from the $\alpha_w$ value. This is useful in that it indicates the actual octave-band or 1/3 octave band absorption coefficients are probably worth looking into in greater detail.

None of the metrics described above gives an accurate representation of the absorptive behavior (or lack thereof) of a material. NRC averages four bands in the speech frequency range. The problem, of course, is that many different combinations of four numbers can result in the same average, as shown in Table 5-2. The same can be said for SAA. Nonetheless, NRC and SAA can be compared to give a little bit more information than each rating gives on an individual basis. If NRC and SAA are very close, the material probably does not have any extreme deviations in absorption across the speech range of frequencies. If SAA is drastically different from NRC, it may be indicative of some large variations at certain 1/3 octave bands. These are, of course, only single number ratings; none of them takes into account the performance of the material below the 200 Hz 1/3 octave band. They can, at most, provide a cursory indication of the relative performance of a material. A full evaluation of the performance of a material should always involve looking at the octave or 1/3 octave band data in as much detail as possible.

5.2.1.5 Interpreting Test Results

As mentioned at the beginning of this chapter, the acoustical treatment industry is rife with misinformation. Test results, sadly, are no exception. Information in manufacturer literature or on their Web sites is fine for evaluating materials on a cursory basis. This information should eventually be verified, preferably with an independent laboratory test report. If manufacturers cannot supply test reports, any absorption data reported in their literature or on their Web sites should be treated as suspect.

When absorption data is evaluated, the source of the data should be understood, both in terms of which standard method was used and which independent test laboratory was used. Again, the test reports can help clear up any confusion. Close attention should be paid to subtle variations in test results, such as a manufacturer who tested the standard-minimum area of material in lieu of the standard-recommended area of material for an ASTM C423 test. If two materials are otherwise similar, a variation in sample size could explain some of the variation in measured absorption.

Additionally, there are reproducibility issues with the reverberation chamber method. Saha has reported that the absorption coefficients measured in different laboratories vary widely, even when all other factors—e.g., personnel, material sample, test equipment, etc.—are kept constant. Cox and D’Antonio have found absorption coefficient variations between laboratories to be as high as 0.40.

Finally, it is worth noting that Sabine absorption coefficients will often exceed 1.0. This is a source of great confusion since theory states that absorption can only vary between 0.00 (complete reflection) and 1.00 (complete absorption). However, the 0 to 1 rule only applies to, for example, normal absorption coefficients, which are calculated using the measurement of direct versus reflected sound intensity. Sabine absorption coefficients, remember, are calculated using differences in decay rate and by dividing the measured absorption by the sample area. In theory, this should still keep the Sabine absorption coefficients below 1.0. However, edge and diffraction effects are present and are frequently cited (along with some nominal hand-waving) to explain away values greater than 1.0. Edge and diffraction effects are true and valid explanations, but can be confusing in their own right. For example, samples are often tested with the edges exposed—i.e., not exposed to sound. Absorption coefficients greater than 1.0 resulting from such a test can therefore be attributed mainly to diffraction effects, which is the process where sound that would not normally be incident on a sample is bent towards the sample and absorbed. The confusion arises when these test results are utilized in applications where the edges of the sample will be exposed to sound.

A better explanation might be simply that Sabine absorption coefficients are not percentages. The variables in the calculation of the Sabine absorption coefficient are rate of decay and test sample area. A change in the former divided by the latter is basically what is being determined, which does not strictly conform to the definition of a percentage. Based on this explanation, an $\alpha_{SAB}$ value greater than 1.0 simply indicates a higher absorption than a value lower than 1.0, all other factors being equal. For example, a material with a Sabine absorption coefficient of 1.05 at 500 Hz will absorb more sound at 500 Hz than the same area of a material having a Sabine absorption coefficient of 0.90, provided that both materials were tested in the same manner.

Regardless of the validity of Sabine absorption coefficients greater than 1.0, they are usually rounded down to 0.99 for the purposes of predictive calculations. This rounding down is especially important if, for example, equations other than the Sabine equation are used to determine reverberation time. Of course, there has been ample debate about this rounding. For example, technically it is not rounding but scaling that is being done. As Saha has pointed out, why only scale the numbers greater than 1.0—what’s to be done, if anything, with the other values?

5.2.2 Porous Absorbers

Porous absorbers are the most familiar and commonly available kind. They include natural fibers (e.g., cotton and wood), mineral fibers (e.g., glass fiber and mineral wool), foams, fabrics, carpets, soft plasters, acoustical tile, and so on. The sound wave causes the air particles to vibrate down in the depths of porous materials, and frictional losses convert some of the sound energy to heat energy. The amount of loss is a function of the density or how tightly packed the fibers are. If the fibers are loosely packed, there is little frictional loss. If the fibers are compressed into a dense board, there is little penetration and more reflection from the surface, resulting in less absorption.

Mainly because there is a veritable plethora of extant information with which to work, the Owens Corning 700 Series of semi-rigid glass fiber boards will be discussed in the next section to not only highlight one of the more popular choices for porous absorber, but also to illustrate various trends—such as absorption dependence on thickness and density—that are not uncommon with porous absorbers in general.
5.2.2.1 Mineral and Natural Fibers

Of the varieties of mineral fiber, one of the most popular is the glass fiber panel or board, Fig. 5-3. The absorption of sound for various densities of Owens Corning 700 Series boards is shown in Figs. 5-4 and 5-5. Fig. 5-4 shows the absorption for 2.5 cm (1 in) thick boards. None of the three densities absorbs well at frequencies below 500 Hz. At the higher audio frequencies, the boards of 48 kg/m³ and 96 kg/m³ (3.0 lb/ft³ and 6.0 lb/ft³, respectively) densities are slightly better than the lower density 24 kg/m³ (1.5 lb/ft³) material. Fig. 5-5 shows a comparison between different densities of the 10.2 cm (4.0 in) thick fiberglass boards. In this case, there is little difference in absorption between the three densities.15

Boards of medium density have a mechanical advantage in that they can be cut with a knife and press-fitted into place. This is more difficult with materials that have a 24 kg/m³ (1.5 lb/ft³) density and lower, such as building insulation. The denser the board, the greater the cost. Most acoustical purposes are well served by glass fiber of 48 kg/m³ (3.0 lb/ft³) density, although some consultants specify a 96 kg/m³ (6.0 lb/ft³) material. A number of consultants regularly specify absorbers that are composed of multiple densities, for example, a combination of Owens Corning 701, 703, and 705. In theory, a multidensity absorber (assuming the least dense material is exposed to the sound source with gradually increasing densities toward the wall) will be as good as or better than a single-density absorber of the same thickness.16 In practice, this tends to hold true.

Fig. 5-6 explores the effect of thickness of 703 Fiberglas on absorption. The absorption of low-frequency sound energy is much greater with the thicker materials.15

---

**Figure 5-3.** Glass fiber absorbers.

A. Raw material.

B. Fabric finished panels.

**Figure 5-4.** The effect of density on the absorption of Owens Corning 700 series glass fiber boards of 2.5 cm (1 in) thickness, Type A mounting.15

**Figure 5-5.** The effect of density on the absorption of Owens Corning 700 series glass fiber boards of 10.2 cm (4 in) thickness.15
Fig. 5-7 shows the effect of air space behind a 2.5 cm (1 in) thick Owens Corning Linear Glass Board. As the air space is increased in steps from 0 to 12.7 cm (0 to 5 in), the lower-frequency absorption increases progressively. It is sometimes cost-effective to use thinner glass fiber and arrange for air space behind it; it is sometimes cost-effective to use glass fiber of greater thickness. At other times, the need for low-frequency absorption is so great that both thick material and air space are required.

In acoustical applications, mineral wool (or rock wool) is another popular variation of mineral fiber board, Fig. 5-8. Figs. 5-9 and 5-10 provide an overview of absorption coefficients for materials available from Roxul. The main difference between glass fiber and mineral wool is that mineral wool is generally made from basalt (glass fiber comes from silicates), which leads to a higher heat tolerance.

Natural fiber materials used in acoustical applications include wood fibers and cotton fibers. Tectum, Inc. manufactures a variety of ceiling and wall panels from aspen wood fibers, which produces a durable acoustical treatment. Absorption coefficients for some Tectum, Inc. materials are shown in Fig. 5-11. There are also an
increasing number of suppliers of natural cotton absorption panels. The absorption of natural cotton panels—so far as they have been developed—appears to be comparable to mineral fiber panels of similar density. Most fibrous absorbers will be covered with some sort of acoustically transparent fabric finish that is both decorative and practical. The fabric finish is decorative because the natural yellow or green of the glass fiber and mineral wool panels tends to be less than aesthetically pleasing; the finish is practical because airborne fibers from mineral fiber materials can be breathing irritants. Perforated metal (with or without powder-coated finish) and plastic coverings with a high percent of open area (much higher than resonant perforated absorbers discussed below) can also be used with fibrous absorbers. Perforated coverings are typically employed for decorative purposes, maintenance purposes, or to protect the panels from high impacts, such as might occur in a gymnasium. Foil and paper finishes are also sometimes available as low-cost means of containing fibers for glass fiber or mineral wool panels. Because of reflections from the foil or paper, the high-frequency absorption of the faced side of the absorber is significantly lower than that of the unfaced side. (The thin foil or paper used is sometimes referred to as a membrane. This has led to confusion with resonant membrane, or diaphragmatic absorbers. For clarity, foil or paper facings as they are applied to fibrous absorber panels are not resonant membranes in the strict sense, but do provide some nominal increases in low-frequency absorption when the foil or paper is exposed to the incident sound.)

To provide some impact resistance, as well as to provide a surface conducive for some office applications (such as for office partitions), a thin (usually 3 mm) glass fiber board of high density (usually 160 to 290 kg/m³ [10 to 18 lb/ft³]) can be applied over the face of a fibrous absorber before the fabric finish is applied. This is often referred to as a tackable surface finish since it can readily accept push pins and thumbtacks.

In terms of installation ease, natural fibers hold some promise since they will offer relief from the itch associated with the handling of mineral fiber boards. Natural fiber products can also be installed without covering, and Tectum, Inc. states that their wood fiber panels can be repainted several times without significant degradation of acoustical performance.

5.2.2.2 Acoustical Foams

There are various types of reticulated open cell foams for acoustical applications, Fig. 5-12. Closed cell foams also find applications in acoustics, but largely as substrates from which acoustical diffusers can be formed. The most common foams used as open cell acoustical absorbers in architectural applications are polyurethane (esters and ethers) and melamine foams. Unlike fibrous boards, foam panels are easy to cut and can be sculpted into shapes and patterns. Besides the ubiquitous wedges and pyramids, acoustical foams have been created with various square, saw tooth, and even curved patterns sculpted into the faces. While removing material generally serves to decrease absorption, creating more exposed
surface area tends to increase it. Figs. 5-13 and 5-14 provide absorption coefficients for different patterns of foam and different thicknesses of foam of the same pattern, respectively, for acoustical foam panels available from Auralex Acoustics, Inc.\textsuperscript{19}

**Figure 5-12.** Open cell polyurethane acoustical foam.

**Figure 5-13.** The effect of shape on the absorption of Auralex Acoustics polyurethane foam panels of 5.1 cm (2 in) thickness, Type A mounting.\textsuperscript{19}

In general, acoustical foams are of lower density than fibrous materials; acoustical foam densities are generally in the 8.0 to 40 kg/m\(^3\) (0.5 to 2.5 lb/ft\(^3\)) range. This means that mineral fiber panels tend to provide higher absorption coefficients than foam panels of the same thickness. However, acoustical foams can generally be installed without any decorative covering, which can make them more cost-effective—mineral fiber panels tend to require a fabric finish, or some other cover to contain airborne fibers. Melamine foams, such as the acoustical products offered by Pinta Acoustic, Inc. (formerly Illbruck) are white in color and have a higher resistance to fire relative to polyurethane foams. However, melamine foams generally have lower absorption coefficients (largely due to lower densities) and tend to be less flexible, making them more prone to damage than polyurethane foams. A sampling of the acoustical performance of some melamine foam products available from Pinta Acoustic, Inc. is provided in Fig. 5-15.\textsuperscript{20}

Melamine foams may be painted (the manufacturer should always be consulted about this), while polyurethane foams should generally not be painted. Because of this, companies offering polyurethane foams generally have a wider variety of colors available.

**Figure 5-14.** The effect of thickness on the absorption of Auralex Acoustics Studiofoam Wedges, Type A mounting.\textsuperscript{19}

**Figure 5-15.** The absorption of Pinta Acoustic melamine foam panels of different thicknesses, Type A mountings.\textsuperscript{20}
5.2.2.3 Acoustical Tiles

Acoustical tiles have the highest density of the porous absorbers. They are widely used for suspended (lay-in) ceiling treatments. Years ago, it was common to see 30 cm × 30 cm (12 in × 12 in) tile mounted directly to a hard plaster (Type A mounting). This is not a very efficient way to use this type of absorber and is no longer popular.

The standard sizes for acoustical tiles are 61 cm square (24 in × 24 in) or 61 cm × 122 cm (24 in × 48 in) and the Sabine absorption coefficients are usually given for Type E400 mounting, which mimics a lay-in ceiling with a 400 mm (16 in) air space. Fig. 5-16 shows the average absorption coefficients of a sampling of 39 different acoustical tiles. The vertical lines at each frequency point indicate the spread of the coefficients for each frequency. It is interesting to note the wide variance possible with different types of tiles.

```
Figure 5-16. The average Sabine absorption coefficients (α_{SAB}) of 39 acoustical ceiling tiles of varying thickness, Type E400 mounting.
```

5.2.2.4 Spray and Trowel Applied Treatments

Some acoustical treatments can be applied by spray and/or trowel. Many are applied, finished, and detailed much like standard plaster—and are even paintable. Special bonding chemicals and processes give these types of materials their absorptive qualities. Some have a gypsum base, which can provide a look similar to normal plaster or gypsum wallboard walls. Acoustical plasters tend to provide high frequency absorption, with poor low frequency performance, especially when applied thinly (<2.5 cm thickness). Acoustical plasters can be an economical option when considering spaces that require large areas of absorption—e.g., a gymnasium ceiling. Some spray applied treatments can provide fireproofing, as well as thermal insulation. They are also popular in historical preservation applications, where the aesthetic appearance of a surface cannot be altered, but the acoustics must be improved to provide better communications in the space.

5.2.2.5 Carpet and Draperies

Carpet is a visual and comfort asset, and it is a porous absorber of sound, although principally at upper audio frequencies. Carpet is what the electrical engineer might call a low-pass filter. Because it is a high-frequency absorber, carpet should be used cautiously as a room treatment. Carpet can make a well-balanced room bass heavy because of its excessive high frequency absorption. The various types of carpet have different sound absorption characteristics. In general, sound absorption increases with pile weight and height; cut pile has greater absorption than loop pile. Pad material has a significant effect on the absorption of a carpet. Generally, the heavier the carpet pad, the more absorption. Impermeable backing should be used with care as it dramatically reduces the effect of the carpet pad and thereby reduces absorption. Due to the limited thickness of carpet, even the deepest possible pile (with the thickest possible pad) will not absorb much low-frequency sound. Fig. 5-17 shows the absorption coefficient for a typical medium-pile carpet, with and without a carpet pad.

```
Figure 5-17. The absorption of loop pile tufted carpet (0.7 kg/m²) with and without carpet pad (1.4 kg/m²), Type A mounting.
```
Draperies are also porous absorbers of sound. Included in the drapery category are drapes, curtains, tapestries, and other fabric wall-hangings, decorative or otherwise. Besides the type and thickness of material, the percent fullness has an effect on how well draperies absorb sound. (The percent fullness is a representation of the amount of extra material in the drapery. For example, 100% fullness would mean that a 3.0 m wide curtain actually consists of a 6.0 m wide piece of material. Similarly, 150% fullness would indicate that a 3.0 m wide drape consists of a 7.5 m wide piece of material; a 6.0 m wide piece of material being used for an 2.4 m wide drape, etc.) Fig. 5-18 shows the absorption coefficients for draperies with different percent fullness.22 While spacing draperies from the wall does increase absorption slightly, it would not appear to be as significant as percent fullness, as indicated by Fig. 5-19.22

5.2.3 Discrete Absorbers

Discrete absorbers can literally be anything. Even an acoustical tile or foam panel is a discrete absorber. The absorption per unit of a tile, panel, board, person, bookshelf, equipment rack, etc., can always be determined. In the context of acoustical treatments, there are two main classes of discrete absorber that should never be ignored: people and furnishings.

5.2.3.1 People and Seats

In many large spaces, people and the seats they sit in will be the single largest acoustical treatment in the room. Any acoustical analyses of sufficiently large spaces should include people in the calculations. How the seats behave acoustically when they are empty is another important consideration. Empty wood chairs will not absorb as much as the people sitting in them. A heavily padded seat may absorb just as much sound as a seated individual. A chair that folds up when not in use may have a hard, plastic cover on the underside of the seat that will reflect sound. Perforating the cover to allow sound to pass in through the bottom of the chair when it is folded up may be a worthwhile consideration for some applications. For more information on the absorption of people, seats, and audience areas in general, refer to Section 7.3.4.4.4.

5.2.3.2 Acoustical Baffles and Banners

In very large rooms, such as domed stadiums, arenas, gymnasiums, factories, and even some houses of worship, absorbers need to be placed high on the ceiling to reduce reverberant sound. Installing spray applied acoustical treatments in such spaces is often uneconomical because it would be too labor-intensive. To solve this problem, prefabricated acoustical treatments that hang from the ceiling are often used. Acoustical baffles are typically 61 cm × 122 cm (24 in × 48 in)—or some other relatively manageable size—and are often approximately 3.8 cm (1.5 in) thick. The core material is often a rigid or semi-rigid mineral fiber, such as glass fiber, with a protective covering of polyester fabric, rip-stop nylon, or PVC. Acoustical foam panels and other porous
absorption panels are often available as baffles as well. Absorption is reported as the number of sabins per baffle. Acoustical baffles are often hung vertically (perpendicular to the floor), but they can also be hung horizontal, or even at an angle. The pattern of hanging can have an effect on the overall performance of the treatments. For example, some applications will benefit more from baffles hung in two or more directions, versus simply hanging all the baffles parallel to each other in one direction. Hanging is often accomplished via factory- or user-installed grommets or hooks. Acoustical banners are simply scaled-up versions of acoustical baffles. The core absorptive material is sometimes of a slightly lower density to facilitate installing the banners so that they can be allowed to droop from a high ceiling. Sizes for banners tend to be large: 1.2 m × 1.5 m (4.0 ft × 50 ft) (larger sizes are not uncommon).

5.2.3.3 Other Furnishings and Objects

Anyone who has moved into a new home has experienced the absorptive power of furnishings. Rooms simply do not sound the same when they aren’t filled with chairs and bookshelves and end tables and knick-knacks and so on. Even in the uncarpeted living spaces in our homes, the addition of even a small number of items can change the acoustical character of the room.

This concept was put to the test when a small room with tile floor and gypsum wallboard walls and ceilings was tested before and after the addition of two couches. The couches in question were fabric—as opposed to leather or leather substitute—and were placed roughly where they eventually wound up staying even after moving in the balance of the room’s furnishings. The absorption—in sabins per couch—is shown in Fig. 5-20. (Fig. 5-20 is for illustrative purposes only—i.e., the absorption shown was not measured in a laboratory.)

5.2.4 Resonant Absorbers

In the most general sense, a resonant absorber employs the resonant properties of a material or cavity to provide absorption. Resonant absorbers are typically pressure devices, contrasted with porous absorbers that are typically velocity devices. In other words, a porous absorber placed at a point of maximum particle velocity of the sound will provide maximum absorption. A resonant absorber placed at a point of maximum particle pressure will provide maximum absorption. This can become important in applications where maximum low-frequency performance is important. A broadband porous absorber spaced away from a surface will be the most effective method of maximizing low-frequency absorption. In contrast, a resonant absorber placed on or at the surface will provide maximum low-frequency absorption.

Resonant absorbers are often described as having been tuned to address a specific frequency range. The meaning of this will become clear below from the equations involved in determining a resonant absorber’s frequency of resonance. It should be noted that many versions of the equations for resonant frequency exist in the literature. Not all of these have been presented accurately and, unfortunately, some equation errors have been perpetuated. Unfortunately, calculating the resonant frequency of a resonant absorber is not straightforward. Careful research and review were undertaken for the sections below. Unless otherwise noted, the Cox and D’Antonio² method of utilizing the basic Helmholtz equation as the starting point for resonance calculations was implemented in the following sections.

5.2.4.1 Membrane Absorbers

Membrane absorbers—also called panel and diaphragmatic absorbers—utilize the resonant properties of a membrane to absorb sound over a narrow frequency range. Nonperforated, limp panels of wood, pressed wood fibers, plastic, or other rigid or semi-rigid material are typically employed when constructing a membrane absorber. When mounted on a solid backing, but separated from it by a constrained air space, the panel will respond to incident sound waves by vibrating. This
results in a flexing of the fibers, and a certain amount of frictional loss results in absorption of some of the sound energy. The mass of the panel and the springiness of the air constitute a resonant system. In resonant systems, peak absorption occurs at the resonance frequency \( f_R \). The approximate \( f_R \) for a membrane absorber is given by Eq. 7-65 in Section 7.3.4.4.2. It should be emphasized that this equation yields an approximate result. Errors in calculated versus measured \( f_R \) as high as 10% have been measured. Nonetheless, membrane absorbers have been successfully used to control specific resonant modes in small rooms. To control room modes, they must be placed on the appropriate surfaces at points of maximum modal pressure. (For a detailed discussion of room modes see Chapter 6.2.) Adding porous absorption, such as a mineral fiber panel (typically glass fiber or mineral wool), to the cavity dampens the resonance and effectively broadens the bandwidth or Q factor of the absorber. If the Q factor is broadened, the absorber will be somewhat effective, even if the desired frequency is not precisely attained.

Additionally, care should be taken during design and construction of membrane absorbers. Changes as small as 1 to 2 mm to, for example, the cavity depth can alter the performance significantly. Fig. 5-21 shows how the calculated resonant frequency varies with air space for various membranes. Other design tips can be found in Section 7.3.4.4.2.

Since membrane absorbers require a high level of precision to perform at the desired frequency, they are often customized for a specific application. Mass production is often uneconomical, although some companies offer membrane absorbers, one of which is the Modex Corner Bass Trap from RPG, Inc., with absorption coefficients as shown in Figure 5-22.²³

Since there have not been many mass-produced membrane absorbers, there is far less empirical test data available on membrane absorbers relative to porous absorbers. Nonetheless, some formal testing of commercially available membrane traps has been undertaken, for example, by Noy et al.²⁴ Results were mixed; some membrane absorbers performed as designed, others performed well (if not exactly how the designer intended), and some did not work at all.

Putting theory into practice, Fig. 5-23 shows a pair of small room response measurements before and after the addition of a membrane absorber. Frequency is plotted linearly on the x axis (horizontal) with the resonance showing up at about 140 Hz. The y axis, going into the page, is the time axis showing the decay of the room coming towards the viewer. The time span on the y axis was about 400 ms. A pair of membrane absorbers was built with \( f_R = 140 \) Hz. One was placed on the ceiling and one on a side wall.

Membrane absorbers are often inadvertently built into the structure of a room. Wall paneling, ceiling tiles, windows, coverings for orchestra pits, and even elements of furniture and millwork can all be membrane absorbers; the only question is at what frequency they resonate. Remember that everything in a room, including the room itself, has some impact on the acoustics of the room. One of the most common inadvertent membrane

---

**Figure 5-21.** Variation of \( f_R \) versus depth of air space for membrane absorbers consisting of common building materials.

**Figure 5-22.** The absorption of a commercial membrane absorber, the Modex Corner Bass Trap from RPG, Inc.²³
absorbers encountered in modern architecture is the gypsum wallboard (GWB) (drywall or sheetrock) cavity. Fortunately, the absorption of the GWB cavity can be calculated, and the calculated results have been shown to be in good agreement with laboratory measurements. Section 9.2.3.1 provides discussion and calculation methods for GWB cavity absorption.

5.2.4.2 Helmholtz Resonators

The ubiquitous cola bottle may be the acoustician’s most cherished conversation piece. Bottles and jugs are probably the most common everyday examples of what are referred to in acoustics as Helmholtz resonators. As part of his exhaustive and painstakingly detailed work in hearing, sound, and acoustics, Hermann von Helmholtz determined and documented the acoustical properties of an enclosed volume with a relatively small aperture. Helmholtz resonators, as we now know them, have specialized absorptive properties for acoustical applications. At the frequency of resonance, absorption is very high. The frequency range of this absorption is very narrow—only a few Hz wide, typically. When absorptive material, such as loose mineral fiber, is used to partially fill a Helmholtz resonator, the effective frequency range is widened.

Eq. 7-69 in Section 7.3.4.4.3 can be used to calculate $f_R$ for a Helmholtz resonator. Commercially, one of the most common products utilizing Helmholtz resonator theory is sound absorbing concrete masonry units (CMU). For example, Fig. 5-24 provides the sound absorption data for SoundBlox products available from Proudfoot.

5.2.4.3 Perforated Membrane Absorbers

Membrane absorbers and Helmholtz resonators are dependent on the size of the air space or cavity they contain. Turning the former into the latter can be accomplished by cutting or drilling openings in the face of the membrane. The tuned cavity of a membrane absorber then becomes the cavity of a Helmholtz resonator. When round holes are used for the openings in the face, a perforated absorber is created. To calculate the $f_R$ for a perforated membrane absorber, first the effective thickness must be calculated. For perforated panels of having holes of diameter $d$ and regular hole spacing $S$ (center-to-center distance between holes), Eq. 5-2 yields the fraction of open area, $\varepsilon$:

$$\varepsilon = \frac{\pi (d/4)^2}{S^2}.$$

$$1/3 \text{Octave band center frequency–Hz}$$

$$\begin{array}{cccc}
\text{102 mm (4 in) block} & \text{152 mm (6 in) block} & \text{203 mm (8 in) block} \\
125 & 125 & 125 \\
160 & 160 & 160 \\
200 & 200 & 200 \\
250 & 250 & 250 \\
315 & 315 & 315 \\
400 & 400 & 400 \\
500 & 500 & 500 \\
630 & 630 & 630 \\
800 & 800 & 800 \\
1000 & 1000 & 1000 \\
1250 & 1250 & 1250 \\
1600 & 1600 & 1600 \\
2000 & 2000 & 2000 \\
2500 & 2500 & 2500 \\
3150 & 3150 & 3150 \\
4000 & 4000 & 4000 \\
\end{array}$$

$\alpha_{SAB}$
To calculate the effective thickness for a perforated absorber, a correction factor, \( \delta \), is required. This factor is often approximated to 0.85, but can be calculated for low values of \( \varepsilon \) (typically <0.16) using

\[
\delta = 0.8(1 - 1.4\sqrt{\varepsilon}) \tag{5-3}
\]

Next, the effective panel thickness \( t' \) for a panel of thickness \( t \) is calculated from Eq 5-3 using \( \delta \)

\[
t' = t + \delta d \tag{5-4}
\]

Finally, \( f_R \) for a panel over an air space of depth \( D \) is found with

\[
f_R = \frac{c}{2\pi N t' D} \tag{5-5}
\]

Care should be taken to be consistent with units. For example, if inches are used to calculate \( \varepsilon \), etc., \( c \) (the speed of sound) should be in inches per second.

The \( f_R \) of perforated absorbers is generally adjusted by changing \( \varepsilon \). Increasing \( \varepsilon \) (larger holes, smaller spacing, or both), decreasing \( D \), or using thinner panels will all increase the \( f_R \). The \( f_R \) can be lowered by decreasing \( \varepsilon \), by increasing \( D \), or by using thicker panels. The \( f_R \) from Eq. 5-5 is not exact, but is close enough for use in the design stage. The air space is often partially or completely filled with porous absorption. The only drawback to this is that absorptive material in contact with the perforated panel can reduce the absorber’s effectiveness.

One of the more obvious perforated membranes that can be used is common pegboard. Standard pegboard tends to create an absorber with an \( f_R \) in the 250–500 Hz range, as shown in Fig. 5-25.\textsuperscript{18} Since perforated absorbers are often considered for low frequency control, it is not uncommon to fabricate customized perforated boards. For example, a hardboard membrane with \( d = 6.4 \text{ mm (0.25 in)} \), \( S = 102 \text{ mm (4 in)} \), \( t = 3.2 \text{ mm (0.125 in)} \), and \( D = 51 \text{ mm (2 in)} \), a perforated absorber tuned to roughly 125 to 150 Hz can be created. The absorption coefficients of such an absorber with 96 kg/m\(^3\) (6 lb/ft\(^3\)) glass fiber filling the air space are shown in Fig. 5-26.

Microperforated materials are one of the most recent developments in the area of acoustical treatments. Extremely thin materials with tiny perforations (<<1 mm) are stretched over an air space and absorption occurs by means of boundary layer effects.\textsuperscript{2} Because they are so thin, microperforated absorbers can be fabricated from visually transparent material. RPG offers the

\begin{figure}[h]
\centering

\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure5-26.png}
\caption{The absorption of a perforated membrane absorber "tuned" to 125–150 Hz, Type A mounting, cavity filled with 96 kg/m\(^3\) (6 lb/ft\(^3\)) glass fiber.}
\end{figure}

5.2.4.4 Slat Absorbers

Helmholtz resonators can also be constructed by using spaced slats over an air space (with or without absorptive
fill). The air mass in the slots between the slats reacts with the springiness of the air in the cavity to form a resonant system, much like that of the perforated panel type. In fact, Eq. 5-5 is again used to calculate the $f_R$ for a slat absorber, but with the following equations for $H$, $G$, and $t'$:

$$\varepsilon = \frac{r}{w + r} \quad (5-6)$$

$$\delta = -\frac{1}{\pi} \ln \left[ \sin \left( \frac{1}{2} \pi \varepsilon \right) \right] \quad (5-7)$$

$$t' = t + 2\delta r \quad (5-8)$$

where,

- $r$ is the slot width,
- $w$ is the slat width.

While $\delta$ is often approximated to a value near 0.6, it is not difficult to calculate. As with perforated absorbers, the above will yield approximate results for the $f_R$ of a slat absorber, which will be fine for most design applications.

In a practical sense, the absorption curve can be broadened by using a variable depth for the air space. Another approach is using slots of different widths. In the structure of Fig. 5-28, both variable air space depth and variable slot width could be used. Porous absorptive fill is shown at the back of the cavity, removed from the slats. This gives a sharper absorption than if the absorbent is in contact with the slats. It should be noted that, all other factors remaining the same, randomly placed slats (yielding randomly sized slots) will lower the overall absorption, while bandwidth is increased.29

**5.2.5 Bass Traps**

Bass trap lore pervades the professional audio industry, particular in the recording industry. Literature on the subject, however, is scarce. The term has become a catchphrase often used by acoustical product manufacturers to include a large variety of acoustical products, often including what are simply broadband absorbers. Very few bass traps are actually effective at absorbing bass. It is simply quite difficult to absorb sounds with wavelengths at or approaching 56 ft (17 m). To most effectively absorb a given frequency at any angle of incidence, including normal incidence the absorbing material should be at least $\frac{1}{10}$ and, ideally, $\frac{1}{4}$ of the wavelength of the lowest frequency of interest. For 20 Hz, this means a depth between 1.7 m (minimum) and 4.3 m (ideal)! It is relatively rare to find someone who is willing to build a device that large to trap bass. This may be necessary in the design of very large rooms, like concert halls, but it is probably more interesting to ask what crime has the 20 Hz committed that it needs to be trapped? As we shall see in the next chapter, the low end performance of small rooms can be reliably predicted from a study of the distribution of room modes. If the modes are distributed properly, trapping may not be needed. On the other hand, imagine that the modes are not distributed properly and the goal is to fix a problem room. If there is enough space to build a bass trap that is large enough to have an impact.
on wavelengths that large, most likely one could move a wall, improving, if not optimizing, the modal distribution and obviating the need for trapping.

Nonetheless, the preceding sections have provided many examples of products that could be designed to trap bass without taking up much space. Additionally, there are good broadband absorbers on the market that extend down into the low-frequency region. The practical limits of size and mounting usually lead to a natural cutoff between 50 and 100 Hz for many broadband absorbers. These products exhibit performance that is highly dependent on placement, especially in small rooms.

### 5.2.6 Applications of Absorption

In large rooms (see Chapter 6 for the definition of large vs small rooms) where there is a statistically reverberant sound field, absorption can be used to actually modify the reverberant field, and the results are predictable and fairly straightforward. The whole concept of reverberation time (RT—discussed in detail in Chapter 6) is a statistical one that is based on the assumption of uniform distribution of energy in the room and complete randomness in the direction of sound propagation. In large rooms, both conditions can prevail.

In small rooms—particularly at low frequencies—the direction of propagation is by no means random. Because of this, the propriety of applying the common RT equations to small rooms is questioned. For small rooms (nonreverberant spaces), absorption is useful for control of discrete reflections from surfaces located in the near field of the source and listener. In rooms the size of the average recording studio or home theater, a true reverberant field cannot be found. In such small rooms, the common RT equations cannot be used reliably. Further, predicting or trying to measure RT in small spaces where a reverberant field cannot be supported is typically less useful relative to other analysis techniques. The results of RT measurements in small rooms will neither show RT in the true sense, nor will they reveal much of value regarding the behavior of sound in a small room relative to the time domain. Typically, it is more useful to examine the behavior of sound in the time domain in more detail in small rooms. Determining the presence of reflections (wanted or unwanted), the amplitude of those reflections, and their direction of arrival at listening positions is typically a better approach. For low frequencies, Chapter 5 provides some small room analysis techniques that are more beneficial than the measurement of RT.

#### 5.2.6.1 Use of Absorption in Reverberant Spaces

In large rooms, the common RT equations can be used with reasonable confidence. When absorptive treatment is not uniformly distributed throughout the space, the Sabine formula is typically avoided in lieu of other formulas. RT is covered in detail in Chapter 6.

In reverberant spaces, the selection of absorbers can be based on the absorption data collected in accordance with ASTM C423, as described in Section 5.2.1.1. Care should be taken, however, to somehow account for effects not directly evident from laboratory measurement methods. As an example, consider a fabric-wrapped, mineral fiber panel that is tested in a Type A mounting configuration. The test specimen is placed in the reverberation chamber directly against a hard (typically solid concrete) surface, often the floor. The absorption coefficients then represent only the absorption provided by the panels. In practice, panels such as these might be directly applied to a GWB surface having absorption characteristics of its own that are significantly different than the solid concrete floor of a reverberation chamber! Applying an absorptive panel to a GWB wall or ceiling not only changes the acoustical behavior of the GWB surface (by changing the mass), but the panel itself will not absorb as measured in the lab, because of the mounting, the size of the room relative to the laboratory test chamber, the proportion of absorptive material relative to the total surface area of the room, etc. This is one example of why the predictive modeling for the acoustics of large spaces can be—like many aspects of acoustics—as much art as science. All acousticians are likely to have methods they use to account for idiosyncrasies that can neither be measured in a laboratory, nor modeled by a computer.

In addition, it is generally agreed among acousticians that reverberation time is no longer considered the single most important parameter in music hall and large auditorium acoustics. Reverberation time is understood to be one of several important criteria of acoustical quality of such halls. Equal or greater stress is now placed on, for example, the ratio of early arriving energy to total sound energy, the presence of lateral reflections, the timing of the arrival of various groups of reflections, and other parameters discussed in detail in Chapter 6.

#### 5.2.6.2 Use of Absorption in Nonreverberant Spaces

In rooms where there is not enough volume or a long enough mean free path to allow a statistical reverberant field to develop, one must view the use of absorption in a somewhat different manner. As alluded to previously, the
common RT equations will not work satisfactorily in these spaces.

Absorption is often used in small rooms to control discrete reflections or to change the way the room feels. Contrary to popular belief, the impression of liveness or deadness is not based on the length of the reverberation time. Rather, it is based on the ratio of direct to reflected sound and on the timing of the early reflected sound field, especially in the first 20 ms or so. Adjusting the acoustics of nonreverberant spaces (sometimes referred to as tuning the room) involves manipulating discrete reflections.

To determine the suitability of a particular absorber, the acoustician needs a direct measurement of the reflected energy off the product. In small rooms—where a significant portion of the spectrum is below $f_1$ (see Chapter 6)—field measurement of absorption, such as the techniques and methods presented in Section 5.2.1.3, might be more appropriate in determining the applicability of a particular absorber to a small room application.

### 5.2.7 Subjective Impact of Absorption

Sometimes it is useful to consider the extremes. It is interesting to note that rooms with no absorption and rooms with total absorption represent the most acoustically hostile spaces imaginable. At one extreme, there is the absorption-free space, also known as the reverberation chamber. A good real-world example of this is a racquetball court. As anyone who has played racquetball can readily attest to, racquetball courts are not acoustically friendly! At the other extreme is the anechoic chamber. This is a room that is totally absorptive and totally quiet. Since an anechoic chamber has no reflected sound and is isolated from sounds from the outside, a good real-world example of this is the desert. Standing in a part of the desert free of reflective surfaces, such as buildings and mountains, located many kilometers from any noise sources, such as highways and people, at a time when there is no wind, the complete lack of sound would be comparable to what one would experience in an anechoic chamber. It is difficult to describe just how disorienting spending time in either of these chambers can be. Neither the reverberation chamber nor the anechoic chamber is a place where a musician would want to spend much time, let alone perform!

The use of absorption has a powerful impact on the subjective performance of a room. If too much absorption is used, the room will feel uncomfortably live—i.e., too much like a reverberation chamber. Additionally, the absorption of any material or device is frequency-dependent; absorbers act like filters to the reflected sound. Some energy is turned into heat, but other frequencies are reflected back into the room. Choosing an absorber that has a particularly nonlinear response can result in rooms that just plain sound strange.

More often than not, the best approach is a combination of absorbers. For example, large spaces that already have the seats, people, and carpet as absorbers may benefit from a combination of membrane absorbers and porous absorbers. In a small room, some porous absorbers mixed with some Helmholtz resonators might provide the best sound for the room. Both of these are examples of the artistic (the aural aesthetic) being equally applied with the science (the acoustic physics).

Experience is important when considering the application of absorption and—more importantly—when considering what a particular application will sound like. The savvy acoustician will realize the aural differences between a small room treated with 5.1 cm (2 in) acoustical foam and a room treated with 2.5 cm (1 in) glass fiber panels. On paper, these materials are quite similar (compare Figs. 5-6 and 5-14). However, the knowledge that a room treated with 9.3 m² (100 ft²) of foam generally sounds darker than a room treated with the same area of 96 kg/m³ fabric-wrapped, glass fiber boards comes only with experience. Likewise, the knowledge that a room treated with a slotted concrete block wall will sound much different than the same room with a GWB wall that is treated with several well-placed perforated absorbers (even though RT predictions for each scenario come out to be approximately the same) comes only with experience.

### 5.2.8 Absorption and Absorption Coefficients of Common Building Materials and Absorbers

Table 5-3 gives the absorption coefficients of various popular building materials.

### 5.3 Acoustical Diffusion

Compared to acoustical absorption, the science of acoustical diffusion is relatively new. The oft-cited starting point for much of the science of modern diffusion is the work of Manfred Schroeder. In fact, acoustically diffusive treatments that are designed using one of the various numerical methods that will be discussed below are often referred to generically as Schroeder diffusers. In the most

basic sense, diffusion can be thought of as a special form of reflection. Materials that have surface irregularities on the order of the wavelengths of the impinging sound waves will exhibit diffusive properties. Ideally, a diffuser will redirect the incident acoustical energy equally in all directions and over a wide range of frequencies. However, it is often impractical to construct a device that can diffuse effectively over the entire audible frequency range. Most acoustical diffuser products are designed to work well over a specific range of frequencies, typically between 2 and 4 octaves above roughly 500 Hz. Of course, just as with absorbers, one must be concerned with the performance of a diffuser.

### 5.3.1 Diffuser Testing: Diffusion, Scattering, and Coefficients

The performance of a diffuser can be expressed as the amount of diffusion and as the amount of scattering provided by a surface. While there is still some disagreement as to diffusion nomenclature, Cox and D’Antonio have attempted to establish a distinction between diffusion and scattering, particularly as it relates to the coefficients that are used to quantify diffuser performance. Of course, just as with absorbers, one must be concerned with the performance of a diffuser.

5.3.1 Diffuser Testing: Diffusion, Scattering, and Coefficients

The performance of a diffuser can be expressed as the amount of diffusion and as the amount of scattering provided by a surface. While there is still some disagreement as to diffusion nomenclature, Cox and D’Antonio have attempted to establish a distinction between diffusion and scattering, particularly as it relates to the coefficients that are used to quantify diffuser performance. In general, diffusion and the diffusion coefficients relate to the uniformity of the diffuse sound field created by a diffuser. This is most easily explained by looking at polar
plots of the diffuse sound field from a diffuser. The less lobing there is in a diffusion polar plot, the more diffusion and the higher the diffusion coefficients.

Scattering and the scattering coefficients relate to the amount of energy that is not reflected in a specular manner. The term specular here denotes the direction of reflection one would expect if the sound were reflecting off a hard flat surface. For example, most high frequency sounds reflect from a hard flat surface at the same angle as the incident sound, Fig. 5-1. This is referred to as specular reflection by Cox and D’Antonio. The more sound that is reflected in a nonspecular manner, the higher the scattering. Therefore, a simple angled wall can provide high scattering but low diffusion, since the reflected sound will still form a lobe, but not in a specular direction. It should be noted that a significant amount of absorption makes it difficult to measure scattering. This makes sense since an absorber does not allow for a high level of specular reflection; absorption can be mistaken for scattering.

The standardized methods for measuring diffusion and scattering coefficients are AES-4id-2001 and ISO 15664, respectively. The AES method provides guidelines for measuring the performance of diffusive surfaces and reporting the diffusion coefficients. These guidelines will allow diffusers of different designs to be objectively compared. The results cannot, however, be incorporated into acoustical modeling programs. For that, the scattering coefficients must be used when measured in accordance with the ISO method.

Both the AES and ISO methods are relatively new; the AES method was formalized in 2001 and the ISO method was published in 2003. Because of this, none of the independent acoustical test laboratories in North America are equipped to perform the AES diffusion test and, as of this writing, only one laboratory in North America is equipped to perform the ISO scattering test. Because of this, diffusion and scattering coefficients for surfaces and treatments (diffusers or otherwise) are difficult to find. Indeed, because so little testing is being performed on diffusers, there is some degree of confusion in the industry as to what diffusion and scattering coefficients actually mean in subjective terms. For example, what does a diffusion (or scattering) coefficient of 0.84 at 2500 Hz sound like? There is no denying that the information is useful and that objective quantification of diffusers is necessary. However, comparing diffusion or scattering coefficients for different materials would be a theoretical exercise at best. The process is further complicated by the fact that commercial diffusers vary dramatically in shape and style; each manufacturer claims some degree of superiority because of some unique application of some innovative mathematics.

Nonetheless, there are diffusion and scattering coefficients available in the literature (Cox and D’Antonio offer a significant amount of laboratory measured diffusion and scattering coefficients), and some manufacturers have begun pursuing independent tests of their diffusive offerings. Fig. 5-29 pictures examples of various commercial diffusers. The next few decades will be a very exciting time for diffusion, particularly if more independent acoustical laboratories begin to offer AES and/or ISO testing services.

![Figure 5-29. Various commercial diffusers.](image)

### 5.3.2 Mathematical (Numerical) Diffusers

The quadratic residue diffuser (QRD) is one form of a family of diffusers known as reflection phase gratings, or more generally, mathematical or numerical diffusers. Numerical diffusers, such as the QRD, are based on the pioneering work of Manfred Schroeder. Numerical diffusers consist of a periodic series of slots or wells of equal width, with the depth determined by a number theory sequence. The depth sequence is developed via Eq. 5-9

\[
\text{well depth factor} = n^2 \mod p
\]

where,
- \( p \) is a prime number,
- \( n \) is an integer \( \geq 0 \).

The “mod” in Eq. 5-9 refers to modulo, which is a number theory mathematical process whereby the first
number, in this case the square of \( n \), is divided by the second number, in this case \( p \), and the remainder is equal to the well depth factor. For example, if \( n = 5 \) and \( p = 7 \), Eq. 5-9 becomes

\[
\text{Well depth factor} = \frac{n^2}{p} \text{ mod } 7
\]

25 divided by 7 = 3 with a remainder of 4.

Therefore:

\[
\text{Well depth factor} = \frac{n^2}{p} \text{ mod } 7 = 4
\]

In a similar manner, the well depth factors for all the other wells are obtained, as shown in Fig. 5-30. Two complete periods—plus an extra well added to maintain symmetry—are shown in Fig. 5-30 for a \( p = 7 \) QRD. Usually the wells are separated by thin, rigid separators (but not always). An important feature of QRD is symmetry. This allows them to be manufactured and utilized in multiple modular forms.

D’Antonio and Konnert have outlined the theory and application of reflection phase-grating diffusers.\(^{32}\) The maximum frequency for effective diffusion is determined by the width of the wells; the minimum frequency for effective diffusion is determined by the depth of the well. Commercial diffusers built on these principles are available from a variety of manufacturers. RPG, Inc. and its founder, Dr. Peter D’Antonio, have done pioneering work in the area of diffusion, particularly with respect to Schroeder diffusion and, more recently, with state-of-the-art diffusive surfaces that are customized for an application through the use of special computer models and algorithms.

Numerical diffusers such as QRDs can be 1D or 2D in terms of the diffused sound pattern. QRDs consisting of a series of vertical or horizontal wells will diffuse sound in the horizontal or vertical directions, respectively. In other words, if the wells run in the ceiling-floor direction, diffusion will occur laterally, from side to side, and the resulting diffusion pattern would resemble a cylinder. (Incident sound parallel to the wells will be reflected more than diffused.) More complex numerical diffusers employ sequences of wells—often elevated blocks or square-shaped depressions—that vary in depth (or height) both horizontally and vertically. Incident sound striking these devices will be diffused in a spherical pattern.

### 5.3.3 Random Diffusion

Besides numerical diffusers, diffusion can also result from the randomization of a surface. In theory, these surfaces cannot provide ideal diffusion. However, listening to the results after treating the surfaces of a room with random diffusers would indicate that, subjectively, they perform quite well. Since any randomization of a surface breaks up specular reflection to some degree, this is not unexpected. The only limitation will be the frequency range of significant diffusion. The rules for well width and depth discussed previously would still apply, albeit in a general sense since the diffusers will not have been designed using a formal number theory algorithm. The benefit of random diffusion is that everyday materials and objects can provide significant diffusion. For example, bookshelves, media storage shelves, decorative trim or plasterwork, furnishings, fixtures, and other decorations can all provide some diffusion. This can be

![Figure 5-30. A profile of two periods (with one extra well to maintain symmetry) of a QRD of prime number \( p = 7 \).](image-url)
particularly helpful when budget is a concern since diffusive treatments tend to cost twice to ten times more than absorptive treatments on a per square foot basis.

5.3.4 Applications of Diffusion

Like absorption, major differences in the size of the space being treated need to be considered when applying diffusion principles. Diffusion tends to provide the most per-dollar-spent benefit in large spaces. Diffusion tends to happen in the far field. In the near field of a diffuser, the scattering effects are typically less pronounced and can actually be less subjectively pleasing than a flat reflective surface in some applications.

For large spaces, diffusion is often employed on the ceiling or rear wall of a space. This provides distribution of the sound energy in the room that envelops a listener. There will be a noticeable (and measurable) reduction in RT, but the reduction is not nearly as severe as it would be with a similar area of absorptive treatment in the same space. Additionally, a typical listener tends not to notice that RT has been reduced, but rather that the decay has been smoothed out, intelligibility has improved, and the room generally sounds better after diffusion has been appropriately applied.

For small spaces, the decision to use diffusion is more challenging. D’Antonio and Cox suggest that the full benefit of diffusers is realized when the listener is a minimum working distance of about 3 m (10 ft) away from the diffusive surface. This tends to happen in the far field. In the near field of a diffuser, the scattering effects are typically less pronounced and can actually be less subjectively pleasing than a flat reflective surface in some applications.

For large spaces, diffusion is often employed on the ceiling or rear wall of a space. This provides distribution of the sound energy in the room that envelops a listener. There will be a noticeable (and measurable) reduction in RT, but the reduction is not nearly as severe as it would be with a similar area of absorptive treatment in the same space. Additionally, a typical listener tends not to notice that RT has been reduced, but rather that the decay has been smoothed out, intelligibility has improved, and the room generally sounds better after diffusion has been appropriately applied.

For small spaces, the decision to use diffusion is more challenging. D’Antonio and Cox suggest that the full benefit of diffusers is realized when the listener is a minimum working distance of about 3 m (10 ft) away from the diffusive surface. This tends to be a good minimum working distance of about 3 m (10 ft) away full benefit of diffusers is realized when the listener is a more challenging. D’Antonio and Cox suggest that the diffusion has been appropriately applied. Improved, and the room generally sounds better after decay has been smoothed out, intelligibility has noticed that RT has been reduced, but rather that the same space. Additionally, a typical listener tends not to notice that RT has been reduced, but rather that the decay has been smoothed out, intelligibility has improved, and the room generally sounds better after diffusion has been appropriately applied.

For small spaces, the decision to use diffusion is more challenging. D’Antonio and Cox suggest that the full benefit of diffusers is realized when the listener is a minimum working distance of about 3 m (10 ft) away from the diffusive surface. This tends to be a good minimum working distance of about 3 m (10 ft) away full benefit of diffusers is realized when the listener is a more challenging. D’Antonio and Cox suggest that the diffusion has been appropriately applied. Improved, and the room generally sounds better after decay has been smoothed out, intelligibility has noticed that RT has been reduced, but rather that the same space. Additionally, a typical listener tends not to notice that RT has been reduced, but rather that the decay has been smoothed out, intelligibility has improved, and the room generally sounds better after diffusion has been appropriately applied.

For small spaces, the decision to use diffusion is more challenging. Additionally, a typical listener tends not to notice that RT has been reduced, but rather that the decay has been smoothed out, intelligibility has improved, and the room generally sounds better after diffusion has been appropriately applied.

5.4 Reflection and Other Forms of Sound Redirection

In addition to diffusion, sound can be redirected by controlled reflection, diffraction, or refraction. Diffraction takes place when sound bends around an object, such as when a passing train is audible behind a wall. The low frequencies from the train rumble have large wavelengths relative to the height of the wall, allowing them to bend over the top of it. This can come into play indoors when sound bends around office partitions, podiums, or other common obstacles.

Refraction is the only form of acoustic redirection that does not involve some sort of object. Acoustic refraction is the bending of a sound wave caused by changes in the velocity of sound through a medium. Refraction is often thought of as an optical phenomenon; however, acoustic refraction occurs when there are temperature gradients in a room. Because the speed of sound is dependent on the temperature of the air, when an acoustic wave passes through a temperature gradient, it will bend toward the cooler air. This can occur indoors when cooler air from air-conditioning vents located on the ceiling blows into a room with warmer air below; the sound will bend upwards until the temperature reaches equilibrium. Even in recording studios, a heating vent blowing warm air over one loudspeaker in a stereo pair can skew the sound towards the other loudspeaker and wreak havoc on the stereo image!

Finally, everything in the room, including the room itself, reflects sound in some way, even the absorbers. One could look at an absorber as an inefficient reflector. When an item is small with respect to the wavelength of sound impinging upon it, it will have little effect on that sound. A foot stool placed in front of a woofer will have little effect on the 1.7 m wavelength of 200 Hz, the 4.4 m wavelength of 100 Hz, or the 6.9 m wavelength of 50 Hz. The wave will diffract around it and continue on its merry way. The wavelength of 8 kHz is 4.3 cm. Just about anything that is placed in front of a tweeter that is reproducing 8 kHz and up can effectively block or redirect the sound.

Although it may seem odd, reflection is a very useful form of acoustic treatment, especially in concert halls. Adding reflections to the direct sound is what makes concert halls what they are. However, adding reflections to a monitoring environment can impede critical analysis by coloring the sound coming from the speakers. It is not a question of reflections being good or bad; rather, the designer must decide to include or exclude reflections based on the use of the facility and the desired outcome.
For more information on the design of usefully reflective surfaces for large spaces, see Chapter 7, especially Section 7.3.4.

### 5.5 Electronic Treatments

Absorptive acoustical treatments effectively add damping to the room. The reduction of decay is generally the goal. It is a myth that electronics can be used in place of absorptive acoustical treatments. There is no electronic device that can be inserted into the signal path that will prevent sound from a loudspeaker from reflecting off the surfaces of the room. Nonetheless, since the beginning of the electroacoustic era, devices such as electronic absorbers and room equalizers have been proposed. Not all of these are without merit. As early as 1953, Olson and May proposed an electronic sound absorber consisting of a microphone, amplifier, and loudspeaker. Over a short distance from the microphone, the device could be tuned to achieve as much as 10 to 20 dB of practical attenuation over a 1 to 2 octave range of low frequencies. Olson and May proposed that their electronic sound absorbers could be used to reduce noise at the ears of airline passengers and factory workers. Unfortunately, the ineffectiveness of this type of absorber over larger distances made it impractical for use in architectural applications. The concept, however, paved the way for future developments.

The invention of the parametric equalizer (PEQ) brought a new wave of hope for electroacoustical treatments. Unfortunately, the insertion of a PEQ into the signal chain, even to reduce narrowband problems in small rooms, usually caused more harm than good. Because of the variability of the sound pressure distribution in a small room, the desired effect of the PEQ was usually limited to a small area of the room. Additionally, phase anomalies usually made the treatment sound unnatural. The use of a PEQ to tune a recording studio control room, for example, came and went quickly and for good reason.

The age of digital signal processing, combined with the availability of high-quality audio equipment to a wider range of users, such as home theater owners, ushered in a new hope for electroacoustical treatments. The most recent devices, while sometimes referred to as room equalization (as in previous decades), are often referred to as digital room correction, or DRC. The most important improvement of these devices over their analog ancestors is their ability to address sound problems occurring in the time/phase domains. The latest in DRC systems are able to address minimum-phase problems, such as axial room modes (see Chapter 6). These problems often manifest themselves not as amplitude problems (which are what would be addressed in the use of analog equalizers), but as decay problems. Modern DRC systems, such as those developed by Wilson et al., that incorporate the latest in digital signal processing, can now actually add the damping that is required to address minimum-phase low-frequency problems. Additionally, many DRC systems require that the room response be measured at multiple listening locations in the room so that algorithms can be used to determine corrections that can benefit a larger area of the room.

The same advances in signal processing have also brought about wider applications for the original electronic sound absorber of Olson and May. Bag End has developed the E-Trap, an electronic bass trap that offers the ability to add significant and measurable damping at two different low frequencies.

While DRC devices and electronic traps offer much in the way of being able to actually address the problems with the loudspeaker-room interface, they cannot be expected to be more than electronic tweaks. They cannot replace a good acoustical room design with proper incorporation of nonelectronic treatments. They can provide some damping, particularly in the lowest octave or two where in many rooms it is often impractical—if not impossible—to incorporate porous or resonant absorbers.

### 5.6 Acoustical Treatments and Life Safety

The most important consideration when selecting acoustical treatments is safety. Most often, common sense should prevail. For example, asbestos acoustical treatments—which were quite popular several decades ago—should be avoided because of the inherent health risks associated with handling asbestos materials and breathing its fibers. Acoustical treatments will have to meet any applicable building codes and safety standards to be used in a particular facility. Specific installations may also dictate that specific materials be avoided because of allergies or special use of the facility—e.g., health care or correctional facilities. Since many acoustical treatments will be hung from walls and ceilings, only the manufacturer-approved mounting methods should be used to prevent injury from falling objects. The two most common health and safety concerns for acoustical treatment materials are flammability and breathability.

Acoustical treatments must not only meet the applicable fire safety codes, but, in general, should not be flammable. The flammability of an interior finish such
as an acoustical treatment is typically tested in accordance with the ASTM E84 standard to measure flammability.\textsuperscript{38} The results of the ASTM E84 test are a flame spread index and a smoke developed index. Building codes further classify materials according to the test results. International Building Code (IBC) classifications are as follows:\textsuperscript{39}

- Class A: Flame spread index = 0–25, smoke developed index = 0–450.
- Class B: Flame spread index = 26–75, smoke developed index = 0–450.
- Class C: Flame spread index = 76–200, smoke developed index = 0–450.

Materials to be used as interior finishes, such as acoustical treatments, are often tested in accordance with ASTM E84, with test results provided in manufacturer literature. The ASTM E84 test results and corresponding IBC classifications for some typical acoustical materials are summarized in Table 5-4.

In general, most acoustical materials are Class A materials. Some acoustical foam treatments, as well as some acoustical treatments made of wood, are Class B. Care should be taken that any acoustical treatments made of foam or wood have been tested and that the manufacturer can provide proof of testing. It should also be noted that some jurisdictions require that acoustical foam materials be subjected to more stringent flammability requirements, such as the NFPA 286 test method.\textsuperscript{40}

With regards to breathability, precautions should be taken if the acoustical treatment material contains fibers that could be respiratory or skin irritants. The fibers of many common acoustical treatments, such as glass fiber and mineral wool panels, are respiratory and skin irritants, but are harmless once the treatments have been installed in their final configuration, usually with a fabric or other material encasing the fibrous board. Nonetheless, precautions such as wearing gloves and breathing masks should be taken when handling the raw materials or when installing the panels. Additionally, damaged panels should be repaired or replaced in order to minimize the possibility of fibers becoming airborne.

Some facilities may have additional safety requirements. Some health care facilities, for example, mold or bacterial growth. Clean room facilities may also prohibit the use of porous materials on the grounds of minimizing the introduction of airborne particles. Correctional facilities will often prohibit any materials that can be burned (including some fire-resistant materials) and securing acoustical treatment panels to walls or ceilings without any removable mechanical fasteners, such as screwed, rivets, bolts, etc. Still other facilities may have safety requirements based on, for example, the heat produced by a piece of machinery, the chemicals involved in a manufacturing process, and so on. The applicable laws, codes, and regulations—including rules imposed by the end user—should always be consulted prior to the purchase, construction, and installation of acoustical treatments.

### 5.7 Acoustical Treatments and the Environment

Acoustical treatments should be selected with an appropriate level of environmental awareness. Depending on the application, selection could include not only what the material itself is made of, but also how it is made, how it is transported to the facility, and how it will be disposed of should it be replaced sometime in the future. Many acoustical treatments, such as those consisting of natural wood or cotton fibers, can contribute to Leadership in Energy and Environmental Design (LEED) certification.

Even acoustical treatments such as polyurethane foam panels, which are a byproduct of the petroleum refining process and can involve the use of carbon dioxide (a greenhouse gas) in the manufacturing process, are becoming more environmentally friendly. For example, one manufacturer of acoustical foam products, Auralex Acoustics, Inc., has begun using soy components in their polyurethane products, thereby reducing the use of carbon-rich petroleum components by as much as 60%.

The best possible environmentally friendly approach to the use of acoustical treatments is to limit their use. The better a facility can be designed from the beginning, the fewer specialty acoustical treatment materials will be required. Rooms from recording studios to cathedrals that are designed with acoustics in mind from the beginning generally require relatively fewer specialty acoustical treatments. Acoustical treatments are difficult to avoid completely; almost every space where the production or reproduction of sound takes place, or where the ability to communicate is tantamount, will require some acoustical treatment. Nonetheless, the most conservative approach to facility design should ensure that only those acoustical treatments that are absolutely necessary are implemented in the final construction.

6.1 Introduction

The acoustics of small rooms is dominated by modes, shape, and reflection management. Acousticians who build large rooms are frequently frustrated with small room design because few of the intellectual tools of the trade that work in large rooms can be applied to small rooms. Getting small rooms to sound right involves art and science. The science part is mostly straightforward. The creative part is quite subjective and a great sounding small room can be just as elusive as a great sounding concert hall.

6.2 Room Modes

A room mode is a phenomenon that occurs whenever sound travels between two reflecting surfaces where the distance between the surfaces is such that the impinging wave reflects back on itself creating a standing wave. The distribution of modes determines the low frequency performance of a small room. Consider a sound source $S$ emitting a sinusoidal signal between two isolated reflecting surfaces as in Fig. 6-1. Starting at a very low frequency, the frequency of the oscillator driving the source is slowly increased. When a frequency of $f_0 = \frac{1130}{2L}$ (in feet) is reached, a so-called standing-wave condition is set up. Consider what is happening at the boundary. Particle velocity must be zero at the wall surface but wherever particle velocity is zero, pressure is at maximum level. The wave is reflected back out of polarity with itself, that is to say that the reflection is delayed by $\frac{1}{2}$ of the period. This results in a cancellation that will occur exactly midpoint between the reflecting surfaces. If the walls are not perfect reflectors, losses at the walls will affect the heights of the maxima and the depths of the minima. In Fig. 6-1 reflected waves traveling to the left and reflected waves traveling to the right interfere, constructively in some places, destructively in others. This effect can be readily verified with a sound level meter which will show maximum sound pressures near the walls and a distinct null midway between the walls.

As the frequency of the source is increased, the initial standing-wave condition ceases, but at a frequency of $2f_0$ another standing wave appears with two nulls and a pressure maximum midway between the walls. Other standing waves can be set up by exciting the space between the walls at whole number multiples of $f_0$. These are called axial modes as they occur along the axis of the two parallel walls.

The two walls of Fig. 6-1 can be considered the east and west walls of a room. The effect of adding two more pairs of parallel walls to enclose the room is that of adding two more axial standing-wave systems, one along the east-west axis and the other along the vertical axis. In addition to the two axial systems that are set up, there will be a standing wave associated with two times the path length that involves all four surfaces. These modes are called tangential modes, Fig. 6-2. Most rooms will have six boundaries and there are modes that involve all six surfaces as well, Fig. 6-3. These modes are called oblique modes.

In 1896 Lord Rayleigh showed that the air enclosed in a rectangular room has an infinite number of normal or natural modes of vibration. The frequencies at which these modes occur are given by the following equation:

$$f = \frac{c}{2N} \left( \frac{p}{L} \right)^2 + \left( \frac{q}{W} \right)^2 + \left( \frac{r}{H} \right)^2$$

(6-1)

where,

- $c$ is the speed of sound, 1130 ft/s (or 344 m/s),
- $L$ is the length of the room in feet (or meters),
- $W$ is the width of the room in feet (or meters),
- $H$ is the height of the room in feet (or meters),
- $p$, $q$, and $r$ are the integers 0, 1, 2, 3, 4, and so on.
If we consider only the length of the room, we set \( q \) and \( r \) to zero, their terms drop out, and we are left with

\[
f = \frac{c}{2} - \frac{1}{N} \frac{1}{(L)^2}
\]

\[
= \frac{c}{2} - \frac{1}{L}
\]

\[
= \frac{1130}{2L}
\]

\[
= \frac{565}{L} \text{ in feet}
\]

\[
= \frac{172}{L} \text{ in meters}
\]

which looks familiar because it is the \( f_0 \) frequency of Fig. 6-1. Thus, if we set \( p = 1 \) the equation gives us \( f_0 \). When \( p = 2 \) we get \( 2f_0 \), with \( p = 3, 3f_0 \) and so on. Eq. 6-1 covers the simple axial mode case, but it also presents us with the opportunity of studying forms of resonances other than the axial modes.

Eq. 6-1 is a 3D statement based on the orientation of our room on the \( x, y, \) and \( z \) axes, as shown in Fig. 6-4. The floor of the room is taken as the \( x \) plane, and the height is along the \( z \) axis. To apply Eq. 6-1 in an orderly fashion, it is necessary to adhere to standard terminology. As stated, \( p, q, \) and \( r \) may take on values of zero or any whole number. The values of \( p, q, \) and \( r \) in the standard order are thus used to describe any mode. Remember that:

- \( p \) is associated with length \( L \).
- \( q \) is associated with width \( W \).
- \( r \) is associated with height \( H \).

Figure 6-2. Tangential room modes.

Figure 6-3. Oblique room modes.

Figure 6-4. The floor of the rectangular room under study is taken to be in the \( xy \) plane and the height along the \( z \) axis.

We can describe the four modes of Fig. 6-1 as 1,0,0; 2,0,0; 3,0,0; and 4,0,0. Any mode can be described by three digits. For example, 0,1,0 is the first-order width mode, and 0,0,2 is the second-order vertical mode of the room. Two zeros in a mode designation mean that it is an \textit{axial mode}. One zero means that the mode involves two pairs of surfaces and is called a \textit{tangential mode}. If there are no zeros in the mode designation, all three pairs of room surfaces are involved, and it is called an \textit{oblique mode}.

6.3 Modal Room Resonances

In order to better understand how to evaluate the distribution of room modes, we calculate the modal frequencies for three rooms. Let us first consider a room with dimensions that \textit{are not} recommended for a sound room. Consider a room with the dimensions of 12 ft long, 12 ft wide by 12 ft high (3.66 m \( \times \) 3.66 m \( \times \) 3.66 m), a perfect cube. For the purposes of this exercise, let us assume that all the reflecting surfaces are solid and massive. Using Eq. 6-1 to calculate only the
axial modes (for now) we see a fundamental mode at 565/12 or 47.08 Hz. If we continue the series, looking at the 1,0,0; 2,0,0; 3,0,0…10,0,0 modes we see the results in Table 6-1.

</table>

Before we continue the calculation, let us examine what this table is indicating. The frequencies listed are those and only those that are supported by these two walls; that is to say there will be some resonance at these frequencies but at no others. When the source is cut off, the energy stored in a mode decays logarithmically. The actual rate of decay is determined by the type of mode and the absorptive characteristics of whatever surfaces are involved with that mode. An observer in this situation, making a sound with frequency content that includes 141 Hz, may hear a slight increase in amplitude depending on the location in the room. The observer will also hear a slightly longer decay at 141 Hz. At 155 Hz, for example, there will be no support or resonance anywhere between these two surfaces. The decay will be virtually instantaneous as there is no resonant system to store the energy. Of course, in a cube the modes supported by the other dimensions (0,1,0; 0,2,0; 0,3,0… 0,10,0 and 0,0,1; 0,0,2; 0,0,3… 0,0,10) will all be identical, Table 6-2.

We can clearly see the triple modes that occur at every axial modal frequency, and there is 47 Hz (equal to \( f_0 \)) between each cluster. The space between each cluster is important because if a cluster of modes or even a single mode is separated by more than about 20 Hz from its nearest neighbor, it will be quite audible as there is no masking from nearby modes. Consider another room that does not have a good set of dimensions for a sound room, but represents a typical room size because
of standard building materials. Our next test room is
16 ft long by 12 ft wide with a ceiling height of 8 ft
(4.88 m × 3.66 m × 2.44 m). Table 6-4 shows the length,
width, and height modes, and Table 6-5 shows the same
data sorted into order according to frequency.

• If we examine the data in Fig. 6-6 we see that there are
some frequencies which are supported by only one dimension. 35 Hz, for example, is only supported by the 16 ft (4.88 m) dimension. Other frequencies, like 70 Hz, occur twice and are supported by length and height. Still others like 141 Hz occur three times and are supported by all three dimensions. In the nomograph of Fig. 6-6, the height of the line indicates the magnitude of the mode. This room is clearly
better than a cube, but it is far from ideal as there are
many frequencies which will stand out. 70 Hz, 141 Hz, 211 Hz, 282 Hz, and 253 Hz are all going to be problem frequencies in this room.

Figure 6-6. Number of modes and frequencies for a room 16 ft × 12 ft × 8 ft. From AcousticX.

Now consider a room that has dimensions that might be well suited for an audio room; 23 ft long by 17 ft wide by 9 ft high ceiling (7 m × 5.18 m × 2.74 m). The sorted data and nomograph are shown in Table 6-6 and Fig. 6-7.

The data in Fig. 6-7 look quite different from the data in Fig. 6-5 and Fig. 6-6. There are no instances where all three dimensions support the same frequency. There is also a reasonably good distribution of modes across the spectrum. There are a few places where the difference between the modes is quite small, like the

</table>

space between the 4,0,0 and the 0,3,0. These three
rooms, the cube, the room with dimensions determined
by the builder, and the last room demonstrate the first
important principle when dealing with room modes.
The ratio of the dimensions determine the distribution of modes. The ratio is determined by letting the smallest dimension be 1 and dividing the other dimensions by the smallest. Obviously, the cube with its ratio of 1:1:1 results in an acoustic disaster. Even though a 12 ft (3.66 m) cube will sound differently from a 30 ft (9 m) cube, both rooms will exhibit the same modal distribution and it is the distribution that overwhelmingly determines the low frequency performance of a small room. The second room determined by the dimension of common building materials has a ratio of 1:1.5:2.0. The ratio is determined by letting the smallest dimension be 1 and dividing the other dimensions by the smallest. So an 8 ft by 16 ft by 24 ft room would have the ratio of 1:2:3. The third room, which seems reasonably good at this point, has a ratio of 1:1.89:2.56. From this we can see that in order to have a reasonable modal distribution one should avoid whole number ratios and avoid dimensions that have common factors.

6.3.1 Comparison of Modal Potency

To this point we have only considered the axial modes. The three types of modes, axial, tangential, and oblique differ in energy level. Axial modes have the greatest energy because there are the shortest distances and fewest surfaces involved. In a rectangular room tangential modes undergo reflections from four surfaces, and oblique modes six surfaces. The more reflections the greater the reflection losses. Likewise the greater the distance traveled the lower the intensity. Morse and Bolt state from theoretical considerations that, for a given pressure amplitude, an axial wave has four times the energy of an oblique wave. On an energy basis this means that if we take the axial waves as 0 dB, the tangential waves are −3 dB and the oblique waves are −6 dB. This difference in modal potency will be even more apparent in rooms with significant acoustical treatment. In practice it is absolutely necessary to calculate and consider the axial modes. It is a good idea to take a look at the tangential modes because they can sometimes be a significant factor. The oblique modes are rarely potent enough in small rooms to make a significant contribution to the performance of the room.

6.3.2 Modal Bandwidth

As in other resonance phenomena, there is a finite bandwidth associated with each modal resonance. The bandwidth will, in part, determine how audible the modes are. If we take the bandwidth as that measured at the half-power points (−3 dB or 1/2), the bandwidth is

\[ \Delta f = \frac{k_n}{\pi} \]

where,

\( \Delta f \) is the bandwidth in hertz,

\( f_2 \) is the upper frequency at the −3 dB point,

\( f_1 \) is the lower frequency at the −3 dB point,

\( k_n \) is the damping factor determined principally by the amount of absorption in the room and by the volume of the room. The more absorbing material in the room, the greater \( k_n \).

If the damping factor \( k_n \) is related to the reverberation time of a room, the expression for \( \Delta f \) becomes

\[ \Delta f = \frac{6.91}{\pi T} \]

\[ = \frac{2.2}{T} \]

where,

\( T \) is the decay time in seconds.

From Eq. 6-4 a few generalizations may be made. For decay times in the range of 0.3 to 0.5 s, typical of what is found in small audio rooms, the bandwidth is in the range 4.4 to 7.3 Hz. It is a reasonable assumption that most audio rooms will have modal bandwidths of the order of 5 Hz. Referring back to Table 6-6 it can be seen that in a few instances there are modes that are within 5 Hz of each other. These modes will fuse into one and occasionally some beating will be audible as the modes decay. Modal frequencies which are separated on both sides by 20 Hz or more will not fuse at all, and will be noticeable as well, although not as noticeable as a double or triple mode. Consider a room with the dimensions of 18 ft × 13 ft × 9 ft (5.48 m × 3.96 m × 2.74 m). The axial frequencies are listed in Table 6-7. There are some frequencies which double, such as 62 Hz and 125 Hz. These are obvious problems.
However 282 Hz is also a problem frequency because it is separated by more than 20 Hz on either side.

**6.4 Criteria for Evaluating Room Modes**

So far we have shown that there are a few general guidelines for designing small rooms with good distribution of room modes. We know that if two or more modes occupy the same frequency or are bunched up and isolated from neighbors, we are immediately warned of potential coloration problems. Over the years, a number of authors have suggested techniques for the assessment of room modes and methods for predicting the low frequency response of rooms based on the distributions of room modes. Most notably Bolt, Gilford, Louden, Bonello, and D’Antonio have all suggested criteria. Possibly the most widely used criteria is that suggested by Bonello.

Bonello’s number one criterion is to plot the number of modes (all the modes, axial, tangential, and oblique) in 1/3 octave bands against frequency and to examine the resulting plot to see if the curve increases monotonically (i.e., if each 1/3 octave has more modes than the preceding one or, at least, an equal number). His number two criterion is to examine the modal frequencies to make sure there are no coincident modes, or, at least, if there are coincident modes, there should be five...
or more modes in that \( \frac{1}{3} \) octave band. By applying Bonello’s method to the 23 ft \( \times \) 17 ft \( \times \) 9 ft room, we obtained the graph of Fig. 6-8. The conditions of both criteria are met. The monotonic increase of successive \( \frac{1}{3} \) octave bands confirms that the distribution of modes is favorable.

It is possible that the critical bands of the ear should be used instead of \( \frac{1}{3} \) octave bands. Actually, \( \frac{1}{3} \) octave bands follow critical bandwidths above 500 Hz better than do \( \frac{1}{3} \) octave bands. Bonello considered critical bands in the early stages of his work but found that one-third octave bands better show subtle effects of small changes in room dimensions.\(^5\) Another question is whether axial, tangential, and oblique modes should be given equal status as Bonello does when their energies are, in fact, quite different. In spite of these questions, the Bonello criteria are used by many designers and a number of computer programs are using the Bonello criteria in determining the best room mode distributions.

D’Antonio et al, have suggested a technique which calculates the modal response of a room, simulating placing a measurement microphone in one corner of a room then energizing the room with a flat power response loudspeaker in the opposite corner.\(^6\) The authors claim that this approach yields significantly better results than any other criteria.

Another tool which historically has been used to help choose room dimensions is the famous Bolt footprint shown in Fig. 6-9. Please note the chart to the right of the footprint which limits the validity of the footprint. The ratios of Fig. 6-9 are all referenced to ceiling height.

### 6.5 Modes in Nonrectangular Rooms

Nonrectangular rooms are often built to avoid flutter echo and other unwanted artifacts. This approach is usually more expensive, therefore it is desirable to see what happens to modal patterns when room surfaces are skewed. At the higher audio frequencies, the modal density is so great that sound pressure variations throughout a rectangular room are small and there is little to be gained except, of course, the elimination of flutter echoes. At lower audio frequencies, this is not the case. The modal characteristics of rectangular rooms can be readily calculated from Eq. 6-1. To determine modal patterns of nonrectangular rooms, however, requires one of the more complex methods, such as the use of finite elements. This is beyond the scope of this book. We, therefore, refer to the work of van Nieuwland and Weber of the Philips Research Laboratories of Eindhoven, the Netherlands, on reverberation chambers.\(^8\)

In Fig. 6-10 the results of finite element calculations are shown for 2D rectangular and nonrectangular rooms of the same area (377 ft\(^2\) or 35 m\(^2\)). The lines are contours of equal sound pressure. The heavy lines represent the nodal lines of zero pressure of the standing wave. In Fig. 6-10 the 1,0,0 mode of the rectangular room, resonating at 34.3 Hz, is compared to a 31.6 Hz resonance of the nonrectangular room. The contours of equal pressure are decidedly nonsymmetrical in the latter. In Fig. 6-10 the 3,1,0 mode of the rectangular room (81.1 Hz) is compared to an 85.5 Hz resonance in the nonrectangular room. Increasing frequency in Fig. 6-10, the 4,0,0 mode at 98 Hz in the rectangular room is

---

Figure 6-9. Room proportion criterion.

![Figure 6-9. Room proportion criterion.](image-url)
compared to a 95.3 Hz mode in the nonrectangular room. Fig. 6-10 shows the 0,3,0 mode at 102.9 Hz of a rectangular room contrasted to a 103.9 Hz resonance in the nonrectangular room. These pressure distribution diagrams of Fig. 6-10 give an excellent appreciation of the distortion of the sound field by extreme skewing of room surfaces.

When the shape of the room is irregular, as in Fig. 6-10, the modal pressure pattern is also irregular. The number of modes per frequency band in the irregular room is about the same as the regular room because it is determined principally by the volume of the room rather than its shape. Instead of axial, tangential, and oblique modes characteristic of the rectangular room, the resonances of the nonrectangular room all have the character of 3D (oblique-like) modes. This has been demonstrated by measuring decay rates and finding less fluctuation from mode to mode. Note that the modes did not go away and that there was not a significant change in the frequency of the modes nor in the distribution of the modes relative to frequency. What changed was the distribution of the modes in the physical space. The benefits of asymmetrical, nonrectangular designs must be measured against the drawbacks as we shall see later on in this chapter.

6.6 Summation of Modal Effect

Room modes determine the performance of small rooms below $f_c$. The following criteria should be applied when evaluating room ratios or dimensions in terms of modal distribution. When considering axial modes, there should be no modes within 5 Hz of each other, and no mode should be greater than 20 Hz from another. Since the modal bandwidth in small rooms is approximately 5 Hz, any modes that are within 5 Hz of each other will effectively merge into one. Modes that are isolated by more than 20 Hz will not have masking from any other modes nearby and will likely stand out. Obviously there should not be any double or triple modes. Some criteria

![Figure 6-10](image-url)

**Figure 6-10.** A comparison of calculated 2D sound fields in rectangular and nonrectangular rooms having the same areas. After Reference 8.
should also be applied to all the modes, the axial, tangential, and oblique. There are many excellent tools for calculating modal distribution.

6.7 The Question of Reverberation

W.C. Sabine, who first formulated the equation to calculate reverberation time, described reverberation in this way: “reverberation results in a mass of sound filling the whole room and incapable of analysis into its distinct reflections.” What Sabine was saying, although he did not use these terms, was that for true reverberation to exist, there needs to be a homogenous and isotropic sound field. Usually such conditions are approached in physically large rooms that do not contain much absorption. Unfortunately the term reverberation is popularly understood to be equivalent to decay. Does reverberation time refer to the decay of a well-established, totally homogenous, diffuse sound field that exhibits no net energy flow due to the richness of the reflections present or does reverberation time refer to the decay of any sound in a room no matter what the nature of the sound is, even if it is not diffuse? To some extent, this is a question of semantics. It is interesting to note that maybe Sabine himself perhaps anticipated the confusion that would eventually arise because in the same paper he wrote:

The word “resonance” has been used loosely as synonymous with “reverberation” and even with “echo” and is so given in some of the more voluminous but less exact popular dictionaries. In scientific literature the term has received a very definite and precise application to the phenomenon where ever it may occur. A word having this significance is necessary; and it is very desirable that the term should not, even popularly, by meaning many things, cease to mean anything exactly.

It is the opinion of this author that this is precisely where we find ourselves today. Without a rigorous definition and application of the concept of reverberation, we are left with something which ceases to mean anything exactly.

When Sabine first measured the decay of the reverberation in Fogg Lecture Hall at Harvard, he did it with an organ pipe and a stopwatch. He had no way of examining the fine detail of the reflections or any of the components of the sound field, nor was he initially looking at decay as a function of frequency. (Later on he looked at decay as a function of frequency, but never connected this to room size or shape.) He could only measure the decay rate of the 513 Hz pipe he was using. The volume of the lecture hall was approximately 96,700 ft\(^3\). The room was large enough that 512 Hz was not going to energize any of the normal room modes. Since there was virtually no absorption in the room whatsoever, it is likely that Sabine was measuring a truly diffuse sound field. It is interesting to note that in Sabine’s early papers he rarely mentions the dimensions other than the volume of the rooms he was working in. He was convinced that it was the volume of the room that was important. The mean free path was also central to his thesis. The \(MFP\) is defined as the average distance a given sound wave travels in a room between reflections. The equation for finding the mean free path is

\[
MFP = \frac{4V}{S}
\]

where,

\(V\) is the volume of the room,
\(S\) is the total surface area.

Consider a small room with dimensions of 12 ft \(\times\) 16 ft \(\times\) 8 ft high (3.66 m \(\times\) 4.88 m \(\times\) 2.44 m). This room will have a volume of 1536 ft\(^3\) (43.5 m\(^3\)) and a total surface area of 832 ft\(^2\) (77.3 m\(^2\)). Putting these numbers into Eq. 6-5 yields a result of a MFP of about 7.38 ft. At the average speed of sound (1130 ft/s or 344 m/s) this distance will be covered in 0.00553 s or 5.53 ms. It is generally accepted that in small rooms, after approximately four to six bounces, a sound wave will have lost most of its energy to the reflecting surfaces and will become so diffuse as to be indistinguishable from the noise floor. This of course depends on the amount of absorption in the room. In very absorptive rooms there may not be even two bounces. In very live hard rooms a wave may bounce more than six times. In this room a single wave will take only 32.6 ms to bounce five times and be gone. Compare this with a large room. Consider a room that is 200 ft long by 150 ft wide with a 40 ft ceiling (61 m \(\times\) 45.7 m 12.2 m). This room will have a \(MFP\) of 54.5 ft (16.61 m). It will take 241.3 ms for a single wave to bounce five times and dissipate.

Sabine was not interested in the shape of the room or even in the distribution of the absorptive material. He focused on the statistical nature of the diffuse sound field and on the rate of decay. Other researchers looked at similar issues eventually dividing the time domain performance into smaller and smaller regions and examining their contributions to the subjective performance of rooms.
Fig. 6-11 is an Envelope* Time Curve of a large, reverberant room, measured using time delay spectrometry. The left side of the graph represents $t_0$ or the beginning of the measurement. Note that this is the point in time what the signal leaves the loudspeaker. If the microphone represents the observer in this system, the observer would not hear anything until $t(0) + t(x)$ where $t(x)$ is the time of takes for the sound to leave the loudspeaker and arrive at the observation point. In this measurement, that time is 50 ms because the loudspeaker was about 56 ft (17 m) away from the microphone. This first arrival is known as the direct sound because it is the sound energy that first arrives at the listener or microphone, before it reflects off of any surface. A careful examination of this graph shows a small gap between the direct sound and the rest of the energy arriving at the microphone. This is known as the initial time gap (ITG) and it is a good indicator of the size of the room. In this room it took about 50 ms for the sound to travel from the loudspeaker to the microphone then another 40 ms (90 ms total) for sound to leave the speaker and bounce off of some surface to arrive at the microphone. Therefore, in this room the ITG is about 40 ms wide.

Fig. 6-12 is an enlargement of the first 500 ms of Fig. 6-11. The ITG can be clearly seen and is about 40 ms long. The sound then takes about 130 ms or so to build up to a maximum at around 270 ms. Fig. 6-12 shows that the sound then decays at a fairly even rate over the next 4 s till the level falls into the noise floor.

If we perform a Schroeder integration28 of the energy then measure the slope and extrapolate down to 60 dB below the peak, we see the reverb time of this room to be on the order of 6.8 s at 500 Hz, Fig. 6-13.

It is useful to take a look at the ETC of a small room for comparison, Fig. 6-14.

Careful examination of Fig. 6-14 reveals a room dominated by strong discrete reflections that start coming back to the observation point within a few ms of the direct sound. By 30 ms after the direct sound, the energy has decayed into the noise floor.

Since there is no significant diffuse or reverberant field in acoustically small rooms, equations having reverb time as a variable are not appropriate.

It is important to understand that small rooms must be treated differently with respect to frequency.

Consider Fig. 6-15. These boundaries should not be understood as absolute or abrupt. They are meant to serve as guidelines and the transitions from one region to another are actually very gradual.

Region 1 is the region from 0 Hz up to the first mode associated with the longest dimension. In this region there is no support from the room at all, and there is not much one can do to treat the room. Region 2 is bounded

---

* The term Energy Time Curve was suggested by Heyser and adopted by Crown and Gold Line, respectively, in their Time Delay Spectrometry software. Recently Davis and Patronis have suggested that Envelope Time Curve is a better label for this graph.

---

![Figure 6-11. ETC of a large reverberant church. Measurement courtesy of Jim Brown.](image)
by the first mode on the low end of the spectrum and \( f \) at the high end, where \( f \approx 3C/RSD \) (rooms smallest dimension). In this region where the room modes dominate the acoustical performance, wave behavior is the best model and some forms of bass absorption can work well. Region 3 spans from \( f \) to roughly four times \( f \). This region is dominated by diffraction and diffusion. The final region is where the wavelengths are generally small relative to the dimensions of the room. In this region, one can use a ray acoustics approach as we are dealing with specular reflections.

The discussion of how to quantify the decay of sound in small rooms continues. Most recording studios, control rooms, and listening rooms are too small to have a completely diffuse sound field, especially at the lower frequencies. In small, acoustically dead rooms the only frequencies that have any significant decay are those that are at or very near to the natural resonances of the room. This decay time is,
strictly speaking, reverberation and should be treated as such. The Sabine equation and its offspring are not going to help in predicting how much absorption is going to be needed to modify a room. More discussion and research are needed to be able to fully quantify the behavior of absorption in small rooms.

As is mentioned in Chapter 5, the standard way to measure acoustical treatment is according to ASTM C 423-00. This is an indirect method that looks at the impact that the material has on a diffuse sound field. In rooms that do not exhibit any diffuse sound field in the frequency range of interest, we need another way to measure acoustic treatment. An alternative method is outlined in Chapter 5.

6.7.1 Room Shape

We have referred to the statistical approach (e.g., reverberation) and the wave approach (modes) to acoustical problems, and now we come to the geometrical approach.

The one overriding assumption in the application of geometrical acoustics is that the dimensions of the room are large compared to the wavelength of sound being considered. In other words, we must be in region 3 of Fig. 6-15 where specular reflection prevails and the short wavelengths of sound allow treating sound like rays.

A sound ray is nothing more than a small section of a spherical wave originating at a particular point. It has a definite direction and acts as a ray of light following the general principles of geometric optics. Geometrical acoustics is based on the reflection of sound rays. This is where the shape of the room is the controlling acoustical aspect. Like the quest for room ratios the search for the perfect room shape is also elusive. Some have suggested that non-parallel surfaces are a must, however there are no perfect shapes. There are some shapes that work well for some applications.

6.7.2 Reflection Manipulation

In open space (air-filled space, of course) sound travels unimpeded in all directions from a point source. In real rooms we don’t have point sources, we have loudspeakers or other sound sources such as musical instruments that do not behave like the theoretical point source. Real sources have characteristic radiation or directional patterns. Of course in real rooms the sound does not travel unimpeded for very long, depending on the MFP. After the sound leaves its source it will bounce off of some surface and will interact with the unreflected sound. This interaction can have a profound impact on the perception of the original sound. There is
an elegant way to model the reflections in a room. The reflection can be considered to come from an image of the source on the opposite side of the reflecting surface and equidistant from it. This is the simple case: one source, one surface, and one image. If this reflecting surface is now taken to be one wall of a room, the picture is immediately complicated. The source now has an image in each of five other surfaces, a total of six images sending energy back to the receiver. Not only that, images of the images exist and have their effect, and so on. A physicist setting out to derive the mathematical expression for sound intensity from the source in the room at a given receiving point in the room must consider the contributions from images, images of the images, images of the images of the images, and so on. This is known as the image model of determining the path of reflections. The technique is fully described in Chapter 9.

6.7.3 Comb Filters

When the direct sound and a reflection combine at some observation point, a spectral perturbation often called a comb filter is produced. The frequency of the first notch and the spacing of the rest of the notches is base on the delay between the two arrivals. The first notch \( F \) in hertz is calculated by

\[
F = \frac{1}{2t}
\]

where,

\( t \) is the delay in seconds.

Each successive notch will be at

\[
\frac{1}{t}
\]

Fig. 6-16 shows the response of a system with a delay of 1.66 ms between the two signals. Reflections can dramatically change the way program material sounds depending on the time of arrival, the intensity, and the angle of incidence relative to the listener. For a more in-depth treatment of how comb filters are created, the reader is referred to reference 16.

In 1971 M. Barron wrote a paper exploring the effects of reflections on the perception of a sound. He was trying to quantify the effects of lateral reflections in concert halls. Although his work was conducted in large reverberant spaces, a number of small room designers look to his work with great interest as he is considering the first 100 ms of a sound field in a room. In small rooms that is often all you will get. Fig. 6-17 is a graphic summary of the effects of a single lateral reflection. It can be seen that the very early reflections, on the order of 0 to 5 ms, can cause image shifts even when very low in amplitude relative to the direct sound. This can be important as one considers, for example, the accepted practice of placing loudspeakers on the meter bridge of a recording console.

Fig. 6-18A shows an ETC of a popular nearfield loudspeaker placed on the meter bridge of a recording console, measured at the mix position. The first spike is of course the direct arrival of the signal from the loudspeaker. The second spike is the reflection off of the face of the console, approximately 1.2 ms later. Fig. 6-18B shows the resulting frequency response when these two signals arrive at the microphone. Finally C is the frequency response of three loudspeaker with the reflection removed. This author finds it curious indeed that this practice of placing a loudspeaker on the console ostensibly to remove the effects of the room and get a more accurate presentation actually results in seriously coloring the response of the speaker, and will
have a significant impact on the ability to accurately perceive a stereo image.

Although Barron did not look at the effect of reflections arriving from below as in the case of a console reflection, the effect is clearly audible. In 1981 C.A.P. Rodgers noted a similarity between the spectral notches created as a result of loudspeaker misalignment and those created by the pinna which have been shown to play an important role in localization. She postulated that the presence of spectral notches would impair or at least confuse the auditory system's ability to decode position cues. This could explain the phenomenon noted by Barron. The very early reflections are those that cause notches similar in spectral positioning to those caused by the pinna. These are the reflections that cause image shifts.

6.8 Small Room Design Factors

The basic tools for looking at small room performance have been addressed. We now turn our attention to small room design factors. We have divided small rooms into three broad categories; precision listening rooms, rooms for microphones, and rooms for entertainment. We are not trying to imply that there is only one way to build a control room or an entertainment room. There are different design criteria for different outcomes. The categories presented here are not intended to be exhaustive; rather they are intended to be general and representative. It should also be noted that we are not including the noise control issues that are often an important part of room design. The reader is referred to Chapter 3 for noise control information.

6.8.1 The Control Room Controversy

Since most control rooms are acoustically small, it is appropriate to discuss control room design in general in this context. Some insist that control rooms should be as accurate as possible. Others insist that since music is rarely listened to in highly precise analytic rooms, recorded music would be better served if control rooms were more like entertainment rooms; not so sterile, but rather designed so that everything sounds subjectively great. Indeed many recordings are made in rooms that are not close to precision listening rooms. This debate will probably never be resolved as long as there are deductive and inductive reasoners, left-brain and right-brain people, artists and engineers. In the next few sections we are not attempting to solve this debate, rather we are trying to set out some simple guidelines. The most important task for the room designer is to listen to the client and not make assumptions about what it is he or she is looking for.

6.8.2 Precision Listening Rooms

These are rooms where the primary goal is for the listener to have as much confidence as possible that what is heard is precisely what is being or has been recorded. Frequently, users of these rooms are performing tasks that require listening analytically to the program and making decisions or judgments about what is heard.
Examples of rooms in this category are recording control rooms, mastering suites, and audio production rooms. The state of the art at this writing does not permit us to design transducers or electronics that are perfect so as to afford the user 100% confidence that what is heard is fully equivalent to what has been or is being recorded. We can, however, design rooms that fully meet this criterion. An anechoic chamber would indeed be 100% neutral to the loudspeaker, allowing the user to hear precisely and only what is coming out of the speaker. The problem is that anechoic chambers are quite possibly the most acoustically hostile places we can imagine. It is difficult to spend a few minutes in an anechoic chamber let alone try to be creative and make artistic decisions about music in one. The challenge is to build a room that will not significantly interact with the loudspeaker by means of room modes or reflections that arrive at the listening position and still be a place that is subjectively acceptable to the user. There have been a number of good approaches to this problem over the years starting with LEDE™, Reflection Free Zone™ (RFZ), and the Selectively Anechoic Space™. Later came Tom Hidley’s neutral room or nonenvironment design and more recently, David Moulton has proposed his wide-dispersion design. These approaches all endorse attenuating or completely eliminating all the early reflections, creating a space that is essentially anechoic when energized by the loudspeakers and listened to in the prescribed position, but in all other ways it is an average room. Reflections can be eliminated or reduced at the listening position by changing the angle of incidence. The energy time curve should be measured to insure that the direct sound is not compromised over the entire listening area.

On the surface one might wonder why all sound rooms are not built this way. The reason is that most people do not listen to music analytically. In precision rooms, music that is poorly recorded will sound that way. One can certainly design rooms where the music sounds better than it does in a precision room. There are artifacts that one can build into a room that are subjectively very pleasing, but they are part of the room and not the recording. The recording engineer generally wants to know what exactly is in the recording. The engineer generally listens to the product in a number of different environments before releasing it to insure that it does hold up even under nonideal conditions.

So-called good sounding artifacts can be observed in the frequency domain as well as the time domain. For example, if a room has an audible room mode at 120 Hz music might sound full and rich in the upper low end and be quite pleasing, however the fullness is in the room, not the recording. The recording may in fact be “thin” or lacking in the low end because the room is adding to the mix. In the time domain, a reflection that occurs in the first 10 ms or so and comes from the side (a lateral reflection) might result in a perception of a stereo image that is much wider than the physical separation of the speakers might allow. This might be perceived as a very good sound stage, but it is an artifact of the room and not of the recording.

Designing such a room is an art and a science. It is beyond the scope of this book to detail a complete room design protocol, however, the steps in designing such a room must include:

1. Choosing a set of room ratios that yield a modal distribution that will result in the best possible low frequency performance.
2. Choosing a symmetrical room shape so that each loudspeaker interacts with the room in exactly the same way.
3. Choosing and placing acoustical treatment so that the early reflections (at least the first 18 ms) are attenuated at and are at least 18 dB below the direct sound. Care should be taken to insure that the treatment chosen exhibits a flat absorption characteristic at the frequency range of interest and at the angles of incidence. The energy time curve should be measured to insure that the direct sound is not compromised over the entire listening area.
4. Placing equipment and furniture in the room in such a way as to not interfere with the direct sound. It should be noted that the recording console is often the most significant acoustical element in the control room.
5. Insuring that there are enough live and diffusive surfaces in the room so that the overall subjective feel of the room is that of a normal room and not an anechoic chamber.

### 6.8.3 Rooms for Microphones

Designers are frequently asked to design rooms that are intended for recording or use with live microphones. Recording studios, vocal booths, and even conference rooms could be part of this category. The criteria in these rooms are almost all subjective. End users want rooms that sound good and that are comfortable to work in. The acoustician is well advised to work with a good interior decorator as a significant part of what makes someone feel comfortable in a room is the way the room is decorated and lit. Obviously noise control is a large
part of the design criteria. There are a few general rules that will help with the acoustics of these small rooms:

1. Like the precision rooms, these rooms will work better if the proportions of the room result in optimal modal distribution.
2. Unlike the precision rooms, studios and vocal booths often work best when they are not symmetrical.
3. Avoid parallel surfaces if possible.
4. Use treatment that is as linear as possible, both statistically and by direct measurement of reflected sound.
5. Avoid treating entire surfaces with a single form of treatment. For example, covering an entire wall with an absorber will usually be less effective than treating some areas and leaving some alone.
6. Listen carefully to the kinds of words the end user employs to describe the space either in terms of what is desired or in terms of something that need modification. Words like *intimate*, *close*, *dark*, *dead*, *quiet* are usually associated with the use of absorption. Words like *open*, *live*, *bright*, *airy* are often used in conjunction with diffusion.
7. Placing absorption in the same plane as the microphone will increase the apparent MFP and result in a longer ITG (initial time gap). This often makes the room seem larger. For example, in a vocal booth that is normally used by standing talent, place the absorption on the walls such that both the talent and the microphone are in the same plane as the absorptive area. In a conference room placing a band of absorption around the room at seated head height will help improve the ability to communicate in the room.

### 6.9 Rooms for Entertainment

There was a serious temptation to call this section “Rooms That Sound Good.” The temptation was resisted to avoid the criticism that the section titles would thus imply that precision rooms don’t sound good. It is a matter of goals. As was pointed out, the purpose of the precision room is analysis. This section will cover rooms that are designed for entertainment.

Of course it is much more difficult to set out design criteria for a good sounding room. As with any subjective goal it comes down to the tastes and preferences of the end user. To a great extent how one approaches an entertainment room depends on the type of system to be used, and the type of entertainment envisioned. An audiophile listening room will be treated differently from a home theater. It should be noted that in the world of home entertainment there exists a very rich audio vocabulary. Some of the words that are used like *spaciousness* and *localization* have meanings that are consistent with the use of these words in the scientific audio community. Subjective words like *air*, *grain*, *definition*, *impact*, and *brittleness* are much more ambiguous and are not yet mapped into the physical domain so that we know how to control them. One of the challenges is when the end user wants two mutually exclusive aspects optimized! The so-called Nippon-Gakki experiments of 1979 quite elegantly showed how different subjective effects can be created by simply moving acoustic treatment to different locations in a room, Fig. 6-19. Note that when localization is rated good, spaciousness is rated poor and vice versa.

Some general points:

1. In home entertainment systems the distribution of room modes is somewhat less important. Having modal support in the low end although inaccurate can result in rooms that sound fuller. This might enhance a home theater system.
2. Absorption should be used sparingly. These rooms should be quiet, not dead. If absorption is to be used, it must be linear.
3. Remember that everything in a room contributes to the acoustics of the room. Most home entertainment rooms will have plush furniture that will be a significant source of absorption. The furnishings should be in place before the final treatment is considered.

The furnishings should be in place before the final treatment is considered.

1. Lateral reflections should be emphasized by using critically placed diffusers. Lateral reflections can dramatically increase the sense of spaciousness in a room.
2. Absorptive ceilings tend to create a sense of intimacy and a feeling of being in a small space. If this is not desired, use some absorption to control the very early reflections but leave the rest live.

7.1 Introduction

With musical or spoken performances in auditoriums and concert halls, acoustic evaluation is mainly based on the subjective perception of audience and performers. These judgements are generally not based on defined criteria, but characterize the sensed tonal perception. Besides the secondary factors influencing the overall acoustic impression like, for instance, comfortableness of the seats; air conditioning; interference level; and optical, architectural, and stylistic impression, it is especially the expectation of the listener that plays a significant role for the acoustic evaluation. If a listener in a classical concert is sitting next to the woodwind instruments but hears the brass instruments much louder, even though he cannot see them, his expectations as a listener, and thus the acoustics are off. Numerous subjective and objective room-acoustical criteria were defined and their correlation determined in order to objectify these judgments. However, these individual criteria are closely linked with each other and their acoustic effects can neither be exchanged nor individually altered. They become effective for judgment only in their weighted totality. The judgment of the performers, on the other hand, can be regarded as a kind of workplace evaluation.

Only the musician, singer or speaker who feels completely at ease with all fringe factors will also praise the acoustical quality. The main factors judged here are the sound volume and the mutual listening, which is also responsible for the intonation. An acoustically adequate response from the auditorium has to be realized for the performers so that his positive correspondence supports the overall artistic experience. The overall acoustic impression of his own work as it is perceived in the reception area plays a very subordinate role for the performer. What is important for him, however, are rehearsal conditions where the acoustics are as close as possible to those of the actual performance and acoustical criteria that depend as little as possible on the occupation density both in the audience area as well as in the platform area.

Generally, a performance room must not show any disturbing reflection characteristics like echo effects or flutter echoes. All seats have to guarantee a good audibility that is in good conformity with the auditory expectation. This requires a balanced sound of high clarity and an adequate spaciousness. Localization shifts or deviations between acoustical and visual directional impression must not occur. If the room is used as a concert hall, the spatial unity between the auditorium and the platform areas has to be maintained in order to avoid sound distortions.

Based on these considerations and well-founded, objective measurement technical examinations and subjective tests, partially in reverberation-free rooms within artificially generated sound fields, it is possible to define room-acoustical quality criteria that enable an optimum listening and acoustical experience in dependence on the usage function of the room. The wider the spectrum of usage is, the broader is the limit of the desirable reference value ranges of these criteria. Without extensive variable acoustical measures—also electronic ones—only a compromise brings about a somewhat satisfactory solution. It stands to reason that this compromise can only be as good as the degree in which the room-acoustical requirements coincide with it.

A precondition for an optimum room-acoustical design of auditoriums and concert halls is the very early coordination in the planning phase. The basis here is the establishment of the room’s primary structure according to its intended use (room shape, volume, topography of the spectators’ and the platform areas). The secondary structure that decides the design of the structures on the walls and ceilings as well as their acoustic effectiveness has to be worked out on this basis. A planning methodology for guaranteeing the room-acoustical functional and quality assurance of first-class concert halls and auditoriums as well as rooms with a complicated primary structure is reflected in the application of simulation tests by means of mathematical and physical models (see also Chapter 35 and Section 7.3.1).

7.2 Room-Acoustical Criteria, Requirements

The acoustical evaluation by listeners and actors of the acoustical playback-quality of a signal that is emitted from a natural acoustic source or via electroacoustical devices, is mostly very imprecise. This evaluation is influenced by existing objective causes like disturbing climatic, seating, and visibility conditions as well as by subjective circumstances like, for instance, the subjective attitude and receptiveness towards the content and the antecedents of the performance. Very differentiated is the subjective rating of music, where the term good acoustics is defined, depending on the genre, as a sufficient sound volume, a good time and register clarity of the sound, and a spaciousness that meets the composition. Timbre changes that deviate from the natural timbre of the acoustic sources and from the usual distance dependence (high-frequency sounds are less effective at a larger distance from the place of performance than at closer range) are judged as being unnatural, if traditional music is concerned. These experiences determine also the listening expectation for
a very spatial and reverberating sound in a large cathedral, whereas one expects a dry sound in the open. Thus deviations from this experience are regarded as being bothersome. A listener seated in the front section of a concert hall expects a clearer sound than one seated in a rear section. On the other hand, however, he wants to enjoy an optimally balanced acoustic pattern on all seats, as he has grown up with the media and mainly postprocessed sound productions that are independent of the room, and thus acquired auditory expectations, which do not allow an evaluation of the objectively existing room.

The evaluation of speech is generally a bit easier, since optimum audibility and clear intelligibility are desired here in an atmosphere that is not influenced by the room or electroacoustical means. Perhaps with the exception of sacral rooms, the spaciousness generally does not play such an outstanding role in this regard, whereas sound volume and intelligibility are all the more important.

Numerous room-acoustical criteria were defined in order to clarify the terms applied for the subjective and objective assessment of a spoken or musical performance. In the following we have listed a relevant selection of them, in which context one should note that there is a close correlation between the individual criteria. One single optimally determined parameter may not at all be acoustically satisfactory, because another parameter influences the judgement in a negative way. For example, the optimum value range of center time and definition can only be evaluated with a subjectively correct estimated reverberation time. The guide values of the reverberance measure are valid only if the clarity measure $C_{80}$ is in the optimal range.

On principle, the room-acoustical quality criteria can be subdivided into time and energy criteria. The main type of use—speech or music—then determines the recommendations for the guide values to be targeted. With multi-purpose halls (without available variable measures for changing the acoustics), a compromise is required that should orient itself on the main type of use.

### 7.2.1 Time Criteria

#### 7.2.1.1 Reverberation Time $RT_{60}$

The reverberation time $RT_{60}$ is not only the oldest, but also the most best-known room-acoustical quantity. It is the time that passes after an acoustic source in a room has been turned off until the mean steady-state sound-energy density $w(t)$ has decreased to $1/1,000,000$—i. e., by $60$ dB

$$w(RT) = 10^{-6} w_0.$$  \hspace{1cm} (7-1)

Thus the time response of the sound energy density in reverberation results as

$$w(t) = w_0 - 6\log\frac{t}{RT} - 13.82 \frac{t}{RT} = w_0.$$ \hspace{1cm} (7-2)

The steady-state condition is reached only after the starting time $t_{st}$ of the even sound distribution in a room (approximately 20 sound reflections within 10 ms) after the starting time of the excitation

$$t_{st} = 1\ldots 2(0.17\ldots 0.34)\sqrt{V}$$ \hspace{1cm} (7-3)

where,

- $t_{st}$ is in ms,
- $V$ is in $m^3$ ($ft^3$).

The defined drop of the sound pressure level of $60$ dB corresponds roughly to the dynamic range of a large orchestra. The listener, however, can follow the decay process only until the noise level in the room becomes perceptible. This subjectively assessed parameter **reverberation time duration** thus depends on the excitation level as well as on the noise level.

The required evaluation dynamic range is difficult to achieve even with objective measuring, especially in the low frequency range. Therefore, the reverberation time is determined by measuring the sound level decay in a range from $-5$ dB to $-35$ dB and then defined as $RT_{30\,\text{dB}}$ (also $RT_{30}$). The initial reverberation time (IRT according to Atal, $RT_{15\,\text{dB}}$ between $-5$ dB and $-20$ dB) and the early decay time (EDT according to Jordan, $RT_{10\,\text{dB}}$ between $0$ dB and $-10$ dB) are mostly more in conformity with the subjective assessment of the duration of reverberation, especially at low-level volumes. This also explains the fact that the reverberation time subjectively perceived in the room may vary, while the values measured objectively according to the classical definition with a dynamic range of $60$ dB or $30$ dB are, except admissible fluctuations, generally independent of the location.

Serving as a single indicator for the principal characterization of the room in an occupied or unoccupied state, the reverberation time is used as the mean value between the two octave bandwidths $500$ Hz and
1000 Hz or the four ⅓ octave bandwidths 500 Hz, 630 Hz, 800 Hz, and 1000 Hz, and referred to as the **mean reverberation time**.

The desirable convenient value of the reverberation time $RT_{60}$ depends on the kind of performance (speech or music) and the size of the room. For auditoriums and concert halls, the desired values of the mean reverberation time for between 500 Hz and 1000 Hz with a room occupation of between 80% and 100% are given in Fig. 7-1 and the admissible frequency tolerance ranges are shown in Figs. 7-2 and 7-3. This shows that in order to guarantee a specific warmth of sound with musical performances, an increase of the reverberation time in the low frequency range is admissible (see Section 7.2.1.2), while with spoken performances a decrease of the reverberation time is desirable in this frequency range (see Section 7.2.2.9).

The reverberation time of a room as defined by Eyring mainly depends on the size of the room and on the sound absorbing properties of the boundary surfaces and nonsurface forming furnishings:

$$RT_{60} = 0.163* \frac{V}{-\ln(1 + \bar{a})S_{tot} + 4mV}$$ (7-4)

where,

$RT_{60}$ is the reverberation time in seconds,

$V$ is the room volume in cubic meters (cubic feet),

$\bar{a}$ is $A_{tot}/S_{tot}$ which is the room-averaged coefficient of absorption,

$A_{tot}$ is the total absorption surface in square meters (square feet),

$S_{tot}$ is the total room surface in square meters (square feet),

$m$ is the energy attenuation factor of the air in m$^{-1}$ (see Fig. 7-4).

The correlation between the mean sound absorption coefficient and the reverberation time for different relations between room volume $V$ and total surface $S_{tot}$ is graphically shown in Fig. 7-5.

The total sound absorption surface of the room $A_{tot}$ consists of the planar absorption surfaces with the corresponding partial surfaces $S_n$ and the corresponding frequency-depending coefficient of sound absorption $\alpha_n$ plus the nonsurface forming absorption surfaces $A_k$ consisting of the audience and the furnishings.

$$A_{tot} = \sum_n \alpha_n S_n + \sum_k A_k$$ (7-5)

For an average sound absorption coefficient of up to $\bar{a} = 0.25$, the Eq. 7-4 by Eyring$^2$ can be simplified by means of series expansion according to Sabine$^4$ to

$$RT = 0.163* \frac{V}{A_{tot} + 4mV}$$ (7-6)

*0.049 for U.S. units
where,

- \( RT_{60} \) is the reverberation time in seconds,
- \( V \) is the room volume in cubic meters (cubic feet),
- \( A_{tot} \) is the total absorption surface in square meters (square feet),
- \( m \) is the energy attenuation factor of the air in \( m^{-1} \), Fig. 7-4.

The correlation between the reverberation time \( RT_{60} \), the room volume \( V \), the equivalent sound absorption surface \( A_{tot} \), and the unavoidable air damping \( m \) is graphically shown in Fig. 7-6.

The above stated frequency-dependent sound absorption coefficient has to be determined by measuring or calculation of the diffuse all-round sound incidence. Measurement is generally done in the reverberation room by using Eq. 7-6. If the sound absorption coefficient is measured by using an impedance tube (or Kundt’s tube) with vertical sound incidence, the results can only be converted to the diffuse sound incidence by means of the diagrams of Morse and Bolt. One can assume that the complex input impedance of the absorber is independent of the angle—i.e., if the lateral sound propagation is inhibited in the absorber (e.g., porous material with a high-specific flow resistance).

Properly speaking, the above-mentioned derivatives of the reverberation time from the sound absorption in the room are only valid for approximately cube-shaped rooms with an even distribution of the sound absorbing surfaces within the room. With room shapes deviating heavily from a square or a rectangle, or in case of a necessary one-sided layout of the absorbing audience area, these factors also have a decisive effect on the
reverberation time. With the same room volume and the same equivalent sound absorption surface in the room, inclining the side wall surfaces towards the room’s ceiling or towards the sound absorbing audience area results in deviations of the measured reverberation time of up to 100%. For numerous room shapes there exist calculating methods with different degrees of exactness, for example, for cylinder-shaped rooms. The cause of these differences lies mainly with the geometrical conditions of the room and their influence on the resulting path length of the sound rays determining the reverberation.

The absorbed sound power $P_{ab}$ of a room can be derived from the ratio energy density $w = \text{sound energy}/\text{volume}$ under consideration of the differential coefficient $P_{ab} = dW/dt$ representing the rate of energy decay in the room and taken from Eqs. 7-5 and 7-6.

$$P_{ab} = \frac{1}{4}cwA$$  \hfill (7-7)

where, $c$ is the sound velocity.

In steady-state, the absorbed sound power is equal to the power $P$ fed into the room. This results in the average sound energy density $w_r$ in the diffuse sound field of the room as

$$w_r = \frac{4P}{cA}$$  \hfill (7-8)

While the sound energy density $w_r$ in the diffuse sound field is approximately constant, the direct sound energy and thus also its density $w_d$ decreases at close range to the source with the square of the distance $r$ from the source, according to

$$w_d = \frac{P}{c} \times \frac{1}{4\pi r^2}$$  \hfill (7-9)

Strictly speaking, this is valid only for spherical acoustic sources; given a sufficient distance it can be applied, however, to most practically effective acoustic sources.

For the sound pressure in this range of predominantly direct sound, this results in a decline with $1/r$. (Strictly speaking, this decline sets in only outside of an interference zone, the near field. The range of this near field is of the order of the dimensions of the source and 0.4 m away from its center.)

If the direct sound and the diffuse sound energy densities are equal ($w_d = w_r$), Eqs. 7-8 and 7-9 can be equated, which means it is possible to determine a specific distance from the source or the reverberation radius (critical distance for omnidirectional sources) $r_H$. With a spherical acoustic source there is

$$r_H = \left(0.3^*\right)^{\frac{1}{2}} \sqrt{\frac{A}{16\pi}}$$

$$\approx \left(0.3^*\right)^{\frac{1}{50}} \sqrt{\frac{A}{50}}$$

$$\approx 0.041(0.043^*) \sqrt{\frac{A}{V}}$$

$$\approx 0.057(0.01^*) \sqrt{\frac{V}{RT_{60}}}$$

* for U. S. units

where,

$r_H$ is in meters or feet,

$A$ is in square meters or square feet,

$V$ is in cubic meters of cubic feet,

$RT_{60}$ is in seconds.

With a directional acoustic source (loudspeaker, sound transducer), this distance is replaced by the critical distance $r_R$

$$r_R = \Gamma(\vartheta) \sqrt{\gamma(r_H)}$$  \hfill (7-11)

where,

$\Gamma(\vartheta)$ is the angular directivity ratio of the acoustic source—the ratio between the sound pressure that is radiated at the angle $\vartheta$ against the reference axis and the sound pressure that is generated on the reference axis at the same distance, in other words, the polars,

$\gamma$ is the front-to-random factor of the acoustic source.

7.2.1.2 Bass Ratio (BR) (Beranek)

Besides the reverberation time $RT_{60}$ at medium frequencies, the frequency response of the reverberation time is of great importance, especially at low frequencies, as compared to the medium ones. The bass ratio—i.e., the ratio between the reverberation times at octave center frequencies of 125 Hz and 250 Hz and octave center frequencies of 500 Hz and 1000 Hz (average reverberation time)—is calculated basing on the following relation:

$$BR = \frac{RT_{125Hz} + RT_{250Hz}}{RT_{500Hz} + RT_{1000Hz}}$$  \hfill (7-12)

For music, the desirable bass ratio is $BR \approx 1.0–1.3$. For speech, on the other hand, the bass ratio should at
most have a value of $BR \approx 0.9–1.0$.

### 7.2.2 Energy Criteria

According to the laws of system theory, a room can be acoustically regarded as a linear transmission system that can be fully described through its impulse response $h(t)$ in the time domain. If the unit impulse $\delta(t)$ is used as an input signal, the impulse response is linked with the transmission function in the frequency domain through the Fourier transform

$$G(\omega) = F\{h(t)\}$$

where,

$$h(t) = F^{-1}\{G(\omega)\}$$

$$= \frac{1}{2\pi} \int_{-\infty}^{+\infty} G(\omega) (j\omega) d\omega.$$  

As regards the measuring technique, the room to be examined is excited with a very short impulse (delta unit impulse) and the impulse response $h(t)$ is determined at defined locations in the room, Fig. 7-7.

Here, the impulse response contains the same information as a quasi-statically measured transmission frequency response.

Generally, the time responses of the following sound-field-proportionate factors (so-called reflectograms) are derived from measured or calculated room impulse responses $h(t)$

- **Sound pressure**: $p(t) \approx h(t)$
  
- **Sound energy density**: $w(t) \approx h^2(t)$
  
- **Ear-inertia weighted sound intensity**: $J_{\omega_0}(t)$
  
- **Sound energy**: $W(t) \approx \int h^2(t') dt'$

### Basic Reflectogram Figures

Figure 7-8. Behavior of sound field quantity versus time (reflectograms) for sound pressure $p(t)$, sound energy density $w(t)$, ear-inertia weighted sound intensity $J_{\omega_0}(t)$ and sound energy $W(t)$.

In order to simplify the mathematical and measuring-technical correlations, a sound-energy-proportional factor is defined as sound energy component $E_f$. Being a proportionality factor of the sound energy, this factor shows the dimension of an acoustical impedance and is calculated from the sound pressure response $p(t)$.

$$E_f = \frac{\int_0^\infty p^2(t') dt'}{\int_0^\infty p^2(t') dt'}$$

where,

- $t'$ is in ms.

For determining a sound-volume-equivalent energy component, $t'$ has to be set to equal $\infty$. In practical rooms of medium size, $t' \approx 800$ ms is sufficient.

For measuring of all speech-relevant room-acoustical criteria, an acoustic source with the frequency-dependent directivity pattern of a human
speaker has, on principle, to be used for exciting the sound field, while with musical performances it is sufficient to use a nondirectional acoustic source for the first approximation.

The majority of the room-acoustical quality criteria is based on the monaural, directionally unweighted assessment of the impulse response. Head-related binaural criteria are still an exception. The influence of the sound-incidence direction of early initial reflections on room-acoustical quality criteria is principally known. Since subjective evaluation criteria are still missing to a large extent, this may also be generally disregarded when measuring or calculating room impulse responses. For the determination of most of the relevant criteria, the energetic addition of the two ear signals of an artificial head is sufficient.

Just like the directional dependence, the frequency dependence of the room-acoustical energy criteria has also not been researched in depth, so that it is generally sufficient at the moment to evaluate the octave with the center frequency of 1000 Hz.

7.2.2.1 Strength Measure (G) (P. Lehmann)

The strength measure $G$ is the ten-fold logarithmic ratio between the sound energy components at the measuring location and those measured at 10 m distance from the same acoustic source in the free field. It characterizes the volume level

$$G = 10 \log \left( \frac{E_{\infty}}{E_{\infty,10 \text{ m}}} \right) \text{ dB} \quad (7-19)$$

Here, $E_{\infty,10 \text{ m}}$ is the reference sound energy component existing at 10 m (32.8 ft) distance with the free sound transmission of the acoustic source.

The optimum values for musical and speech performance rooms are located between $+1 \text{ dB} \leq G \leq +10 \text{ dB}$ which means that the loudness at any given listener’s seat in real rooms should be roughly equal to or twice as high as in the open at 10 m (32.8 ft) distance from the sound source.$^8,^9$

7.2.2.2 Sound Pressure Distribution ($\Delta L$)

The decrease of sound pressure level $\Delta L$ in dB describes the distribution of the volume at different reception positions in comparison with a reference measuring position or also for a specific measuring position on the stage in comparison with others. If the sound energy component at the reference measuring position or for the reference measuring position on stage is labeled with $E_0$ and at the reception measuring position or for the measuring position on stage with $E$, one calculates a sound pressure level distribution $\Delta L$

$$\Delta L = 10 \log \left( \frac{E_{\infty}}{E_{\infty,0}} \right) \text{ dB}. \quad (7-20)$$

It is advantageous for a room if $\Delta L$ for speech and music is in a range of $0 \text{ dB} \geq \Delta L \geq -5 \text{ dB}$.

7.2.2.3 Interaural Cross-Correlation Coefficient (IACC)

The IACC is a binaural, head-related criterion and serves for describing the equality of the two ear signals between two freely selectable temporal limits $t_1$ and $t_2$. In this respect, however, the selection of these temporal limits, the frequency evaluation as well as the subjective statement, are not clarified yet. In general, one can examine the signal identity for the initial reflections ($t_1 = 0 \text{ ms}, t_2 = 80 \text{ ms}$) or for the reverberation component ($t_1 \geq t_{st}, t_2 \geq RT_{60}$ [see Section 7.2.1.1]). The frequency filtration should generally take place in octave bandwidths of between 125 Hz and 4000 Hz.

The standard interaural cross-correlation function $IACF^{10,11}$ is defined as

$$IACF_{t_1 t_2}(\tau) = \frac{\int_{f_1}^{f_2} p_L(t) \times p_R(t + \tau) dt}{\int_{f_1}^{f_2} p_L^2(t) dt \times \int_{f_1}^{f_2} p_R^2(t) dt} \quad (7-21)$$

where,

$p_L(t)$ is the impulse response at the entrance to the left auditory canal,

$p_R(t)$ is the impulse response at the entrance to the right auditory canal.

Then the interaural cross-correlation coefficient IACC is

$$IACC_{t_1 t_2} = \max |IACF_{t_1 t_2}(\tau)|$$

for $-1 \text{ ms} < \tau < +1 \text{ ms}$. 
7.2.2.4 Center Time \((t_s)\) (Kürer)

For music and speech performances, the center time \(t_s\) is a reference value for spatial impression and clarity and results at a measuring position from the ratio between the summed-up products of the energy components of the arriving sound reflections and the corresponding delay times and the total energy component. It corresponds to the instant of the first moment in the squared impulse response and is thus determined according to the following ratio:

\[
    t_s = \frac{\sum t_i E_i}{E_{ges}} \tag{7-22}
\]

The higher the center time \(t_s\) is, the more spatial the acoustic impression is at the listener’s position. The maximum achievable center time \(t_s\) is based on the optimum reverberation time. According to Hoffmeier,\(^{12}\) there is a good correlation between center time and intelligibility of speech with a frequency evaluation of four octaves between 500 Hz, 1000 Hz, 2000 Hz, and 4000 Hz.

For music, the desirable center time \(t_s\) is \(t_s \approx 70\) to 150 ms with a 1000 Hz octave, and for speech \(t_s \approx 60\) to 80 ms with four octaves between 500 and 4000 Hz.

7.2.2.5 Echo Criterion \((EK)\) (Dietsch)

If we look at the build-up function of the center time \(t_s(\tau)\):

\[
    t_s(\tau) = \frac{\int_0^\tau [p(t)]^n dt}{\int_0^\tau [p(t)]^n dt} \tag{7-23}
\]

where,

\[
    n = 0.67 \quad \text{with speech}\quad \text{and} \quad n = 1 \quad \text{with music.}
\]

Comparing it with the difference quotient

\[
    EK(\tau) = \frac{\Delta t_s(\tau)}{\Delta t_E} \tag{7-24}
\]

we can discern echo distortions for music or speech when applying values of \(\Delta t_E = 14\) ms for music and \(\Delta t_E = 9\) ms for speech, ascertained by subjective tests.\(^{13}\) The echo criterion depends on the motif. With fast and accented speech or music, the limit values are lower.

For \(50\%\) \((EK_{50\%})\) and \(10\%\) \((EK_{10\%})\), respectively, of the listeners perceiving this echo, the limit values of the echo criterion amount to:

- Echo perceptible with music for \(EK_{50\%} \geq 1.8\); \(EK_{10\%} > 1.5\) for two octave bands \(1\ kHz\) and \(2\ kHz\) mid frequencies.
- Echo perceptible with speech for \(EK_{50\%} \geq 1.0\); \(EK_{10\%} > 0.9\) for one octave band \(1\ kHz\).

7.2.2.6 Definition Measure \(C_{50}\) for Speech (Ahnert)

The definition measure \(C_{50}\) describes the intelligibility of speech and also of singing. It is generally calculated in a bandwidth of four octaves between 500 Hz and 4000 Hz from the tenfold logarithm of the ratio between the sound energy arriving at a reception measuring position up to a delay time of 50 ms after the arrival of the direct sound and the following energy:

\[
    C_{50} = 10\log\left(\frac{E_{50}}{E_{\infty} - E_{50}}\right) \tag{7-25}
\]

A good intelligibility of speech is generally given when \(C_{50} \geq 0\ dB\).

The frequency-dependent definition measure \(C_{50}\) should increase by approximately 5 dB with octave center frequencies over 1000 Hz (starting with the octave center frequencies 2000 Hz, 4000 Hz, and 8000 Hz), and decrease by this value with octave center frequencies below 1000 Hz (octave center frequencies 500 Hz, 250 Hz, and 125 Hz).

According to Hühne and Schroth,\(^{14}\) the limits of the perception of the difference of the definition measure are at \(\Delta C_{50} \approx \pm 2.5\ dB\).

An equivalent, albeit less used criterion, is the degree of definition \(D\), also called \(D_{50}\), that results from the ratio between the sound energy arriving at the reception measuring position up to a delay time of 50 ms after the arrival of the direct sound and the entire energy (given in %) is

\[
    D = \frac{E_{50}}{E_{\infty}} \tag{7-26}
\]

The correlation with the definition measure \(C_{50}\) is determined by the equation
One should thus strive for an intelligibility of syllables of at least 85%, \( D = D_{50} \geq 0.5 \), or 50%.

### 7.2.2.7 Speech Transmission Index (STI) (Houtgast, Steeneken)

The determination of the STI values is based on measuring the reduction of the signal modulation between the location of the sound source—e.g., on stage—and the reception measuring position with octave center frequencies of 125 Hz up to 8000 Hz. Here Steeneken and Houtgast\(^15\) have proposed to excite the room or open space to be measured with a special modulated noise and then to determine the reduced modulation depth.

The authors proceeded on the assumption that not only reverberation and noise reduce the intelligibility of speech, but generally all external signals or signal changes that occur on the path from source to listener. For ascertaining this influence they employ the modulation transmission function (MTF) for acoustical purposes. The available useful signal \( S \) (signal) is put into relation with the prevailing interfering signal \( N \) (noise). The determined modulation reduction factor \( m \) is a factor that characterizes the interference with speech intelligibility

\[
m(F) = \frac{1}{\sqrt{1 + \left(\frac{2\pi F(RT)}{13.8}\right)^2}} \times \frac{1}{1 + 10^{\frac{(SNR - 10dB)}{10}}} \tag{7-28}
\]

where,

- \( F \) is the modulation frequency in hertz,
- \( RT_{60} \) is the reverberation time in seconds,
- \( SNR \) is the signal/noise ratio in dB.

To this effect one uses modulation frequencies from 0.63 Hz to 12.5 Hz in third octaves. In addition, the modulation transmission function is subjected to a frequency weighting (WMTF—weighted modulation transmission function), in order to achieve a complete correlation to speech intelligibility. In doing so, the modulation transmission function is divided into 7 octave bands, which are each modulated with the modulation frequency.\(^14\) This results in a matrix of \( 7 \times 14 = 98 \) modulation reduction factors, \( m_i \).

The (apparent) effective signal-noise ratio \( X \) can be calculated from the modulation reduction factors \( m_i \)

\[
X_i = 10 \log \left( \frac{m_i}{1 - m_i} \right) \text{ dB} \tag{7-29}
\]

These values will be averaged and for the seven octave bands the Modulation Transfer Indices \( MTI = (X_{\text{average}} + 15)/30 \), are calculated. After a frequency weighting in the seven bands (partially separated for male or female speech) you obtain the Speech Transmission Index, \( STI \).

The excitation of the sound field is done by means of a sound source having the directivity behavior of a human speaker’s mouth.

In order to render twenty years ago this relatively time consuming procedure in real-time operation, the RASTI-procedure (rapid speech transmission index) was developed from it in cooperation with the company Brüel & Kjær.\(^16\) The modulation transmission function is calculated for only 2 octave bands (500 Hz and 2 kHz) which are especially important for the intelligibility of speech and for select modulation frequencies—i.e., in all for only nine modulation reduction factors \( m_i \). However, this measure is used increasingly less.

Note: Schroeder\(^42\) could show that the 98 modulation reduction factors \( m(F) \) may also be derived from a measured impulse response

\[
m(F) = \frac{\int_0^\infty h^2(t) e^{-2\pi F t} \, dt}{\int_0^\infty h^2(t) \, dt} \tag{7-30}
\]

This is done now with modern computer-based measurement routines like MLSSA, EASERA, or Win-MLS.

A new method to estimate the speech intelligibility measures an impulse response and derives STI values with the excitation with a modulated noise. The frequency spectrum of this excitation noise is shown in Fig. 7-9.

You recognize \( \frac{1}{2} \)octave band noise, radiated through the sound system into the room. By means of a mobile receiver at any receiver location the STIPa values can be determined.\(^8,9\) Any layman may use this method and no special knowledge is needed. It is used more and more to verify the quality of emergency call systems (EN 60849),\(^33\) especially in airports, stations or large malls.

According to the definition the STI-value is calculated by using the results of Eq. 7-29.
Based on the comparison of subjective examination results with a maximum possible intelligibility of syllables of 96%, the STI values are graded in subjective values for syllable intelligibility according to Table 7-1 (EN ISO 9921: Feb. 2004).

### 7.2.2.8 Articulation Loss, Alcons, with Speech (Peutz, Klein)

Peutz\(^{17}\) and Klein\(^{18}\) have ascertained that the articulation loss of spoken consonants Alcons is decisive for the evaluation of speech intelligibility in rooms. Starting from this discovery they developed a criterion for the determination of intelligibility:

\[
Alcons \approx 0.652 \left( \frac{E_{\infty} - E_{35}}{E_{35}} \right) RT_{60} \%
\]  

(7-32)

where,

- \(r_{LH}\) is the distance sound source-listener,
- \(r_H\) is the reverberation radius or, in case of directional sound sources, critical distance \(r_R\),
- \(RT_{60}\) is the reverberation time in seconds.

From the measured room impulse response one can determine Alcons according to Peutz,\(^{17}\) if for the direct sound energy one applies the energy after about 25 ms to 40 ms (default 35 ms), and for the reverberation energy the residual energy after 35 ms

\[
Alcons \approx 0.652 \left( \frac{E_{\infty} - E_{35}}{E_{35}} \right) RT_{60} \%
\]  

(7-33)

Assigning the results to speech intelligibility yields Table 7-2.

### Table 7-2. Subjective Weighting for Alcons

<table>
<thead>
<tr>
<th>Subjective Intelligibility</th>
<th>Alcons</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ideal intelligibility</td>
<td>≤3%</td>
</tr>
<tr>
<td>Good intelligibility</td>
<td>3–8%</td>
</tr>
<tr>
<td>Satisfactory intelligibility</td>
<td>8–11%</td>
</tr>
<tr>
<td>Poor intelligibility</td>
<td>&gt;11%</td>
</tr>
<tr>
<td>Worthless intelligibility</td>
<td>&gt;20% (limit value 15%)</td>
</tr>
</tbody>
</table>

Long reverberation times entail an increased articulation loss. With the corresponding duration, this reverberation acts like noise on the following signals and thus reduces the intelligibility.

Fig. 7-10 shows the articulation loss, Alcons, as a function of the SNR and the reverberation time \(RT_{60}\). The top diagram allows us to ascertain the influence of the difference \(L_R\) (diffuse sound level) – \(L_N\) (noise level) and of the reverberation time \(RT_{60}\) on the Alcons value, which gives \(ALcons_{R/N}\). Depending on how large the SNR \((L_D - L_R)\) is, this value is then corrected in the bottom diagram in order to obtain \(ALcons_{D/R/N}\). The noise and the signal level have to be entered as dBA values.

The illustration shows also that with an increase of the SNR to more than 25 dB, it is practically no longer possible to achieve an improved intelligibility. (In praxis, this value is often even considerably lower, since with high volumes, for example above 90 dB, and due to the heavy impedance changes in the middle ear that set on here as well as through the strong bass emphasis that occurs owing to the frequency-dependent ear sensitivity.)

### 7.2.2.9 Subjective Intelligibility Tests

A subjective evaluation method for speech intelligibility consists in the recognizability of clearly spoken pronounced words (so-called test words) chosen on the
basis of the word-frequency dictionary and a language-relevant phoneme distribution. In German intelligibility test logatoms (monosyllable consonant-vowel-groups that do not readily make sense, so that a logical supplementation of logatoms that were not clearly understood during the test is not possible—e.g., grirk, spres) are used for exciting the room. In English-speaking countries, however, test words as shown in Table 7-3 are used. There are between 200 and 1000 words to be used per test. The ratio between correctly understood words (or logatoms or sentences) and the total number read yields the word or syllable or sentence intelligibility \( V \) rated in percentages. The intelligibility of words \( V_W \) and the intelligibility of sentences \( V_S \) can be derived from Fig. 7-11.

| Table 7-3. Examples of English Words Used in Intelligibility Tests |
|-----------------------------------|-----------------|-----------------|-----------------|-----------------|
| aisle                             | done            | jam             | ram             | tame            |
| barb                              | dub             | law             | ring            | toil            |
| barge                             | feed            | lawn            | rip             | ton             |
| bark                              | feet            | lisle           | rub             | trill           |
| baste                             | file            | live            | run             | tub             |
| bead                              | five            | loon            | sale            | vouch           |
| beige                             | foil            | loop            | same            | vow             |
| boil                              | fume            | mess            | shod            | whack           |
| choke                             | fuse            | met             | shop            | wham            |
| chore                             | get             | neat            | should          | woe             |
| cod                               | good            | need            | shrill          | woke            |
| coil                              | guess           | oil             | sip             | would           |
| coon                              | hews            | ouch            | skill           | yaw             |
| coop                              | hive            | paw             | soil            | yawn            |
| cop                               | hod             | pawn            | soon            | yes             |
| couch                             | hood            | pews            | soot            | yet             |
| could                             | hop             | poke            | soup            | zing            |
| cow                               | how             | pour            | spill           | zip             |
| dale                              | huge            | pure            | still           |                 |
| dame                              | jack            | rack            | tale            |                 |

Figure 7-10. Articulation loss Alcons as a function of the level ratio between diffuse sound \( L_R \) and direct-sound level \( L_D \), reverberation time \( RT_{60} \) and noise level \( L_N \).

Figure 7-11. Assessment of the quality of speech intelligibility as a function of syllable intelligibility \( V_L \), word intelligibility \( V_W \), and sentence intelligibility \( V_S \).

Table 7-4 shows the correlation between the intelligibility values and the ratings.
The results of the subjective intelligibility test are greatly influenced by speech velocity which includes the number of spoken syllables or words within the articulation time (articulation velocity) and the break time. Therefore so-called predictor sentences are often used to precede the words or logatoms that are not part of the test. These sentences consist of three to four syllables each, for example: “Mark the word...”, “Please write down....”, “We’re going to write....” Additionally to providing a continuous flow of speech, this also serves for guaranteeing that the evaluation takes place in an approximately steady-state condition of the room.

There is a close correlation between the subjectively ascertained syllable intelligibility and room-acoustical criteria. For example, a long reverberation time reduces the syllable intelligibility\(^20\) Fig. 7-12 owing to the occurrence of masking effects, despite an increase in loudness, see Eq. 7-8.

Quite recently, comprehensive examinations concerning the frequency dependence of speech-weighting room-acoustical criteria were conducted in order to find the influence of spatial sound coloration.\(^12\) It was ascertained that with broadband frequency weighting between 20 Hz and 20 kHz the definition measure \(C_{50}\) (see Section 7.2.2.6) correlates very insufficiently with the syllable intelligibility. Through a frequency evaluation across three to four octaves around a center frequency of 1000 Hz, however, the influence of the sound coloration can sufficiently be taken into account. Even better results regarding the subjective weightings are provided by the frequency analysis, if the following frequency responses occur, Fig. 7-13.

As the definition declines with rising frequency due to sound coloration, the intelligibility of speech is also low (bad intelligibility \(\to 3\)). This includes also the definition responses versus frequency with a maximum value at 1000 Hz, poor intelligibility \(\to 4\) in Fig. 7-13.

The definition responses versus rising frequency to be aimed at for room-acoustical planning should either be constant (good intelligibility \(\to 1\)) or increasing (very good intelligibility \(\to 2\)). With regard to auditory psychology, this result is supported by the importance for speech intelligibility of the consonants situated in this higher-frequency range.

The determination of speech intelligibility through the definition measure \(C_{50}\) can easily lead to faulty results as the mathematical integration limit of 50 ms is not a jump function with regards to intelligibility without knowledge of the surrounding sound reflection distribution.

The best correlation with the influence of the spatial sound coloration exists between the subjective speech intelligibility and the center time \(t_S\) (see Section 7.2.2.4) with a frequency weighting between the octave of 500 Hz to the octave of 4000 Hz. According to Hoffmeier,\(^12\) the syllable intelligibility \(V\) measured at the point of detection is then calculated as

\[
V = 0.96 \times V_{sp} \times V_{SNR} \times V_R
\]

(7-34)

where,

\(V_{sp}\) is the influence factor of the sound source (trained speaker \(V_{sp} = 1\), untrained speaker \(V_{sp} \approx 0.9\),

\(V_{SNR}\) is the signal to noise ratio factor.

\(V_R\) is the reference factor.
**VSNR** is the influence factor of the useful level (speech level) $L_s$ and of the disturbance level $L_{st}$ according to Fig. 7-14,\(^6\)

$$V_R = -6 \times 10^{-6} \left( \frac{L_s}{ms} \right)^2 - 0.0012 \left( \frac{L_s}{ms} \right) + 1.0488$$

![Figure 7-14. Syllable intelligibility factor $V_{SNR}$ as a function of speech sound pressure level $L_s$ and noise pressure level $L_{N\bar{m}}$.](image)

The correlation shown in Fig. 7-15 can also be derived between articulation loss and syllable intelligibility. For low reverberation times, syllable intelligibility is almost independent of the articulation loss. An inverse correlation behavior sets in only with increasing reverberation time. It is evident that with the usual $Alcons$ values between 1% and 50%, syllable intelligibility can take on values between 68% and 93% (meaning a variation of 25%) and that for an articulation loss <15% (the limit value of acceptable intelligibility) the syllable intelligibility $V_s$ reaches always, independently of the reverberation time, values over 75% which corresponds roughly to a definition measure of $C_{50} > -4$ dB.

This correlation can also be seen in Fig. 7-16, which shows the correlation between measured RASTI-values and articulation loss $Alcons$. One sees that acceptable articulation losses of $Alcons < 15\%$ require RASTI values in the range from 0.4 to 1 (meaning between satisfactory and excellent intelligibility). Via the equation

$$RASTI = 0.9482 - 0.1845 \ln(Alcons) \quad (7-35)$$

it is also possible to establish an analytical correlation between the two quantities. In good approximation this relationship may be used not only for RASTI but for STI as well.

![Figure 7-15. Syllable intelligibility $I_s$ as a function of the articulation loss $Alcons$. Parameter: reverberation time $RT_{60}$. Preconditions: approximate statistical reverberation behavior; signal-to-noise ratio (SNR) ≥ 25 dB.](image)

![Figure 7-16. Relationship between $Alcons$ values and RASTI values.](image)

### 7.2.2.10 Clarity Measure ($C_{80}$) for Music (Abdel Alim)

The clarity measure $C_{80}^{21}$ describes the temporal transparency of musical performances (defined for an octave center frequency of 1000 Hz) and is calculated from the tenfold logarithm of the ratio between the sound energy arriving at a reception measuring position up to 80 ms after the arrival of the direct sound and the following sound energy.
The value for a good clarity measure $C_{80}$ depends strongly on the musical genre. For romantic music, a range of approximately $-3 \text{ dB} \leq C_{80} \leq +4 \text{ dB}$ is regarded as being good, whereas classic and modern music will allow values up to $+6$ to $+8 \text{ dB}$.

According to Höhne and Schroth, the perception limit of clarity measure differences is about $\Delta C_{80} = \pm 3.0 \text{ dB}$.

According to Reichardt et al., there is an analytical correlation between the clarity measure $C_{80}$ and the center time $t_S$, as given by

\[
\begin{align*}
C_{80} &= 10.83 - 0.95t_S \\
t_S &= 114 - 10.53C_{80}
\end{align*}
\]  

(7-37)

where,

- $C_{80}$ is in dB,
- $t_S$ is in ms.

This correlation is graphically depicted in Fig. 7-17.

\[C_{80} = 10\log\left(\frac{E_{80}}{E_\infty - E_{80}}\right) \text{ dB} \quad (7-36)\]

\[K_T = 10\log\left(\frac{E_{\infty, 100\text{ Hz}}}{E_\infty, 500\text{ Hz}}\right) \text{ dB} \quad (7-38)\]

\[K_H = 10\log\left(\frac{E_{\infty, 3150\text{ Hz}}}{E_\infty, 500\text{ Hz}}\right) \text{ dB} \quad (7-39)\]

The measures correlate with the subjective impression of the spectral sound coloration conditioned by the acoustical room characteristics. Optimum values are $K_{T,H} = -3$ to $+3 \text{ dB}$.

7.2.2.12 Spatial Impression Measure ($R$) for Music (U. Lehmann)

The spatial impression measure $R^{24,25}$ consists of the two components spaciousness and reverberance. The spaciousness is based on the ability of the listener to ascertain through more or less defined localization that a part of the arriving direct sound reaches him not only as direct sound from the sound source, but also as reflected sound from the room’s boundary surfaces (the perception of envelopment in music). The reverberance is generated by the nonstationary character of the music that constantly generates build-up and decaying processes in the room. As regards auditory perception, it is mainly the decaying process that becomes effective as reverberation. Both components are not consciously perceived separately, their mutual influencing of the room is very differentiated.\(^{26}\) Among the energy fractions of the sound field that increase the spatial impression are the sound reflections arriving after 80 ms from all directions of the room as well as sound reflections between 25 ms and 80 ms, that are geometrically situated outside a conical window of $\pm 40^\circ$, whose axis is formed between the location of the listener and the center of the sound source. Thus all sound reflections up to 25 ms and the ones from the front of the above-mentioned conical window have a diminishing effect on the spatial impression of the room. The tenfold logarithm of this relation is then defined as the spatial impression measure $R$ in dB.

\[
R = 10\log\left[\frac{E_{\infty} - E_{25}}{E_{25} + (E_{80R} - E_{25R})}\right] \text{ dB} \quad (7-40)
\]

where,

- $E_\infty$ is the sound energy fraction measured with a directional microphone (beaming angle $\pm 40^\circ$ at 500 Hz to 1000 Hz, aimed at the sound source).

One achieves a mean (favorable) room impression if the spatial impression measure $R$ is within a range of approximately $-5 \text{ dB} \leq R \leq +1 \text{ dB}$.
Spatial impression measures below –5 dB up to –10 dB are referred to as being less spatial, others between +1 dB up to +7 dB as very spatial.

### 7.2.2.13 Lateral Efficiency (LE) for Music (Jordan), (LF) (Barron) and (LFC) (Kleiner)

For the subjective assessment of the apparent extension of a musical sound source—e.g., on stage—the early sound reflections arriving at a listener’s seat from the side are of eminent importance as compared with all other directions. Therefore the ratio between the laterally arriving sound energy components and those arriving from all sides, each within a time of up to 80 ms, is determined and its tenfold logarithm calculated therefrom.

If one multiplies the arriving sound reflections with \( \cos^2 \sigma \), being the angle between the direction of the sound source and that of the arriving sound wave, one achieves the more important evaluation of the lateral reflections. With measurements this angle-dependent evaluation is achieved by employing a microphone with bi-directional characteristics.

Lateral Efficiency, \( LE \), is

\[
LE = \frac{E_{80Bi} - E_{25Bi}}{E_{80}} \quad (7-41)
\]

where, \( E_{Bi} \) is the sound energy component measured with a bidirectional microphone (gradient microphone).

The higher the lateral efficiency, the acoustically broader the sound source appears. It is of advantage if the lateral efficiency is within the range of 0.3 \( \leq LE \leq 0.8 \).

For obtaining a uniform representation of the energy measures in room acoustics, these can also be defined as lateral efficiency measure \( 10 \log LE \). Then the favorable range is between –5 dB \( \leq 10 \log LE \leq –1 \) dB.

According to Barron it is the sound reflections arriving from the side at a listener’s position within a time window from 5 ms to 80 ms that are responsible for the acoustically perceived extension of the musical sound source (contrary to Jordan who considers a time window from 25 ms to 80 ms). This is caused by a different evaluation of the effect of the lateral reflections between 5 ms and 25 ms.

The ratio between these sound energy components is then a measure for the lateral fraction \( LF \):

\[
LF = \frac{E_{80Bi} - E_{5Bi}}{E_{80}} \quad (7-42)
\]

where,

\( E_{Bi} \) is the sound energy component, measured with a bidirectional microphone (gradient microphone).

It is an advantage if \( LF \) is within the range of \( 0.10 \leq LF \leq 0.25 \), or, with the logarithmic representation of the lateral fraction measure \( 10 \log LF \), within \(-10 \) dB \( \leq 10 \log LF \leq –6 \) dB.

Both lateral efficiencies \( LE \) and \( LF \) have in common that, thanks to using a gradient microphone, the resulting contribution of a single sound reflection to the lateral sound energy behaves like the square of the cosine of the reflection incidence angle, referred to the axis of the highest microphone sensibility. Kleiner defines, therefore, the lateral efficiency coefficient \( LFC \) in better accordance with the subjective evaluation, whereby the contributions of the sound reflections vary like the cosine of the angle.

\[
LFC = \frac{\int_{0}^{80} |p_{Bi}(t) \times p(t)| dt}{E_{80}} \quad (7-43)
\]

### 7.2.2.14 Reverberance Measure (H) (Beranek)

The reverberance measure describes the reverberance and the spatial impression of musical performances. It is calculated for the octave of 1000 Hz from the tenfold logarithm of the ratio between the sound energy component arriving at the reception measuring position as from 50 ms after the arrival of the direct sound and the energy component that arrives at the reception position within 50 ms.

\[
H = 10 \log \left( \frac{E_{50}}{E_{50}} \right) \text{ dB} \quad (7-44)
\]

In contrast to the definition measure \( C_{50} \) an omnisource is used during the measurements of the reverberance measure \( H \).

Under the prerequisite that the clarity measure is within the optimum range, one can define a guide value range of 0 dB \( \leq H \leq +4 \) dB for concert halls, and of \(-2 \) dB \( \leq H \leq +4 \) dB for musical theaters with optional use for concerts. A mean spatial impression is achieved if the reverberation factor \( H \) is within a range of \(-5 \) dB \( \leq H \leq +2 \) dB.

Schmidt examined the correlation between the reverberance measure \( H \) and the subjectively perceived reverberation time \( RT_{sub} \), Fig. 7-18. For a reverberance measure \( H = 0 \) dB, the subjectively perceived reverbera-
tion time coincides with the objectively measured reverberation time.

7.2.2.15 Register Balance Measure (BR) (Tennhardt)

With musical performances, the relation of the partial volumes of individual orchestra instrument groups between each other and to the singer is an important quality criterion for the balance (register balance) and is defined by the frequency-dependent time structure of the sound field. The register balance measure $BR$ between two orchestra instrument groups $x$ and $y$ is calculated from the A-frequency weighted volume-equivalent sound energy components of these two groups, corrected by the reference balance measure $B_{xy}$ of optimum balance.

$$BR_{xy} = 10\log\left(\frac{E_{x}}{E_{xy}}\right) + B_{xy} \quad (7-45)$$

where,

$B_{xy}$ is in dBA.

Significant differences in balance do not occur if $4 \text{ dBA} < B_R < -4 \text{ dBA}$ and if this tendency occurs binaurally.

7.3 Planning Fundamentals

### 7.3.1 Introduction

When planning acoustical projects one has to start out from the fundamental utilization concept envisaged for the rooms. In this respect one distinguishes between rooms intended merely for speech presentation, rooms to be used exclusively for music performances, and a wide range of multipurpose rooms.

In the following we are going to point out the most important design criteria with the most important parameters placed in front. Whenever necessary the special features of the different utilization profiles will be particularly referred to.

Strictly speaking, acoustical planning is required for all rooms as well as for open-air facilities, only the scope and the nature of the measures to be taken vary from case to case. The primordial task of the acoustician should, therefore, consist in discussing the utilization profile of the room with the building owner and the architect, but not without taking into consideration that this profile may change in the course of utilization, so that an experienced acoustician should by no means fail to pay due attention to the modern trends as well as to the utilization purposes which may arise from or have already arisen from within the environs of the new building or the facility to be refurbished, respectively.

On the one hand it is certainly not sensible for a small town to try to style the acoustical quality of a hall to that of a pure concert hall, if this type of event will perhaps take place no more than ten times a year in the hall to be built. In this case a multipurpose hall whose acoustical properties enable symphonic concerts to be performed in high quality is certainly a reasonable solution, all the more if measures of variable acoustics and of the so-called electronic architecture are included in the project.

In rooms lacking any acoustical conditioning whatsoever, on the other hand, many types of events can be performed only with certain reservations, which have to be declined from the acoustical point of view.

Table 7-5 shows the interrelation between utilization profile and effort in acoustical measures. These
measures can be characterized as follows:

**Table 7-5. Interrelation Between Utilization Profile and Acoustical Measures**

</tbody>
</table>

**Auditoriums, congress centers** are mainly used for speech presentation. They are mostly equipped with a sound reinforcement system, but may sometimes also do without it. Music performances without sound reinforcement systems take place in a reduced style as a setting for ceremonial acts and festivities. Owing to the short reverberation time abiding their utilization concept, larger concert performances mostly require in such rooms the room-acoustical support of electroacoustical equipment (see Section 36.1).

**Spoken-drama theaters** serve in their classical form for speech presentation with occasional accompaniment by natural music instruments and vocalists. Apart from serving as a support for solo instruments in a music performance, utilization of electroacoustical systems is reserved almost exclusively for playing-in effects or for mutual hearing.

**Multigene theaters** are gaining in the theater scene an ever-growing importance against the pure music or spoken-drama theater. The presentation of speech or music from natural sources must be possible here without compromise. While the classical music or spoken-drama theater got along with an average reverberation time of about 1 s, the trend in the planning of modern multigene theaters tends to a somewhat longer reverberation time of up to 1.7 s with a strong portion of definition-enhancing initial sound energy and a reduced reverberance measure (less energy at the listener seat after 50 ms than within the first 50 ms). Here it may also be appropriate to make use of variable acoustics for reverberation time reduction, if, for example, electroacoustical performances (shows, pop concerts, etc.) are presented. This reverberation time reduction should be obtained by shortening the travel paths of the sound reflections rather than by sound absorption measures which tend to reduce loudness. The separation of room volumes (e.g., seats on the upper circle, reverberation chambers) leads mostly to undesirable timbre changes, unless these volumes are carefully dimensioned.

Electroacoustical systems have in multigene theaters mostly mutual hearing and playing-in functions. Concert presentations on the stage with natural sound sources require the additional installation of a concert enclosure.

**Opera houses** having a large classical theater hall must be capable of transmitting speech and music presentations of natural sources in excellent acoustic quality without taking recourse to sound reinforcement. Speech is mainly delivered by singing. In room-acoustical planning of modern opera houses the parameters are therefore chosen so as to be more in line with musical requirements (longer average reverberation time of up to 1.8 s, greater spaciousness, spatial and acoustical integration of the orchestra pit in the auditorium). Electroacoustical means are used for reproducing all kinds of effects signals and for playing-in functions (e.g., remote choir or remote orchestra). This implies that the sound reinforcement system is becoming more and more an artistic instrument of the production director.

Concert presentations on the stage with natural sound sources also require the additional installation of a concert enclosure which has to form a unity with the auditorium as regards proper sound mixing and irradiation.

**Multipurpose halls** cover the widest utilization scope ranging from sports events to concerts. This implies that variable natural acoustics are not efficient as a planning concept, since the expenditure for structural elements generally exceeds the achievable benefit. Parting from a room-acoustical compromise solution tuned to the main intended use, with a somewhat shorter reverberation time and consequently high definition and clarity, appropriately built-in structural elements (enclosures) have to provide for the proper sound mixing required for concerts with natural music instruments, while prolongation of reverberation time as well as enhancement of spatial impression and loudness can be achieved by means of electroacoustical systems of electronic architecture (see Section 7.4).

To a greater extent sound systems are used here to cover speech amplification and the needs of modern rock and pop concerts.
Classical concert halls serve first of all for music events ranging from soloist presentations to the great symphony concert with or without choir. They are mostly equipped with a pipe organ and their room-acoustical parameters must satisfy the highest quality demands. Electroacoustical systems are used for vocal information and for mutual listening with special compositions, but are generally still ruled out for influencing the overall room-acoustical parameters.

General concert halls can be used for numerous music performances, among others for popular or pop concerts. Here it is the use of an electroacoustical sound reinforcement system that overrides the room-acoustical parameters of the hall. In accordance with the variety of events to be covered by these halls, they should be tuned to a frequency-independent reverberation time of the order of 1.2 s and feature high clarity.

Sports halls, gymnasiums have to provide an acoustical support for the mutual emotional experience. This concerns, first of all, the supporting acoustic correspondence of the spectators between themselves and the performers. Thus there are only few sound absorbing materials to be used in the spectators’ areas and sound reflecting elements to be provided towards the playing field. The ceiling of the playing field should be more heavily damped so as to enable it to be used also for music events, in which case an electroacoustical sound reinforcement system is to be used. The same applies to open and partially or fully covered stadiums where sound absorption above the playing field is a natural feature with the open ones.

Show theaters are generally used only on negligibly few occasions with natural acoustics, an exception being “Singspiel” theaters with an orchestra pit. Predominantly, however, an electroacoustical sound reinforcement system is used for the functions of play-in and mutual hearing as well as half or full playback. The room-acoustical parameters of the theater room have, with this form of utilization to comply with, the electroacoustical requirements. The reverberation time should therefore not exceed a frequency-independent value of 1.4 s and the sound field should have a high diffusivity so that the electroacoustically generated sound pattern does not get distorted by the acoustics of the room.

Rooms with variable acoustics controlled by mechanical means show some positive result only in a certain frequency range, if corresponding geometric modifications of the room become simultaneously visible. The room-acoustical parameters have always to coincide with the listening experience that means they must also be perceived in a room-size and room-shape-related manner. Experimental rooms and effect realization (e.g., in a virtual stage setting of a show theater) are, of course, excluded from this mode of consideration. In theater rooms and multipurpose halls it is possible to vary the reverberation time by mechanical means within a range of about 0.5 s without detrimental effect on spatial impression and timbre. At any rate one should abstain from continuously variable acoustic parameters, house superintendent acoustics, since possible intermediate steps could lead to uncontrolled and undesirable acoustic settings.

Sacral rooms. Here we have to distinguish between classical church rooms and contemporary modern sacral buildings. With the classical rooms it is their size and importance that determine their room-acoustical parameters—e.g., a long reverberation time and an extreme spaciousness. Short reverberation times sound inadequate in such an environment. The resulting deficiency in definition, inconvenient—e.g., during the sermon—has to be compensated by providing additional initial reflections through architecturally configured reflectors, or nowadays, mostly through an electroacoustical sound system. With music presentations one has, in various frequency domains, to adapt the style of playing to the long decay time (cf. Baroque and Romanesque churches). Electroacoustical means can serve here only for providing loudness.

From the acoustical point of view, modern church buildings acquire to an increasing degree the character of multipurpose halls. Thanks to appropriately adapted acoustics and the use of sound reinforcement systems they are not only adequate for holding religious services, but can also be used as venues for concerts and conferences in good quality.

7.3.2 Structuring the Room Acoustic Planning Work

7.3.2.1 General Structure

The aim of room-acoustical planning consists of safeguarding the acoustical functionality under the envisaged utilization concepts of the auditorium for the performers as well as for the audience. With new buildings such details should be considered in the planning phase, whereas with already existing rooms an appropriate debugging should be an essential part of the
refurbishment. Point of departure in this respect is a purposeful influencing control of the primary structure of the performance room. This concerns, among other things:

- The size of the room.
- The shape of the room.
- Functional-technological circumstances, for instance the platform or stage arrangement, the installation of balconies or galleries, lighting installations, and the arrangement of multimedia equipment.
- The topography regarding the arrangement of performers and listeners, like for instance the sloping of tiers or the proscenium area in front of the stage opening.

Based on these premises, the secondary structure of the room will be acoustically determined. This structure concerns essentially:

- The arrangement and distribution of frequency-dependent sound-absorbing as well as sound-reflecting faces.
- The subdivision of the surface structure for directional and diffuse sound reflections.
- The frequency-dependent effect of uneven surfaces.
- The architectural-stylistic conformation of all boundary surfaces of the room.

### 7.3.2.2 Room Form and Sound Form

There exists a correspondence between the shape of a room (room form) in its primary structure and the resulting sound. The term sound form refers in this context to the reverberation timbre which is herewith divided into its low-frequency portion (warmth) and its high-frequency portion (brilliance).

The method used for assessing the acoustical quality of concert halls is based on a paper by Beranek\(^9\) in which one finds a list of seventy concert halls arranged in six subjective categories according to their acoustical quality. Of all these there are three halls listed in the category A+ as outstanding or superior and six halls in the category A as excellent. Eight of these are shoebox-shaped, a fact that gives rise to the question as to whether a good roomacoustical quality is linked to a rectangular shape of the room.

The concert halls selected by Beranek for the categories A+ and A allow the following pairs of values to be ascertained in an occupied hall, Table. 7-6.

Table 7-7 shows that, in shoebox-shaped rooms, the brilliance is lower in comparison to rooms of polygonal primary shape. However, on the basis of the brilliance ratio \(TR_1\) no such significant difference can be shown between rooms of a quasi-circular ground plan (five halls) and those having diverse trapezoidal primary shapes (nine halls).

### 7.3.3 Primary Structure of Rooms

#### 7.3.3.1 Volume of the Room

As a rule, the first room-acoustical criterion to be determined as soon as the intended purpose of the room has been clearly established, is the reverberation time (see Section 7.2.1.1). From Eq. 7-6 and the correlation between reverberation time, room volume and equivalent sound absorption area, graphically depicted
166 Chapter 7

In Fig. 7-6, it becomes evident that the room volume must not fall short of a certain minimum if the desired reverberation time is to be achieved with the planned audience capacity.

For enabling a tentative estimate of the acoustically effective room size required with regard to its specific use, there serves the volume index \( k \), which indicates the minimum room volume in m\(^3\)/listener seat, Table 7-8. In case an auditorium is used for concert events, the volume of the concert enclosure is added to the volume of the auditorium without increasing, however, the seating capacity of the auditorium by the number of the additional performers (orchestra, choir). For theater functions the volume of the stage house behind the portal is left out of account.

The minimum required acoustically effective room volume is calculated as follows:

\[
V = k \times N \tag{7-46}
\]

where,

- \( V \) is the acoustically effective room volume in m\(^3\),
- \( k \) is the volume index according to Table 7-5 in m\(^3\)/seat,
- \( N \) is the seating capacity in the audience area.

If a given room is to be evaluated regarding its suitability for acoustic performances, the volume index may be useful for providing a rough estimate and simultaneously for determining the scope of additional sound-absorptive measures.

If the volume index falls short of the established guide values, the desirable reverberation time cannot be achieved by natural acoustics. With very small rooms, especially orchestra rehearsal rooms, it is moreover possible that loudness results in excessive fortissimo (in a rehearsal room of 400 m\(^3\) (14,000 ft\(^3\)) volume and with 25 musicians, may reach up to 120 dB in the diffuse field). In rooms of less than 100 m\(^3\) (3500 ft\(^3\)) the eigen-frequency density results are insufficient. This leads to a very unbalanced frequency transmission function of the room giving rise to inadmissible timbre changes.

Excessive loudness values require additional sound-absorptive measures, which may bring about too heavy a loudness reduction for low-level sound sources.

On the other hand, it is not possible to increase seating capacity and room volume just as you like, because of the increase of the equivalent sound absorption area and the unavoidable air absorption, Fig. 7-4. The attainable sound energy density in the diffuse field decreases as well as the performance loudness (see Eq. 7-8). Moreover the distances within the performance area and to the listener are dissatisfactory expanded this way. For these reasons it is possible to establish an upper volume limit for rooms without electroacoustic sound reinforcement equipment (i.e., with natural acoustics) that should not be exceeded, Table 7-2. These
values depend, of course, on the maximum possible power of the sound source. By choosing Eq. 7-8 in level representation and using the reverberation time formula by Sabine,\(^6\) one obtains the correlation between sound power level of the sound source \(L_W\) in dB and sound pressure level \(L_{\text{diff}}\) in dB in the diffuse sound field, as a function of the room parameters, volume \(V\) in m\(^3\), and reverberation time \(RT_{60}\) in s.\(^6\)

\[
L_{\text{diff}} = L_W - 10 \log \frac{V}{T} \text{ dB} + 14 \text{ dB*} 
\]

* add 29.5 dB in U.S. system.

The graphical representation of this mathematical relation is shown in Fig. 7-19. For determining the attainable sound pressure level in the diffuse sound field one can proceed from the following sound power levels \(L_W\).\(^{3,29,30}\)

The dynamic range of a talker is about 40 dB and that of soloist singers about 50 dB. Without taking into account the timbre of a sound source, the SNR should generally be at least 10 dB with pianissimo or whispering.

With large room volumes and high frequencies, the increase of energy attenuation loss caused by the medium air should not be neglected. This shall be illustrated by an example: in a concert hall with a room volume of 20,000 m\(^3\) (700,000 ft\(^3\)), the unavoidable air attenuation at 20°C and 40% relative humidity accounts for an additional equivalent sound absorption area which at 1000 Hz corresponds to an additional 110 persons and at 10 kHz to 5000 additional persons.

#### 7.3.3.2 Room Shape

The shape of a room allows a wide margin of variability, since from the acoustical point of view it is not possible to define an optimum. Depending on the intended purpose, the shape implies acoustical advantages and disadvantages, but even in the spherical room of a large planetarium, it is by room-acoustical means (full absorbing surfaces) possible to achieve good speech intelligibility. Acoustically unfavorable, however, are room shapes that do not ensure an unhindered direct sound supply nor any omnidirectional incidence of energy-rich initial reflections in the reception area, as is the case, for instance, with coupled adjoining rooms and low-level audience areas under balconies or galleries of low room height.

When selecting different room shapes of equal acoustically effective volume and equal seating capacity there may result very distinct characteristics as regards the overall room-acoustical impression. A more or less pronounced inclination of the lateral boundary surfaces may produce different reverberation times.\(^{31}\) In combination with a sound reflecting and not much
structured ceiling layout, prolongation of the reverberation time up to a factor of two results and is especially large if long-delayed sound reflection groups are produced by side wall surfaces that are inclined outwards and upwards. But if these wall surfaces are inclined towards the sound-absorbing audience area, the shorter path lengths thus achieved may considerably reduce the reverberation time as compared to the usual calculating methods with vertical boundary surfaces.

Also with similar room shapes, different room-acoustical conditions are obtained by just varying the furnishing of the room (platform, audience areas). All acoustically usable room shapes have in common that the unhindered direct sound and energy-rich initial reflections reach the listener. Deviations from this rule occur through direct-sound shading in the orchestra pit of an opera theater. Diffraction compensates this effect partially and the listening experience is adapted to a different sound impression which is similar to the case of unhindered sound irradiation. The initial reflections must arrive at the listener’s seat within a path difference to direct sound of approximately 17 m (50 ms) for speech and 27 m (80 ms) for music performances.

Decisive for an adequate spatial impression with musical performances are, first of all, the lateral sound reflections. The more the spaciousness is supported this way, the more the orchestra sound gains, according to Meyer,30 in volume and width. The increase of sound intensity perceptible with forte-play is thus enhanced beyond the mere loudness effect so that the subjectively perceived dynamic range is expanded. By the same token, spaciousness is subjectively enhanced by an increased loudness of the sound source.

From these general premises it is, for different arrangement patterns between performers and listeners, possible to derive universally valid guidelines for fundamental room-acoustical problems of certain typical room ground-plan layouts. In this regard one can distinguish between purely geometrical layouts with parallel boundary lines (rectangle, square, hexagon) on all sides, with at least two mutually slanted boundary lines (trapezoid) and generally curved boundary lines (circle, semicircle, ellipse) and irregular layouts with asymmetric or polygonal boundary lines.

7.3.3.2.1 Ground Plan

For obtaining lateral sound reflections, a room with a rectangular ground plan is very well suited if the performance zone is arranged at an end wall and the width of the room is in the range of 20 m (66 ft), Fig. 7-20A. This is the typical example of the linear contact in a shoebox layout of a classic concert hall (Symphony Hall Boston, Musik-vereinssaal Vienna, Konzerthaus Berlin).

If the performance zone is shifted from the end wall towards the middle of the room, Fig. 7-20B, a circular contact may come into being as a borderline case, where audience or a choir may be arranged laterally or behind the platform. Owing to the relatively pronounced frequency-dependent directional characteristic of most sound sources (singers, high-pitched string instruments, etc.) there occur herewith, especially in the audience area arranged behind the platform, intense balance problems which may even lead to unintelligibility of the sung word and to disturbing timbre changes. On lateral seats at the side of the platform, the listening experience can be significantly impaired due to room reflections where visually disadvantaged instruments are perceived louder than instruments located at closer range. This effect is even enhanced by lateral platform boundary surfaces, whereas an additional rear sound reflection area supports sound mixing. Often these acoustical disadvantages are, however, subordinated to the more eventful visual experiences.

If the performance zone is arranged in front of a longitudinal wall, Fig. 7-20C, short-time lateral initial reflections get missed especially with broad sound sources (orchestras), whereby the mutual hearing and consequently the intonation get impaired. Soloist concerts or small orchestras (up to about six musicians) may still provide satisfactory listening conditions, if ceiling height and structure provide clarity-enhancing sound reflections. By means of a sound-reflecting rear wall combined with adjustable lateral wall elements which do not necessarily disturb the visual impression, it is possible to attain good room-acoustical conditions with not too long rooms (up to about 20 m or 66 ft). For spoken performances this way of utilization provides advantages because of the short distance to the talker,
but has disadvantages due to timbre changes impairing intelligibility. As the talker chooses to speak towards the audience seats in the middle of the room, the lateral seating areas are bound to be disadvantaged on account of the frequency-dependent directional characteristic. According to Meyer, the sound pressure level reduction laterally to the talker when articulating the vowels “o,” “a,” and “e” is 0 dB, 1 dB, and 7 dB, respectively.

A special case of the rectangular room ground plan is the square with approximately equal side lengths. Especially for multi-purpose use such halls allow the realization of diverse forms of confrontation with the audience for which good acoustical conditions are given in small rooms with about 500 seats, assuming some basic principles are considered, Fig. 7-21A to C. Room variant A represents the classical linear contact ensuring a good direct-sound supply to the listeners, especially with directional sound sources (talkers, singers, directional instrumental groups). Variant B offers an acoustically good solution for sound sources of little extension (talkers, singers, chamber music groups), since a good lateral radiation into the room is given. It is true, however, that in the primary structure there is a lack of lateral sound reflections for supporting mutual hearing and intonation in the performance zone. The amphitheatrical arrangement shown in variant C is suitable for only a few kinds of performance, since apart from visual specialities there are above all acoustic balance problems to be expected. With directional sound sources—e.g., talkers and singers—the decrease of the direct sound by at least 12 dB versus the straight-ahead viewing direction produces intelligibility problems behind the sound source.

The trapezoidal ground plan enables, on principle, two forms of confrontation: the diverging trapezoid with the lateral wall surfaces diverging from the sound source and the converging trapezoid with the sound source located at the broad end side. The latter ground plan layout, however, is from the architectural point of view not used in its pure form, Fig. 7-22.

Variations of the first ground plan layout with a curved rear wall are designated as fan-shaped or piece of pie. The room-acoustical effect of the trapezoidal layout depends essentially on the diverging angle of the side wall surfaces. The room shape shown in Fig. 7-22A produces room-acoustical conditions, which are similarly favorable as those in a rectangular room used for music, if the diverging angle is slight. With wider diverging angles, the energy-rich initial reflections, especially from the side walls, are lacking in the whole central seating area, which is a characteristic conditioned by this primary structure. A principal comparison of the fraction of lateral sound energy produced merely by the ground plan layout is shown in Fig. 7-23. As was to be expected, the comparable, relatively narrow ground plan of the rectangular shape shows a higher lateral sound fraction than the diverging trapezoid. For spoken performances this situation is relatively uninteresting, since in most cases the lacking early lateral reflections can be compensated by early reflections from the ceiling. If the performance zone is shifted in an amphitheater-like solution to the one-third point of the room ground plan, Fig. 7-22B, this variant is suitable only for musical performances. The listeners seated behind the performance zone especially receive a very spatial, lateral-sound accentuated sound impression.

The room acoustically most favorable with a trapezoidal layout is that of a converging trapezoid with the performance zone located at the broad end side, Fig. 7-22C. Already without additional measures on the side of the platform, the audience areas receiving low early lateral sound energy gets reduced to a very small area in front of the sound source; almost all of the other part of the audience areas receives a strong lateral energy fraction, Fig. 7-23. Unfortunately, this room shape has only perspectives for architectural realization in combination with a diverging trapezoid as a platform area. The arrangement of so-called vineyard terraces constitutes herewith a very favorable compromise solution in which wall elements in the shape of converging trapezoids are additionally integrated in the seating area. The effective surfaces of these elements direct energy-rich initial reflections into the reception area, Fig. 7-24. Examples of projects accomplished in this technique are
the concert halls of the Gewandhaus in Leipzig and De Doelen in Rotterdam.\textsuperscript{33}

This combination of a ground plan layout can also be realized in the shape of a hexagon which is a common application of a regular polygon ground plan. Elongated hexagons show room-acoustical properties similar to those of the combination of a diverging and a converging trapezoid or, provided the converging or diverging angle is slight, to those of a rectangular room. If the ground plan is that of a regular hexagon, the necessary lateral sound reflections are lacking especially with musical performances. Thanks to its varied uses and the short distances between the performance and reception zones it provides, this shape is rather advantageous for congress and multipurpose halls from the acoustical point of view. The amphitheaterlike arrangement of stage and audience of Fig. 7-25D shows acoustical similarities to the rectangular variant of Fig. 7-20C. With sound sources having a pronounced directional characteristic there occur timbre and clarity problems for listeners seated at the sides and behind the platform area, which cannot be compensated by means of additional secondary structures along the walls.

Ground plans with monotonically curved boundary surfaces (circle, semicircle, Figs. 7-26A to D) produce, due to their concave configuration towards the sound source and especially if the tiers are only slightly sloped or not at all, undesirable sound concentrations. On account of the curved surfaces, the sound pressure level may, in the concentration point, even surpass that of the original sound source by 10 dB and thus become an additional disturbing sound source. The resulting wave front responses which depend on frequency, travel time, and circle diameter, are shown in Fig. 7-27.\textsuperscript{34} One recognizes instances of migrating punctual and flat-spread sound concentration (the so-called caustic), which even after long travel times never do lead to a uniform sound distribution. Without any structuring in the vertical plane and without broadband secondary structures, rooms having a circular ground plane are acoustically suited neither for speech nor for musical performances.

With asymmetrical ground plans, Fig. 7-26E, there exists, for musical performances, the risk of a very poor correlation between the two ear signals, an effect that may give rise to an exaggerated spaciousness. Energy-rich initial reflections are to underline the visual asymmetry only as far as required for the architectural comprehension of the room, otherwise the room
produces balance problems with musical performances, leaving questions regarding the arrangement of the orchestra instrument groups unsolved. Elliptical ground plans, Fig. 7-26F, are, without reflection-supporting measures, acoustically suited only for locally fixed sound sources. This general utilization is not recommended owing to the focus formation in the performance zone as well as in the audience area. This refers especially to the atrium courtyards of unstructured glass walls and plane floor in large office buildings, which are a modern architectural trend. These functionally designed entrance foyers are often used for large musical events which, however, can in no way satisfy any room-acoustical requirements.

7.3.3.2.2 Ceiling

In general, the ceiling configuration contributes little to spaciousness of the sound field, but all the more to achieving intelligibility with speech, clarity with music, volume, and guidance of reverberation-determining room reflections. For speech, the reverberation time should be dimensioned as short as possible. Therefore the ceiling should be configured in such a way that possibly each first sound reflection reaches the middle and rear audience areas, Fig. 7-28. For musical performances the mean ceiling height has to comply with the volume-index requirements. For achieving an as long as possible reverberation time, the ceiling should have its maximum height where the length or width of the room is maximal. The repeated reflection of the sound energy by the involved boundary surfaces produces long travel times, while the required slightness of energy reduction by the reflections has to be insured by a negligible sound absorption coefficient of these surfaces.
to an adequately chosen geometry and size of the surfaces involved in this reverberation-time generating mechanism, it is possible to reduce the reverberation time in the low frequency range in a desirable fashion, while the sound impression is not deprived of its stimulating sound energy by sound absorption measures. In the concert hall of the Gewandhaus in Leipzig,\(^3\) the room has its widest extension in the rear audience area, so that here, as a result of simulation measurements in a physical model (see Section 7-3), the height of the ceiling was chosen to have its maximum, Fig. 7-29A and B. In contrast to that, the maximum room width of the concert hall of the Philharmonie Berlin, Fig. 7-29C and D is in the region of the platform. To realize an optimum reverberation time, the maximum room height has to be above the platform.

This also explains why it was necessary to arrange room-height reducing panels in this concert hall. With music, the ceiling above the performance zone must neither fall below nor exceed a certain height in order to support the mutual hearing of the musicians and to avoid simultaneously the generation of disturbing reflections. According to reference 3, the lower limit of the ceiling height in musical performance rooms is 5 to 6 m (16 to 19 ft), the upper limit about 13 m (43 ft).

In large rooms for concert performances, the ceiling configuration should provide clarity-enhancing sound reflections in the middle and rear audience areas and simultaneously avoid disturbing reflections via remote boundary surfaces. Owing to the geometrical reflection, a plain ceiling arrangement, Fig. 7-30A, supplies only a slight portion of sound energy to the rear reception area, but in the front area (strong direct sound), the sound reflected by the ceiling is not required. In the rear ceiling area, however, the sound energy is reflected towards the rear wall from where it is returned, according to the unfavorable room geometry, as a disturbing echo (so-called theater echo), to the talker or the first listener rows. Keeping this in mind, the ceiling surfaces above the performance zone and in front of the rear wall should point perpendicular towards the middle seating area, Figs. 7-30B to D.

Monotonically curved ceilings in the shape of barrel vaults or cupolas show focusing effects, which in the neighborhood of such focuses may produce considerable disturbances in the listener or performer areas. The center

Figure 7-29. Various concert halls.
of curvature should therefore be above half the total height of the room or below twice the height, Fig. 7-31.

\[ r \leq \frac{h}{2} \text{ or } r \geq 2h \quad (7-48) \]

According to Cremer\(^9\) it is guaranteed in this case that there do not originate from the curved ceiling any stronger reflections towards the receiving area than from a plain ceiling at apex height.

7.3.3.2.3 Balconies, Galleries, Circles

With proper arrangement and dimensioning, balconies and circles may have an acoustically favorable effect, since they contribute to a broadband diffuse sound dispersion and are also able to supply initial reflections for enhancing clarity and spatial impression. In this respect it is necessary, however, to decide if these reflections are desirable. Fig. 7-32A shows a graph of long-delayed sound reflections which give rise to very disturbing echo phenomena, the so-called theater echoes. Instrumental in the generation of these reflections is, first of all, the rear wall in combination with horizontal architectural elements (circle, gallery, balcony, ceiling). The disturbing effect of these sound reflections has to be avoided. Protruding balconies are, thanks to their horizontal depth, capable of shading these corner reflectors and to turn the reflections into useful sound, Fig. 7-32B.

The arrangement of far protruding circles is acoustically problematical with regard to the depth \( D \) (distance of the balustrade or of a room corner above it from the rear wall) and the clearance height \( H \) of the circle above the parquet or between two circles arranged one above the other. If the protrusion is very deep, the room area situated below it is shaded against reverberant sound and clarity-enhancing ceiling reflections. This area may be cut off from the main room and have an acoustic pattern of its own with strongly reduced loudness, unless certain construction parameters are observed, Fig. 7-33.\(^2,7,9\)

7.3.3.3 Room Topography

7.3.3.3.1 Sloping of Tiers, Sight Lines

For all room-acoustical parameters describing time and registers clarity, the energy proportion of direct sound and initial reflections is of great importance. With the sound propagating in a grazing fashion over a plain audience area there occurs a strong, frequency-dependent attenuation (see Section 7.3.4.4.4). Also, visually, such a situation implies considerable disadvantages by obstruction of the view towards the performance area. These disturbing effects are avoided by a sufficient and, if possible, constant superelevation of the visual line.
According to Fig. 7-34, this is the superelevation of the visual line (virtual line between eye and reference point) of a tier \( n + 1 \) as against tier \( n \).

With a tier arrangement having a constant step height (continuous sloping in the longitudinal direction of the room), it is not possible to achieve a constant superelevation \( c \). Mathematically it is the curve of a logarithmic spiral in which the superelevation increases alongside the distance from the reference point that realizes a constant superelevation of the visual line.\(^{34} \)

As this implies, however, steps of different height for the individual tiers, a compromise must be found by either adapting the step height or by combining several tiers in small areas of constant sloping. In concert halls, the areas arranged in the shape of vineyard terraces (see Section 7.3.3.2.1) constitute, in this respect, an acoustically and optically satisfactory solution.

The eye level \( y(x) \) is calculated with

\[
(a, b) = \text{Coordinates of the first row (eye level)}. \\
(x_n, y_n) = \text{Coordinates of the nth row}. \\
(x_{n+1}, y_{n+1}) = \text{Coordinates of the (n+1)th row}. \\
c = \text{Sight line superelevation (requirement: c = constant)}. \\
d = \text{Tier spacing}. \\
y = \text{Eye level} = \text{tier level} + 1.2 \text{ m}.
\]

**Figure 7-32.** Echo phenomena due to edge reflections.

**Figure 7-33.** Geometry of circle arrangement in A. Music and opera houses, multigenre theaters and B. concert halls.
\[ y = y_0 + \frac{cx}{d} \ln \frac{x}{a} + \frac{x}{a} (b - y_0) \]  \hspace{1cm} (7-49)

where,

\[ y \hspace{0.5cm} \text{for} \hspace{0.5cm} y_0 = 0 \]

\[ y = \frac{cx}{d} \ln \frac{x}{a} + \frac{bx}{a} \]

The superelevation of the visual line should amount to at least 6 cm (2.5 in).

For estimating the required basic sloping of tiers one should keep in mind that the platform must be completely observable from all seats during the performances. The reference point to be chosen to this effect should, if possible, be the front edge of the platform. Using a reasonable platform height between 0.6 to 1 m (2 to 3.3 ft), the results of the sloping values are shown in Fig. 7-35A.

By increasing the distance between first tier and viewing point (observable area of the platform) it is, of course, possible to notably reduce the necessary sloping of tiers, Fig. 7-35B.

With a plain parquet arrangement, which is the case in concert halls serving also for banquets or with classicist architecture (Musikvereinssaal Vienna, Konzerthaus Berlin, Symphony Hall Boston, Herkulessaal Munich, etc.), a certain though normally somewhat dissatisfactory compensation is possible by means of an appropriate vertical staggering within the performance area (especially feasible for concert performances). For a basic platform height of 0.6 to 0.8 m (2 to 2.6 ft) it is possible to derive the theoretical required sloping heights from Eq. 7-49. With a length of a plain seating area of about 14 m (46 ft), a vertical staggering of the musicians on the platform must be about 3 m (10 ft), and with 18 m (59 ft) vertical staggering must be 4 m (13 ft). These values are generally not easy to realize, but show the necessity of an ample vertical staggering of the orchestra on the platform in rooms with plain parquet arrangement. However, if the optimum sloping of tiers according to Eq. 7-49 is realized on principle, it is possible for a sound source situated in the middle of the orchestra about 6 m (20 ft) behind the front edge of the platform to achieve the required view field angle by an elevation of 0.25 m (≈1 ft), and for the entire depth of the orchestra arrangement this elevation amounts to only about 1 m (≈3.3 ft). In concert halls with a sufficient sloping of tiers in the audience area, vertical staggering of the orchestra plays no more than a subordinate role for the unhindered direct sound supply to the audience area.

7.3.3.3.2 Platform Configuration in Concert Halls

With concert performances, the performance area for the orchestra (platform) must be an acoustical component of the auditorium, which means that both sections of the room must form a mutually attuned unity. This unity must not be disturbed by intermediate or other built-in elements. Any individual room-acoustical behavior of its own of a too small concert stage enclosure must be avoided. As used to be the case with many opera houses, this has a sound coloration deviating from that of the main auditorium and will be perceived as alienated. The volume of a concert stage enclosure should be at least 1000 m³ (35,300 ft³).36 The sloping angles of the lateral boundary walls, referred to the longitudinal axis of the room, should be relatively flat. Takaku36 defines an inclination index \( K \) according to Eq. 7-50

\[ K = \frac{\sqrt{\frac{WH}{\pi}} - \sqrt{\frac{wh}{\pi}}}{D} \]  \hspace{1cm} (7-50)

where,

\( K \) is the inclination index,
\( W \) is the proscenium width,
\( H \) is the proscenium height,
Chapter 7

Figure 7-36. Geometrical parameters of a concert enclosure.

Optimum conditions for the mutual hearing of the musicians are achieved for a concert stage enclosure in the shape of a truncated pyramid, Fig. 7-36, with $K \leq 0.3$.\textsuperscript{36}

The more pronounced the diffuse subdivision of the inner surfaces of the concert stage enclosure, the smaller results the dependence of the room-acoustical parameters on the inclination index $K$.

If the platform boundaries are not formed by acoustically favorable solid wall and ceiling surfaces, additional elements have to be installed. The surface-related mass of the planking of these platform boundary surfaces should be chosen in such a way that the sound energy reduction by absorption results as little as possible. (The thinner the boundary walls the higher the low-frequency absorption.) To this effect, area-related masses of about 20 kg/m$^2$ (0.85 lbs/ft$^2$) are generally sufficient, in the neighborhood of bass instruments about 40 kg/m$^2$ (1.7 lbs/ft$^2$).

The vibration ability of the platform floor has only an insignificant influence on its sound radiation. With a relatively thin platform floor (12.5 mm (0.5 in) plywood\textsuperscript{37} there may well result a sound amplification of between 3 dB to 5 dB in the lower-frequency range, but one should also not forget in this respect the positive psychological feedback of a vibrating floor on the players.\textsuperscript{3} As a rule, the area-related mass of the platform floor should not fall below 40 kg/m$^2$.

By comparison with a rigid floor, a vibrating platform floor has, for the sound radiation of the bass string instruments with pizzicato play (faster decay resulting in a dry sound), the disadvantage of a reduced airborne sound energy, which can, however, be technically compensated with bow strokes.\textsuperscript{3} This is why the platform floor should be frequency-tuned as low as possible.

The platform boundary surfaces should be structured in such a way that the mutual hearing of the musicians is supported, disturbing echo phenomena (e.g., by parallel wall surfaces) are avoided, and a well-mixed sound pattern gets radiated into the audience area. Obtaining a thorough mixing of the sound pattern requires a frequency-independent substructure of the boundary surfaces.

The space required per musician is about 1.4 m$^2$ (15 ft$^2$) for high-pitched string and brass instruments, 1.7 m$^2$ (18 ft$^2$) for low-pitched string instruments, 1.2 m$^2$ (13 ft$^2$) for woodwind instruments and 2.5 m$^2$ (27 ft$^2$) for the percussion. From this one can infer that, with due consideration of the participation of soloists (tail piano, etc.), the area of a concert platform (without choir) should generally not fall much below 200 m$^2$ (2200 ft$^2$), in which case the width should be about 18 m (60 ft) at the level of the high-pitched strings, and the maximum depth about 11 m (36 ft).

Depending on the sloping of tiers in the audience area (see Section 7.3.3.3.1), a vertical staggering of the orchestra is necessary especially if the audience area in the parquet is level or only slightly sloping. In the Musikvereinssaal Vienna the level difference on the platform is 1.8 m (6 ft), in the Berliner Philharmonie, which was destroyed during WWII, it was 2.8 m (9.2 ft). In such a case it is necessary to have one step in the string group approximately 250 mm (10 in), the following steps to and between the two rows of woodwind instruments should each be 500 mm (20 in) high. For the brass instruments or the percussion a further step of about 150 mm (6 in) is sufficient.

A choir, which in the staging of a grand concert, is normally lined up behind the orchestra, can profit only from the lateral wall surfaces and the ceiling of the room with regard to clarity-enhancing sound reflections, the floor area is shaded. Since according to Meyer\textsuperscript{3} the main radiation axis of the singers’ strongest sound fractions is inclined about 20° downwards, the choir line-up should be relatively steeply staggered in order to insure clarity and definition of articulation in the choir sound. With a flat line-up, however, only reverberance is increased. This is perceived as disturbing in rooms with a long reverberation time, whereas it may be rather desirable in reverberation-poor rooms. The optimum value of vertical staggering within a choir is about 45°—i.e., the steps should be equal in breadth and height in order to enable simultaneously an unhindered sound radiation to the lateral boundary surfaces of the room.\textsuperscript{3}
7.3.3.3 Orchestra Pit

On principle, the arrangement of the orchestra with musical stage plays in the so-called pit at the border line between stage and auditorium is acoustically unfavorable by comparison with orchestra arrangements on the stage (e.g., stage music), but has developed historically from the performing practice in the 19th century. In most baroque theaters the musicians were seated either at the same level as the first listeners’ rows or only a few steps lower. They were separated from the audience area only by an about 1 m (3.3 ft) high balustrade. With the introduction of an orchestra pit, the visual contact between listener and stage was later reduced, especially when the orchestras grew larger. Room-acoustical shortcomings lie herewith in the problem of balance between the singing/speech on stage and the accompanying orchestra in the pit. Owing to the size and equipment of the stage area, the loudness of the singers gets altered with growing distance from the orchestra so that balance problems increase especially in case of low singing loudness and unfavorable pitch levels.

A further aspect concerns the register and time correspondence between stage and pit on which depend the intonation and ensemble playing.

The geometrical separation between the two performance areas (stage and orchestra pit) should, in modern opera houses, be as little as possible, not only in dependence on dramaturgical arguments, but also for visual and functional reasons. Consequently, the orchestra pit slides beneath the stage, so as to avoid that the distance of the first rows from the stage increases still further. The practicability of the thus formed covered area of the orchestra pit (proscenium area), required for dramaturgical reasons, implies that the covered area becomes bigger and bigger, while the open coupling space of the pit to the auditorium gets smaller and smaller. The orchestra pit thus becomes an independent room tightly packed with musicians and with low boundary surfaces, a low-volume index, and a nonreflecting subceiling (opening) representing the outlet for irradiation of the more or less well mixed orchestra sound to the auditorium. Owing to the reduced distance of the musicians from the boundary surfaces, the sound pressure level in the pit increases by up to about 4 dB, whereby the mutual hearing of the musicians is supported for low-volume playing. With increased loudness the mutual hearing gets disadvantageously limited to loud instrumental groups in the low- and medium-frequency range.

Sound-absorbing wall or ceiling coverings or adjustable wall elements with preferential effect in the low- and medium-frequency range, arranged in the neighborhood of loud instruments, reduce the loudness desirably, but not the direct sound irradiation into the auditorium. This supports the clarity of the sound pattern. If the orchestra pit level is very low, about 2.5 m (8.2 ft), direct sound fractions reach the parquet level only by diffraction, causing the sound pattern to be very bass-accentuated. Brilliance and temporal clarity become adequate only at those places where visual contact to the instrument groups is given (circles).

Acoustic improvement of this situation may be achieved on the one hand by a wider opening of the orchestra pit, so that energy-rich initial reflections are enabled via a corresponding structure of the adjacent proscenium area (proscenium ceiling and side wall design). On the other hand the pit depth should not exceed certain limits. By means of subjective investigations with varying height of the pit floor, optimum solutions may easily be found here in combination with an adequate positioning of the instruments in the pit. With a balustrade height of about 0.8 m (2.6 ft), lowering the front seating area of the pit floor (high-pitch strings) to about 1.4 m (4.6 ft) produces generally good acoustical conditions. Towards the rear the staggering should go deeper.

Provided the orchestra plays with adapted loudness, an acceptable solution consists in an almost complete opening of the orchestra pit towards the proscenium side walls and an as little as possible covering towards the stage. If the open area amounts to at least 80% of the pit area, the orchestra pit becomes acoustically part of the auditorium and the unity of the sound source is insured also with respect to coloration (example: Semperoper Dresden). Another solution consists of an almost completely covered orchestra pit with a small coupling area to the auditorium. This requires, however, a correspondingly large pit volume with a room height of at least 3 m (10 ft) (example: Festspielhaus Bayreuth). Common opera houses lie with their orchestra pit problems half-way between these two extremes. If there is a large orchestration accommodated in the pit, less powerful singers on the stage may easily become acoustically eclipsed. More favorable conditions can be obtained in this case by means of a pit covering, provided a sufficient volume is given, or by positioning the orchestra on a lower pit floor level.

Apart from the sound reflecting and sound absorbing boundary surfaces arranged in the pit for supporting the mutual hearing and the intonation, the inner faces of the pit balustrade should point perpendicularly towards the stage (slight inclinations on the side of the balustrade). In this way the stage is better supplied with initial reflections from the pit, whereas the pit receives a first
reflection from sound sources on the stage. Convex curves (in the vertical domain) combined with a sound-absorbing effect in the low-frequency range are, in this respect, especially advantageous for making the supporting effect register-independent on the one hand and brilliance enhancing on the other hand. The edge of the stage above the pit vis-à-vis the conductor should be conformed geometrically in such a way that additional initial reflections are directed to the audience area. The lateral configuration of the pit opening, combined with an appropriate subconstruction of the proscenium side wall, should insure a maximum of sound reflections towards the pit and the stage.

7.3.4 Secondary Structure of Rooms

7.3.4.1 Sound Reflections at Smooth Plane Surfaces

With the reflection of sound rays from boundary surfaces, one can principally define three types of reflection which differ from one another by the relation between the linear dimensions and the wavelength and by the relation between the reflected and the incident sound ray, Fig. 7-37.

- **Geometrical reflection**, Fig. 7-37A: \( b < \lambda, \alpha = \beta \) (specular reflection according to the reflection law in one plane perpendicular to the carrier wall).
- **Directed (local) reflection**, Fig. 7-37B: \( b > \lambda, \alpha = \beta \) (specular reflection according to the reflection law, referred to the effective structural surface).
- **Diffuse reflection**, Fig. 7-37C: \( b \approx \lambda \), (no specular reflection, without a preferred direction).

A geometrical sound reflection occurs at a sufficiently large surface analogously to the reflection law of optics: the angle of incidence \( \alpha \) is equal to the angle of reflection \( \beta \) and lies in a plane perpendicular to the surface, Fig. 7-38. This reflection takes place only down to a lower limit frequency \( f_{\text{low}} \)

\[
f_{\text{low}} = \frac{2c}{(b \cos \alpha)^2} \times \frac{a_1 a_2}{a_1 + a_2}
\]

(7-51)

where,

- \( c \) is the velocity of sound in air.

Below \( f_{\text{low}} \) the sound pressure level decay amounts to 6 dB/octave.\(^{38}\)

Eq. 7-51 has been graphically processed, Fig. 7-39.\(^3\)

With a reflector extension of 2 m (6.6 ft) at a distance of 10 m (3 ft) each from the sound source and to the listener, the lower limiting frequency is, for example,

about 80 Hz with vertical sound incidence and about 1600 Hz with an incidence angle of 45°. If this reflector is installed as a panel element in the front part of the platform, the frequency region of the sound reflections is about one octave lower with almost platform-parallel arrangement than in a 45° inclined position. The desired limiting frequency goes down to lower values under the following circumstances:

- The bigger the effective surface.
- The nearer to the sound source and to the listener the reflector is installed.
- The smaller the sound incidence angle.

Apart from the geometry of the reflectors, the area-related mass of the same also has to be consistent with certain limit values in order to obtain a reflection with as little a loss as possible. If the reflectors are employed for speech and singing in the medium and high-frequency ranges, a mass of about 10 kg/m² (1.7 lbs/ft²) is sufficient (e.g. a 12 mm (½ in) plywood plate). If the effective frequency range is expanded to bass instruments, a mass of about 40 kg/m² (1.7 lbs/ft²) has to be aspired (e.g., 36 mm [1.5 in] chipboard). With reflectors additionally suspended above the performance zone, the statically admissible load often plays a
restrictive role for the possible mass of the reflectors. For spoken performances an area-related mass of 5 to 7 kg/m² (0.2 to 0.3 lbs/ft²) may still produce acceptable results, to which effect plastic mats of high surface density are suitable. The additional room-acoustical measure usually employed for enhancing the sound reflection of bass instruments with music performances consists in appropriate wall surfaces, so that the installation of heavy panels can be abandoned. In this case an area-related mass of 20 kg/m² (0.8 lbs/ft²) is sufficient.

If a multiple reflection occurs close to edges of surfaces, there results, if the edge is at right angle to the surface, a sound reflection with a path parallel to the direction of the sound incidence, Fig. 7-40. In corners, this effect acquires a 3D nature, so that the sound always gets reflected to its source, independently of the angle of incidence. With long travel paths it is possible that very disturbing sound reflections are caused at built-in doors, lighting stations, setoffs in wall paneling, which for the primary structure of a room are known as “theater echo” (see Section 7.3.3.2.2).

7.3.4.2 Sound Reflection at Smooth Curved Surfaces

If the linear dimensions of smooth curved surfaces are much bigger than the wavelength of the effective sound components, the sound is reflected from these surfaces according to the laws of concentrating reflectors. Concavely curved 2D or 3D surface elements may, under certain geometrical conditions, lead to sound concentrations while convex curvatures always have a sound scattering effect.

For axis-near reflection areas (incident angle less than 45°) of a surface curved around the center of curvature $M$, it is possible to derive the following important reflection variants, Fig. 7-41.

**Circular Effect.** The sound source is located in the center of curvature $M$ of the reflecting surface, Fig. 7-41A. All irradiated sound rays become concentrated in $M$ after having covered the radius twice, so that a speaker may, for instance, be heavily disturbed by his own speech.
Elliptical Effect. If the sound source is located between half the radius of curvature and the full radius of curvature in front of the reflecting surface, a second sound concentration point is formed outside the center of curvature, Fig. 7-41B. If this second focus is located within the performance zone or the audience area, it is perceived as very disturbing, since distribution of the reflected sound is very unbalanced. With extended sound sources like an orchestra, curved surfaces of this kind produce a heavily register-dependent sound balance.

Parabolic Effect. If in a rather narrow arrangement the sound source is located at half the center of curvature, Fig. 7-41C, the curved surface acts like a so-called parabolic reflector that generates an axis-parallel bundle of rays. This produces, on the one hand, a very uniform distribution of the reflected portion of the sound irradiated by the source, but on the other hand there occurs an unwanted concentration of noise from the audience area at the location of the sound source.

Hyperbolic Effect. If the distance of the sound source from the curved surface is smaller than half the radius of curvature, Fig. 7-41D, the reflecting sound rays leave the surface in a divergent fashion. But the divergence is less and thus the sound intensity at the listener’s seat is higher than with reflections from a plain surface. The acoustically favorable scattering effect thus produced is comparable to that of a convexly curved surface, but the diverging effect is independent of the distance from the curved reflecting surface.

7.3.4.3 Sound Reflections at Uneven Surfaces

Uneven surfaces serve as the secondary structure of directional or diffuse sound reflections. This refers to structured surfaces with different geometrical intersections in the horizontal and vertical planes (rectangles, triangles, sawtooth, circle segments, polygons) as well as 3D structures of geometrical layout (sphere segments, paraboloids, cones, etc.) and free forms (relievos, moldings, coves, caps, ornaments, etc.). Also by means of a sequence of varying wall impedances (alternation of sound reflecting and sound absorbing surfaces), it is possible to achieve a secondary structure with scattering effect.

To characterize this sound dispersion of the secondary structure one makes a distinction between a degree of diffusivity \( d \) and a scattering coefficient \( s \).

Typically for the homogeneity of the distribution of the sound reflections is the so-called frequency-dependent degree of diffusivity \( d \).\(^{47}\)

\[
d = \frac{\left( \sum_{i=1}^{n} 10^{10} \right)^2 - \sum_{i=1}^{n} \left( 10^{10} \right)^2}{(n - 1) \sum_{i=1}^{n} \left( 10^{10} \right)^2} \quad (7-52)
\]

This way angle-dependent diffusion balloons may be generated. Depending on the number of \( n \) receiver positions hi-res=level values are supplied to form the balloon.

High diffusion degrees close to one will be reached for half-cylinder or half-sphere structures. Nevertheless the diffusion degree \( d \) is more or less a qualitative measure to evaluate the homogeneity of scattering.

On the other side and as a quantitative measure to characterize the amount of scattered energy in contrast to the specular reflected or absorbed energy, the frequency-dependent scattering coefficient \( s \) is used.\(^{50}\)

This scattering coefficient \( s \) is used in computer programs to simulate the scattered part of energy especially by using ray tracing methods.

The coefficient \( s \) will be determined as the ratio of the nonspecular (i.e., of the diffuse reflected) to the overall reflected energy.

\[
s = \frac{\text{diffuse-reflected Energy}}{\text{overall-reflected Energy}}
\]

\[
= \left( 1 - \frac{\text{geometric-reflected Energy}}{\text{overall-reflected Energy}} \right) \quad (7-53)
\]
The measurement and calculation of the scattering coefficient under random sound impact take place in the reverberation chamber.39,48,49

All these parameters don’t say too much about the angular distribution of the reflected sound energy. But there exist many examples of rooms in which the secondary structure is intended to realize a directional reflection in which the angle of sound reflection does not correspond to the angle of sound incidence, as referred to the basic surface underlying the primary structure. In this case of directional sound reflection, one has to consider parameters determining, among other things, the diffusivity ratio \( D_{\text{diff}} \) and the maximum displacement \( d_\alpha \), Fig. 7.42.42

**Figure 7-42.** Parameters for characterizing the directivity of uneven surfaces.

- **Diffusivity ratio** \( D_{\text{diff}} \): sound pressure level difference between the directional and the diffuse sound components \( L_{\text{max}} \) and \( L_{\text{diff}} \) respectively.
  - \( D_{\text{diff}} \) characterizes the directional effect of a structure.

- **Attenuation of Maximum** \( \Delta a_{\text{max}} \): sound pressure level difference between the directional reflection (local maximum, \( \beta_{\text{max}} \)) of the structure, as compared with a plain surface.
  - \( \Delta a_{\text{max}} \) characterizes the sound pressure level of the reflection.

- **Displacement of Maximum** \( d_\alpha \): angle between geometrical and directional reflections.
  - \( d_\alpha \) characterizes the desired change of direction of the reflection.

- **Angular range of uniform irradiation** \( \Delta \alpha \): 3 dB bandwidth of the reflection.
  - \( \Delta \alpha \) characterizes the solid-angle range of uniform sound reflection.

Guide values \( D_{\text{diff}} \) for the octave midband frequency of 1000 Hz are based on subjective sound-field investigations in a synthetic sound field, Table 7-9.

An example for a sawtooth structure is shown in Fig. 7.43. This side wall structure has at a sound incidence angle of 50° and a speech center frequency of about 1000 Hz, energy-rich directional sound reflections \( (D_{\text{diff}} \geq 10 \, \text{dB}) \) with a displacement of maximum of \( d_\alpha = 20^\circ \) (reflection angle 30°). Additionally directional and diffuse sound components being perceptible from about 3000 Hz \( (D_{\text{diff}} = 6 \text{ to } 8 \, \text{dB}) \). The attenuation of maximum \( \Delta a_{\text{max}} \) was 5 dB at 1000 Hz and 11 dB at 5000 Hz by comparison with a carrier panel of geometrical sound reflection.

Periodical structures of elements having a regular geometrical cut (rectangle, isosceles triangle, sawtooth, cylinder segment) may show high degrees of scattering, if the following dimensions are complied with, Fig. 7-44.3,40

For a diffuse scattering in the maximum of the speech-frequency range, the structure periods are therefore about 0.6 m (2 ft), the structure widths between 0.1 to 0.4 m (0.33 to 1.3 ft), and the structure heights maximally about 0.3 m (1 ft). With rectangular structures the sound scattering effect is limited to the relatively small band of about one octave, with triangular structures to maximally two octaves. Cylinder segments or geometrical combinations can favorably be used for more broadband structures, Fig. 7-43. In a wide-frequency range between 500 Hz and 2000 Hz, a cylinder segment structure is sufficiently diffuse, if the structure width of about 1.2 m (4 ft) is equal to the structure period, and the structure height is between 0.15 and 0.20 m (0.5 and 0.7 ft). With a given structure height \( h \) and a given structure width \( b \) it is, according to Eq. 7-54, possible to calculate the required curvature radius \( r \) as
A special form of a diffusely reflecting surface can be realized by lining up phase-grating structures of varying depths. Based on the effect of coupled $\lambda/2$ runtime units, these structures produce on the surface a local distribution of the reflection factor and hence of the sound particle velocity. Every component of this velocity distribution produces thereby a sound irradiation into another direction. If according to Schroeder\(^{41}\) one distributes these reflection factors in accordance with the maximum sequences of the number theory (e.g., Barker code, primitive root diffusor PRD, square-law residual series QRD), and separates these trough structures from each other by thin wall surfaces, one obtains diffuse structures of a relatively broadband effect (up to two and more octaves), Fig. 7-45. With perpendicular sound incidence, the minimum frequency limit $f_{\text{low}}$ for the occurrence of additional reflection directions is approximately

$$ f_{\text{low}} \approx \frac{c}{2d_{\text{max}}} \quad (7-55) $$

where,

- $c$ is the velocity of sound in air in m/s (ft/s),
- $d_{\text{max}}$ is the maximum depth of structure in m (ft)

Nowadays calculation programs are available to calculate the scattering coefficients for angle-dependent sound impact by using Boundary Element Methods, Fig. 7-46.
7.3.4.4 Sound Absorbers

Sound absorbers can occur in the shape of surfaces, built-in elements, pieces of furniture, or in the form of unavoidable environmental conditions (e.g., air) as well as arrangements conditioned by utilization of the room (e.g. spectators, decorations). According to their preferential effect in a determined frequency range one distinguishes on principle between

- Absorbers in the low-frequency range between approximately 32 Hz and 250 Hz.
- Absorbers in the medium-frequency range between approximately 315 Hz and 1000 Hz.
- Absorbers in the high-frequency range between approximately 1250 Hz and 12 kHz.
- Broadband absorbers.

For acoustical characterization of a sound absorber there serves its frequency-dependent sound absorption coefficient $\alpha$ or the equivalent sound absorption area $A$. For an area of size $S$ one determines the equivalent sound absorption area $A$ as

$$A = \alpha S \quad (7-56)$$

The sound power $W_i$ being incident on an area of size $S$ of a sound-absorbing material or a construction is designated as sound intensity $I_i$, part of which is reflected as sound intensity $I_r$ and the rest is absorbed as sound intensity $I_{abs}$. The absorbed sound intensity consists of the sound absorption by dissipation (transformation of the sound intensity $I_\delta$ in heat, internal losses by friction at the microstructure or in coupled resounding hollow spaces), and of the sound absorption by transmission (transmission of the sound intensity $I_\tau$ into the coupled room behind the sound absorber or into adjacent structural elements).

$$I_i = I_r + I_{abs}$$

$$= (I_r + I_\delta + I_\tau) \quad (7-57)$$

With the sound reflection coefficient $\rho$ defined as

$$\rho = \frac{I_r}{I_i} \quad (7-58)$$

and the sound absorption coefficient $\alpha$ as

$$\alpha = \frac{I_\delta + I_\tau}{I_i}$$

$$= \frac{I_{abs}}{I_i} \quad (7-59)$$

as a sum of the dissipation coefficient $\delta$

$$\delta = \frac{I_\delta}{I_i} \quad (7-60)$$

and the transmission coefficient

$$\tau = \frac{I_\tau}{I_i} \quad (7-61)$$

Eq. 7-57 becomes

$$1 = \rho + \delta + \tau$$

$$= (\rho + \alpha) \quad (7-62)$$

The transmission coefficient $\tau$ plays a role when considering the sound insulation of structural components. For nonmovable, monocoque, acoustically hard material surfaces (e.g., walls, windows), it is, according to Cremer,\textsuperscript{48} possible to consider the frequency dependence of the transmission coefficient as a low-pass behavior which surpasses the given value up to a limit frequency $f_c$. With a negligible dissipation coefficient it is furthermore possible to equate the transmission coeffi-

7.3.4.4.1 Sound Absorption Through Porous Materials

The effect of sound absorption is based essentially on the transformation of sound energy in thermal energy by air particles moving in open, narrow, and deep pores. Closed pores like those existing in foamed materials used for thermal insulation are unsuited for sound insulation. For characterizing the materials the so-called porosity $\sigma$ is used. This represents the ratio between open air volume $V_{air}$ existing in the pores and the overall volume $V_{tot}$ of the material

$$\sigma = \frac{V_{air}}{V_{tot}}$$  \hspace{1cm} (7-63)

With a porosity of $\sigma = 0.125$, it is possible for high frequencies to obtain a maximum sound absorption coefficient of only $\alpha = 0.4$, and with $\sigma = 0.25$ of $\alpha = 0.65$. Materials with a porosity of $\sigma \geq 0.5$ enable a maximum sound absorption coefficient of at least 0.9. Usual mineral, organic, and naturally growing fibrous insulating materials feature porosities of between 0.9 and 1.0 and are thus very well suited for sound absorption purposes in the medium- and high-frequency ranges.29

Apart from porosity it is also the structure coefficient $s$ and the flow resistance $\Xi$ which influence the sound absorbing capacity of materials. The structure coefficient $s$ can be calculated from the ratio between the total air volume $V_{air}$ contained in the pores and the effective porous volume $V_w$

$$s = \frac{V_{air}}{V_w}$$  \hspace{1cm} (7-64)

The insulating materials most frequently used in practice have structure factors of between 1 and 2—i.e., either the total porous volume is involved in sound transmission or the dead volume equals the effective volume. Materials with a structure factor of the order of ten show a sound absorption coefficient of maximally 0.8 for high frequencies.8

The flow resistance exerts an essentially higher influence on sound absorption by porous materials than the structure factor and the porosity. With equal porosity, for instance, narrow partial volumes offer a higher resistance to particle movement than wide ones. This is why the specific flow resistance $R_s$ is defined as the ratio of the pressure difference before and behind the material with regard to the speed of the air flowing through the material $v_{air}$

$$R_s = \frac{\Delta p}{v_{air}}$$  \hspace{1cm} (7-65)

where, $R_s$ is the specific flow resistance in Pa s/m (lb s/ft³), $\Delta p$ is the pressure difference in Pa (lb/ft²), $v_{air}$ is the velocity of the passing air in m/s (ft/s).

With increasing material thickness the specific flow resistance in the direction of flow increases as well.

7.3.4.4.2 Sound Absorption by Panel Resonances

Thin panels or foils (vibrating mass) can be arranged at a defined distance in front of a rigid wall so that the withdrawal of energy from the sound field in the region of the resonance frequency of this spring-mass vibrating system makes the system act as a sound absorber. The spring action is produced herewith by the rigidity of the air cushion and the flexural rigidity of the vibrating panel. The attenuation depends essentially on the loss factor of the panel material, but also on friction losses at the points of fixation.43 The schematic diagram is shown in Fig. 7-47, where $d_L$ is the thickness of the air cushion and $m'$ the area-related mass of the vibrating panel.

The resonance frequency of the vibrating panel mounted in front of a rigid wall with attenuated air space and lateral coffering is calculated approximately as

$$f_R \approx \frac{60}{\sqrt{m'd_L}}$$  \hspace{1cm} (7-66)

* 73 in U.S. units

where,

- $f_R$ is in Hz,
- $m'$ is in kg/m² (lb/ft²),
- $d_L$ is in m (ft).

**Figure 7-47.** General structure of a panel resonator.

In practical design one should moreover take into account the following:

- The loss factor of the vibrating panel should be as high as possible.43
• The clear spacing of the coffering should be, in
general, smaller in every direction than 0.5 times the
wavelength in case of resonance, but not fall short of
0.5 m (1.7 ft).
• The minimum size of the vibrating panel must not
fall short of 0.4 m² (4.3 ft²).
• The air-space damping material should be attached to
the solid wall so that the panel vibration is not
impaired in any way.
• The sound absorption coefficient depends on the Q
factor of the resonance circuit and amounts at the res-
onance frequency to between 0.4 and 0.7 with
air-cushion damping and to between 0.3 and 0.4
without air-cushion damping. At an interval of one
octave from the resonance frequency one must
reckon that the sound absorption coefficient is
halved.

An effective method for increasing the acoustically
effective resonance frequencies of panel resonators
consists of reducing the vibrating mass of heavy panels
by means of holes arranged in defined patterns. In this
case the correlations are governed by analogous regu-
larities, if the area-related mass \( m' \) of the panels is replaced
by the effective hole mass \( m'_L \). For circular holes of
radius \( R \) and a hole-surface ratio \( \varepsilon \), Fig. 7-48, the hole
mass is calculated as

\[
m'_L = 1.2 \times \frac{l^*}{\varepsilon}
\]

(7-67)

** 0.37 for U.S. system
where,

- \( m'_L \) is the area-related air mass of circular openings in
  kg/m² (lb/ft²),
- \( l^* \) is the effective panel thickness with due consider-
ation of the mouth correction of circular openings of
  radius \( R \) in meters (ft)
- \( \varepsilon \) is the hole-area ratio according to Fig. 7-47 for
circular openings

\[
l^* \approx 1 + \frac{\pi R}{2},
\]

(7-68)

\[
\varepsilon = \frac{\pi R^2}{ab}.
\]

Provided the hole diameters are sufficiently narrow,
the damping material layer arranged between the perfo-
rated panel and solid wall can be replaced by the friction
losses produced in the openings. By using transparent
materials—e.g., glass—it is possible to fabricate opti-
cally transparent, so-called micro-perforated absorbers.
The diameters of the holes are in the region of 0.5 mm
(0.02 in) with a panel thickness of 4 to 6 mm (0.16 to
0.24 in) and a hole-area ratio of 6%. For obtaining
broadband sound absorbers, it is possible to resort to
variable perforation parameters (e.g., scattered perfora-
tion) varying thickness of the air cushion and composite
absorbers combined of various perforated panels.

Figure 7-48. Hole-area ratio of perforated panels with
round holes.

A very recent development are microperforated foils
of less than 1 mm (0.04 in) thickness which also produce
remarkable absorption when placed in front of solid
surfaces. The transparent absorber foil can be advan-
tageously arranged in front of windows either fixed or also
as roll-type blinds in single or double layer.44

7.3.4.4.3 Helmholtz Resonators

Helmholtz resonators are mainly used for sound absorp-
tion in the low-frequency range. Their advantage, as
compared with panel absorbers (see Section 7.3.4.4.2),
lies in their posterior variability regarding resonance
frequency and sound absorption coefficient as well as in
the utilization of existing structural cavities which must
not necessarily be clearly visible. According to Fig.
7-49, a Helmholtz resonator is a resonance-capable
spring-mass system which consists of a resonator
volume \( V \) acting as an acoustical spring and of the mass
of the resonator throat characterized by the opening
cross section \( S \) and the throat depth \( l \). In resonance
condition and if the characteristic impedance of the
resonator matches that of the air, the ambient sound
field is deprived of a large amount of energy. To this
effect a damping material of a defined specific sound
impedance is placed in the resonator throat or in the
cavity volume.
The resonance frequency of a Helmholtz resonator is generally calculated as

\[
f_R = \frac{c}{2\pi \sqrt{V(l + 2\Delta l)}}
\]

(7-70)

where,
- \(c\) is the speed of sound in air, approximately 343 m/s (1130 ft/s),
- \(S\) is the cross-sectional area of the resonator in m\(^2\) (ft\(^2\)),
- \(V\) is the resonator volume in m\(^3\) (ft\(^3\)),
- \(l\) is the length of the resonator throat in m (ft),
- \(2\Delta l\) is the mouth correction.

In case of a square opening

\[2\Delta l \approx 0.9a,\]

where,
- \(a\) is the edge length of the square opening.

For circular openings the resonance frequency \(f_R\) in Hz is calculated approximately from Eq. 7-70:

\[
f_R \approx \frac{100*R}{\sqrt{V(l + 1.6R)}}
\]

(7-71)

where,
- \(R\) is the radius of the circular opening in m (ft),
- \(V\) is the resonator volume in m\(^3\) (ft\(^3\)),
- \(l\) is the length of the resonator throat in m (ft).

7.3.4.4.4 Sound Absorption by the Audience

The efficiency of sound absorption by the audience depends on many factors, for instance the occupation density, the spacing of seats and rows, the clothing, the type and property of the seats, the sloping of tiers and the distribution of the persons in the room. In a diffuse sound field the location of the sound source towards the audience area is of minor importance in this regard. Fig. 7-50 shows a survey of the values of the equivalent sound absorption area per person for a variety of occupation densities and seating patterns in a diffuse sound field. Since in many types of rooms the reverberation time for medium and high frequencies is determined almost exclusively by the sound absorption of the audience, one has to reckon with a rather high error rate, if the range of dispersion of the factors influencing the sound absorption capacity of the audience is to be taken into account when determining the resonance frequency, Fig. 7-50. A still wider range of dispersion of the sound absorption area occurs with the musicians and their instruments, Fig. 7-51. The unilateral arrangement of the listener or musician areas prevailing in most rooms tends to disturb the diffusivity of the sound field heavily so that the above-mentioned measured values may be faulty, Figs. 7-50 and 7-51.

![General structure of a Helmholtz resonator.](image)

**Figure 7-49.** General structure of a Helmholtz resonator.

![Survey of the values of the equivalent sound absorption area per person for a variety of occupation densities and seating patterns in a diffuse sound field.](image)

**Figure 7-50.** Equivalent sound absorption area in m\(^2\)/person of audience.

![Survey of the values of the equivalent sound absorption area per musician for musicians with and without instruments.](image)

**Figure 7-51.** Equivalent sound absorption area in m\(^2\)/person of musicians.

Especially with an almost plain arrangement of the audience and performance areas there occurs for the direct sound and the initial reflections a frequency-dependent additional attenuation through the grazing sound incidence on the audience area. This is intensified by the fact that the sound receivers—i.e., the ears—are
located in this indifferent acoustical boundary region, so that the influence of this additional attenuation becomes particularly relevant for the auditory impression. According to Mommertz\textsuperscript{45} this effect of additional attenuation can be attributed to three causes:

1. The periodical structure of seat arrangement compels a guided wave propagation for low frequencies. In the frequency range between 150 Hz and 250 Hz, this additional attenuation causes a frequency-selective level dip which is designated as \emph{seat dip effect}. An example is given in Fig. 7-52 for a frequency of about 200 Hz.\textsuperscript{45}

2. The scattering of sound at the heads produces an additional attenuation especially in the frequency range between 1.5 kHz and 4 kHz, which is designated as \emph{head dip effect}, Fig. 7-52. The magnitude of the effect depends largely on the seat arrangement and the orientation of the head with regard to the sound source.

3. In combination with the incident direct sound, the scattering at the shoulders produces a very broadband additional attenuation through interference. It is possible to define a simple correlation between the so-called elevation angle, Fig. 7-53, and the sound level reduction in the medium-frequency range at ear level of a sitting person.\textsuperscript{45}

\[
\Delta L = -20\log(0.2 + 0.1\gamma) \tag{7-72}
\]

where,
\(\Delta L\) is in dB,
\(\gamma\) is in degrees, \(\gamma < 8^{\circ}\).

![Figure 7-53. Geometric data for determining the elevation angle above a sound reflecting plane.](image)

The elevation angle of 7\(^{\circ}\) suffices to cut the level reduction to a negligible amount of less than 1 dB. The reflection plane defined in Fig. 7-53 lies herewith \(h_s = 0.15\) m (0.5 ft) below ear level, for example, at shoulder level of a sitting person (approximately 1.05 m [3.5 ft] above the upper edge of floor). According to Reference 45, the additional attenuation depends herewith only on the elevation angle, no matter if tier sloping is effected in the audience area or in the performance area.

![Figure 7-54. Sound pressure level reduction by sound dispersion at shoulder level of sitting persons as a function of the elevation angle.](image)

Fig. 7-54 shows the influence of the height of the sound source above the ear level of a person sitting in a row at a distance source-receiver of 15 m (50 ft), on the frequency-dependent additional attenuation caused by a grazing sound incidence over an audience.\textsuperscript{45} The receiver level is herewith 1.2 m (4 ft) above the upper edge of the floor, the height of the source above the floor is represented in this example as being 1.4 m and 2.0 m (4.6 ft and 6.6 ft). With a level difference of only 0.2 m (0.66 ft) between source and receiver, one can clearly recognize the additional timbre change of the direct sound component and of the initial reflections by attenuation in the low- and medium-frequency ranges, whereas with a level difference of 0.8 m (2.6 ft) the sound level attenuations get reduced to below 3 dB.

Fig. 7-55 shows a graphical representation of the correlation resulting from Eq. 7-72. One sees that with a plain arrangement of source and receiver the resulting level reduction may be up to about 14 dB, whereas an
7.4 Variation of Room Acoustics by Construction or Electroacoustic Methods

7.4.1 Variable Acoustics

The manipulation of room acoustic properties is universally known by the term vario-acoustics as well as variable acoustics. What variable manipulations are possible in variable acoustics? The primary structures (volume, dimensions, shape) and the secondary structures (reflective, diffuse, absorptive) of a room have a huge influence on its acoustic properties.

Acoustical parameters describing the acoustical overall impression of rooms are determined by the utilization function (see Section 7.3.1). If this function is unambiguously defined, as is the case, for example, with auditoriums and concert halls for symphonic music, the result corresponds, provided an appropriate planning was carried out, to the utilization-relevant room-acoustical requirements. Things look quite different, however, for rooms having a wide utilization range—i.e., so-called multipurpose halls. For speech and music performances which use exclusively sound reinforcement, a short reverberation time with little rise in the low-frequency range as well as a reduced spaciousness of the natural sound field are desirable. For vocal and music performances with mainly natural sound sources, however, a longer reverberation time with enhanced spaciousness is aspired to. The timbre of the room should herewith show more warmth in the lower frequency range. As regards their room-acoustical planning, most multipurpose halls feature a compromise solution which is harmonized with their main utilization variant and does not allow any variability. The acoustically better solution lies in the realization of variable acoustics within certain limits. This aim can be achieved by architectural or electroacoustical means.

Another range of application for purposefully variable room-acoustical parameters is by influencing the reverberation time, clarity and spaciousness of rooms which owing to their form and size meet with narrow physical boundaries in this respect. This concerns mainly rooms with too small a volume index (see Section 7.3.2.1), or such containing a large portion of sound-absorbing materials. Architectural measures for achieving desirable modifications of room-acoustical parameters are applicable here only to a limited extent, since they are bound to implement methods allowing a deliberate modification of the temporal and frequency-dependent sound energy behavior of the sound field. The effectiveness of these methods is here-with determined by the correspondingly relevant sound energy component of the room-acoustical parameter. Achieving a desired reverberation-time and spaciousness enhancement requires a prolongation of the travel path of sound reflections and a reduction of the sound absorption of late sound reflections (enhancement of reverberant energy). In this respect, more favorable results can be obtained by electroacoustical means, particularly because in such rooms the sound-field structure does not contribute essentially to the manipulated parameters. From a practical point of view Section 7.4 is mainly dedicated to the presentation of electronic procedures for reverberation-time prolongation. Equivalent architectural measures will be explained only on fundamental lines.

7.4.1.1 Fundamentals of Variable Acoustics

In the planning and realization of measures enabling variation of room-acoustical parameters, it is necessary to comply with essential aspects so that the listener’s subjective listening expectation in the room is not spoiled by an excessive range of variability:

1. The measures viable for realizing variable acoustics by architectural as well as electroacoustical means can be derived from the definitions of the room-acoustical parameters to be varied (see Section 7.2.2). Additional sound reflections arriving exclusively from the direction of the sound source surely enhance clarity, but boost spaciousness as little as an additional lateral sound energy prolongs reverberation time. Spaciousness-enhancing and reverberation-time prolonging sound reflections must essentially impact on the listener from all directions of the room. By means of appropriately dimensioned additional architec-
Acoustics for Auditoriums and Concert Halls

It is possible to achieve good results in this respect. Realization of the same, however, often implies high technical expenditure and costs. For influencing the reverberation time, for instance, these include the coupling or uncoupling of additional room volumes or the prolongation of the travel path of sound reflections with simultaneous reduction of the sound absorption of late sound reflections. A desired reduction of reverberation time and spatial impression can be achieved by means of variable sound-absorbing materials (curtains, slewable wall elements of different acoustic wall impedance) which have to be effective over the whole frequency range required by the performance concerned.

2. The coupling of acoustically effective room volumes has to be done in such a way that these acoustically form a unity with the original room. Otherwise there occur disturbing effects like timbre changes and double-slope reverberation-time curves. Incorrect dimensioning often results, owing to an acoustical orientation towards the additional room volume, in a heavily frequency-dependent spaciousness of the decay process in the sound field. The frequency-dependent reverberation time of the additional room volume must be a bit longer than or at least as long as that of the original room.

In the opposite case of reducing the reverberation time by uncoupling the additional room volume, it is for the remaining room volume necessary to provide the sound-field structure required for the desired variation. For instance, there is more sound energy to be allocated to the initial reflections and in the decay process—which is now to be supplied with less sound energy—there must not occur any irregularities.

3. The variation depth achievable by means of variable acoustics must be acoustically perceptible to a significant degree. The distinctive threshold of, for example, subjectively perceived reverberation time changes is not independent of the absolute value of the reverberation time. Variations of 0.1 s to 0.2 s are at medium frequencies and a reverberation time of up to 1.4 s to 1.5 s is subjectively less clearly perceived than above this limit value. Thus a reverberation-time prolongation from 1.0 s to 1.2 s attained with much technical effort is almost not audible, whereas one from 1.6 s to 1.8 s is already significantly audible.

4. The listening experience has to tally with the overall visual impression of the room—too heavy deviations are perceived as disturbing and unnatural. This aspect has to be taken into account especially with small room volumes, if an excessively long reverberation time is produced by an electronic enhancement system (except for acoustic disassociation effects).

5. The sound-field structure of the original room has to remain unchanged if measures of variable acoustics are implemented. Additionally modified sound reflections have to correspond to the frequency and time structure of the room. This aspect holds true for architectural as well as electroacoustical measures—e.g., for reverberation enhancement. Coupled additional room volumes must not involve any distinctive timbre changes compared with the main room. Electroacoustical room simulators with synthetically produced sound fields are allowed to change the transmission function only in compliance with the original room, except if alienation effects are required for special play-ins.

6. An enhancement of reverberation time and spaciousness is possible only within permissible boundaries in which the overall acoustic impression is not noticeably disturbed. This boundary is all the lower the more the manipulation makes the sound field structure deviate from that of the original room.

Aspects to Be Considered with the Realization of Variable Acoustics. In keeping with the envisaged target, the following main realization objectives can be formulated for variable acoustics:

1. Large Room Volume (Large Volume Index) or Reverberant Rooms

• **Task of variable acoustics:** Enhancement of clarity and definition. Reduction of reverberation time and spaciousness.

• **Architectural solution:** Apart from an appropriate tiering arrangement of the sound sources, variable ceiling panels and movable wall elements have to be placed at defined distances for enhancing the clarity of music and the definition of speech. Modified inclinations of walls, built-in concert shells near stage areas in theaters, etc., create new primary reflections that are in harmony with the variants of purpose.

Broadband sound absorbers in the shape of variable mechanisms for low frequencies, combined with curtain elements or slewable boundary elements of differing acoustic wall impedance, reduce reverberation time and diminish spaciousness. When arranging variable sound absorbers it is necessary to pay attention to the
frequency dependence of these elements. Slots between the installed slewable wall elements may, depending on the position of the elements, function as unwanted additional bass absorbers. In case of exclusive use of curtain arrangements, the low-frequency fraction is at a disadvantage giving rise to a brilliance-poor sound pattern.

An effective broadband reduction of the reverberation time can be achieved by deliberately influencing the late sound reflection mechanism. This may be realized by means of mobile room dividing wall parts which shorten the travel distances of sound reflections at the points of maximum length or width of the room and direct the reflections toward the sound-absorbing listener area. To this effect it is also possible to perform a room reduction, for example, by detaching the room volume above or below a balcony or a gallery.

• Electronic solution: An additional electronic architecture system serves for enhancing definition and clarity. Reducing reverberation time or diminishing spaciousness however, are not possible by electronic means.

2. Little Room Volume (Small Volume Index) or Highly Sound-Absorbent Rooms

• Task of variable acoustics: Enhancement of reverberation time and spaciousness.
• Architectural solution: One solution for enhancing reverberation time consists of the coupling of additional room volumes in acoustical unity with the main room. By means of a purposive sound reflection guidance at the point of maximum room length or width, it is possible to realize long travel paths by letting the sound repeatedly be reflected between the room boundary faces and the room ceiling, thus having it belatedly absorbed by the listener area (cf. large concert hall in the Neues Gewandhaus Leipzig). This way it is first of all the early decay time, which is mainly responsible for the subjectively perceived reverberation duration, which is prolonged.
• Electronic solution: Influencing reverberation time and spaciousness is quite possible by electronic means, if the physical and auditory-psychological limitations are observed. Viable solutions are described in detail in Section 7.4.2.

In general variable-acoustics is steadily losing ground because of its high costs and low effect in comparison with the use of correctly designed sound systems.

7.4.2 Electronic Architecture

Establishing good audibility in rooms, indoors as well as in the open air, has been and remains the object of room acoustics. This is the reason why room acoustics is called architectural acoustics in some countries.

The architectural measures have far-reaching limitations. These shortcomings are:

• The sound source in question has only a limited sound power rate.
• Changes of room acoustics may make huge changes in the architectural design and thus cannot always be optimally applied.
• The measures regarding room acoustics may make a considerable amount of constructional changes and these can only be done optimally for one intended purpose of the room.
• The constructional change, despite its high costs, results in only a very limited effect.

Because of these reasons sound systems are increasingly being used to influence specific room acoustic properties, thus improving audibility. This holds true regarding an improvement of intelligibility as well as of spaciousness. So one can speak of a good acoustic design if one cannot distinguish, when listening to an event, whether the sound quality is caused only by the original source or by using an electroacoustic installation.

Another task of sound installation techniques consists of electronically modified signals that remain uninfluenced by specific properties of the listener room. It is necessary to suppress, as far as possible, the acoustic properties of the respective listener room by using directed loudspeaker systems. It is also possible to create a dry acoustic atmosphere by using suitable supplementary room-acoustic measures.

Reverberation (the reverberation time of a room) cannot be reduced by means of sound systems. At the typical listener seat the level of the direct sound is of great significance. Also short-time reflections, enhancing intelligibility of speech and clarity of music, can be provided by means of sound reinforcement.

The following sound-field components can be manipulated or generated:

• Direct sound.
• Initial reflections with direct-sound effect.
• Reverberant initial reflections.
• Reverberation.

For this reason electronic techniques were developed that opened up the possibility of increasing the direct or
reverberation time and energy in the hall—i.e., directly influencing the acoustic room properties.

Such a method for changing the room-acoustic properties of rooms is now called the application of electronic architecture.

7.4.2.1 Use of Sound Delay Systems for Enhancing Spaciousness

These procedures act in particular on the sound energy of the initial reflections affecting the reverberant sound.

7.4.2.1.1 Ambiophony

This procedure, which is already obsolete, makes use of delaying devices reproducing not only the discrete initial reflections; but also the reverberation tail. The reflection sequences have herewith to be chosen in such a way that no comb-filter effects, such as flutter echoes, will be produced with impulsive music motifs. The functioning of a simple ambiophonic system can be described as follows: to the direct sound emanating directly from the original source and directly irradiated into the room, there are admixed delayed signals produced by an adequate sound delaying system (in the initial stages this was just a magnetic sound recording system) which are then irradiated like reflections arriving with corresponding delay from the walls or the ceiling. This requires additional loudspeakers appropriately distributed in the room for irradiating the delayed sound as diffusely as possible. For further delaying the sound it is possible to arrange an additional feedback from the last output of the delay chain to the input. A system of this kind was first suggested by Kleis and was installed realized in several large halls.

7.4.2.1.2 ERES (Electronic Reflected Energy System)

This procedure was suggested by Jaffe and is based on a simulation of early reflections used for producing so-called reverberant-sound-efficient initial reflections, Fig. 7-56.

Thanks to the arrangement of the loudspeakers in the walls of the stage-near hall area and to the variability range available for delay, filtering and level regulation of the signals supplied to them, adapted lateral reflections can be irradiated. The spatial impression can thus be amply influenced by simulating an acoustically wider portal by means of a longer reverberation time or a narrower portal by using a shorter reverberation time.

Figure 7-56. ERES/AR system in the Sivia Hall in the Eugene Performing Arts Center, Eugene, Oregon.

This gives the capability of:

- Adaptation to acoustical requirements.
- Simulation of different hall sizes.
- Optimization of definition and clarity.

Jaffe and collaborators speak of electronic architecture. It is certainly true that this selective play-in of reflections does simulate room-acoustical properties the room in question is devoid of, so as to compensate shortcomings in its room-acoustical structure. After installing the first system of this kind in the Eugene Performing Arts Center in Oregon, Jaffe-Acoustics have installed further ones in a large number of halls in the United States, Canada and other countries.

The electronic delay procedure in sound reinforcement systems has meanwhile become a general practice all over the world and is now the standard technique used for the play-in of delayed signals (e.g., for simulating late reflections). In this sense one may well say that electronic architecture is used in all instances where such reflections are used on purpose or unintentionally.

7.4.2.2 Travel-Time-Based Reverberation-Time Enhancing Systems

This procedure is mainly used for enhancing the late reverberant sound energy combined with an enhancement of the reverberation time.
7.4.2.2.1 Assisted Resonance

For optimizing the reverberation time in the Royal Festival Hall built in London in 1951, Parkin and Morgan\textsuperscript{56,57} suggested a procedure permitting an enhancement of the reverberation time especially for low frequencies, Fig. 7-57.

Parkin and Morgan proceeded on the assumption that in any room there exist a multitude of eigenfrequencies which give rise to standing waves with nodes and antinodes decaying by an e-function according to the absorption characteristics of the surface involved. This decay process is characteristic for the reverberation time of the room at the corresponding frequency. Any standing wave has its specific orientation in space and a microphone is installed at the point where a sound pressure maximum (vibration antinode) occurs for a given frequency. The energy picked up from the microphone is supplied via an amplifier to a loudspeaker installed at a distant antinode of the same standing wave, so that the energy lost by absorption is compensated. The energy at that frequency can thus be sustained for a longer period (assisted resonance). By enhancing the amplification it is possible to considerably prolong the reverberation time for this frequency (until feedback sets in). Thanks to the spatial distribution of the irradiating loudspeakers this applies accordingly to the spatial impression.

These considerations hold true for all eigenfrequencies of the room. The arrangement of the microphones and loudspeakers at the locations determined by the antinodes of the individual eigenfrequencies may, however, be difficult. The microphones and loudspeakers are therefore installed at less critical points and driven via phase shifters. In the transmission path there are additionally inserted filters (Helmholtz resonators, bandwidth approximately 3 Hz) which allow the transmission channel to respond only at the corresponding eigenfrequency. Care should be taken that the irradiating loudspeakers are not arranged at a greater distance from the performance area than their corresponding microphones, since the first arrival of the reverberant signal may produce mislocalization of the source.

This procedure, which has meanwhile become obsolete, was installed in a large number of halls. In spite of its high technical expenditure and the fact that the system required can be used only for the assisted resonance, it was for a long period one of the most reliable solutions for enhancing the reverberation time without affecting the sound, particularly at low frequencies.

7.4.2.2.2 Multi-Channel-Reverberation, MCR

Using a large number of broadband transmission channels whose amplification per channel is so low that no timbre change due to commencing feedback can occur, was suggested first by Franssen.\textsuperscript{58} While the individual channel remaining below the positive feedback threshold provides only little amplification, the multitude of channels is able to produce an energy density capable of notably enhancing the spatial impression and the reverberation time.

The enhancement of the reverberation time is determined by

\[
\frac{T_m}{T_o} = 1 + \frac{n}{50}
\]  

(7-73)

If the reverberation time is, for instance, to be doubled (which means doubling the energy density),
there are $n = 50$ individual amplification chains required. Ohsmann $^{59}$ has investigated in an extensive paper the functional principle of these loudspeaker systems and has shown that the prognosticated results regarding enhancement of the reverberation time cannot be achieved in practice. He also quotes the fact that Franssen “did not sufficiently consider the cross couplings between the channels” as a possible reason for the deviation from theory. $^1$

A system technologically based on this procedure is offered by Philips under the name of Multi-Channel Amplification of Reverberation System (MCR). It serves for enhancing reverberation and spaciousness. $^{60}$ According to manufacturer’s specifications a prolongation of the average reverberation time from approximately 1.2 to 1.7 s is achieved for ninety channels. Even longer reverberation enhancements are said to be possible. There exist numerous implementations in medium-sized and large halls (the first was in the POC Theater in Eindhoven, Fig. 7-58).

7.4.2.3 Modern Procedures for Enhancing Reverberation and Spaciousness

7.4.2.3.1 Acoustic Control System (ACS)

This procedure was developed by Berkhout and de Vries at the University of Delft. $^{61}$ Based on a wave-field synthesis approach (WFS) the authors speak of a holographic attempt for enhancing the reverberation in rooms. In essence, it is really more than the result of a mathematical-physical convolution of signals captured by means of microphones in an in-line arrangement (as is the case with WFS). The room characteristics are predetermined by a processor, which produces, in the end, a new room characteristic with a new reverberation time behavior, Fig 7-59.

Figure 7-59. Principle of the Reverberation on Demand System (RODS).

The upper block diagram shows the principle of the ACS circuit for a loudspeaker-microphone pair. One sees that the acoustician formulates the characteristics of a desired room—e.g., in a computer model—transfers these characteristics by means of suitable parameters to a reflection simulator and convolutes these reflection patterns with the real acoustical characteristics of a hall. Fig. 7-60 shows the complete block diagram of an ACS system.

Unlike other systems, the ACS does not use any feedback loops—thus timbre changes owing to self-excitation phenomena should not be expected. The system is functioning in a series of halls in the Netherlands, Great Britain and in the United States.

7.4.2.3.2 Reverberation on Demand System, RODS

With this system a microphone signal is picked near the source and passed through a logical switching gate before reaching a delay line with branched members. This output is equipped with a similar gate. A logical control circuit opens the input gate and closes the output gate when the microphone signal is constant or rising.
Vice versa, it closes the input gate and opens the output gate when the microphone signal is falling, Fig. 7-60. An acoustical feedback is thus avoided, but this system fails to enhance the lateral energy with continuous music, which makes it unsuitable for music performances. It is no longer used.

7.4.2.3.3 LARES

The LARES system by the Lexicon Company uses modules of the standardized Room Processor 480L which, when fed by special software, simulates the desired decay curves, Fig. 7-61. A large number of loudspeakers are required in the wall and ceiling areas. The input signals are picked up by just a few microphones in an area near the source. On account of the time-variant signal processing (a large quantity of independent time-variant reverberation devices), the adjustment of reverberation times is not exactly repeatable. Common computer-controlled measuring software (based, e.g., on MLS) is thus unable to measure decay curves. Apart from the ASC system, LARES installations are very widespread in Europe and the United States. Well known are the systems installed in the Staatsoper Berlin, the Staatsschauspiel Dresden, and the Seebühne (floating stage) in Mörbisch/Austria.

7.4.2.3.4 System for Improved Acoustic Performance (SIAP)

The basic principle of SIAP consists in picking up the sound produced by the source by means of a relatively small number of microphones, processing it appropriately (by means of processors which convolute, that is overlay electronically the room-acoustical parameters of a room with target parameters) and then feeding it back into the hall by an adequate number of loudspeakers, Fig. 7-62. The aim is to produce desired natural acoustical properties by electronic means. For obtaining spatial diffusivity a large number of different output channels are required. Moreover, the maximally attainable acoustic amplification is dependent on the number of uncorrelated paths. Compared with a simple feedback channel, a system with 4 inputs and 25 outputs is able to produce a 20 dB higher amplification before feedback sets in. This holds true, of course, only under the assumption that each and every input and output path is sufficiently decoupled from the other input/output paths. Each listener seat receives sound from several loudspeakers, each of which irradiates a signal somewhat differently processed than any of the others (!).

7.4.2.3.5 Active Field Control, AFC

The AFC system by Yamaha makes active use of acoustic feedback for enhancing the sound energy density and thereby also the reverberation time. When using the acoustic feedback it is, however, important to avoid timbre changes and to insure the stability of the system. To this effect one uses a specific switching circuit, the so-called Time Varying Control (TVC) which consists of two components:

- Electronic Microphone Rotator (EMR).
- Fluctuating FIR (fluc-FIR).

The EMR unit scans the boundary microphones in cycles while the FIR filters impede feedback.

For enhancing the reverberation, the microphones are arranged in the diffuse sound field and still in the close-range source area (gray dots in Fig. 7-63 on the right). The loudspeakers are located in the wall and ceiling areas of the room. For enhancing the early reflections there are four to eight microphones arranged in the ceiling area near the sources. The signals picked up by these are passed through FIR filters and reproduced as
lateral reflections by loudspeakers located in the wall and ceiling areas of the room. The loudspeakers are arranged in such a way that they cannot be located, since their signals are to be perceived as natural reflections.

Furthermore the AFC system allows signals to be picked up in the central region of the audience area and the reproduction of them via ceiling loudspeakers in the area below the balcony for the sake of enhancing spaciousness.

7.4.2.3.6 Virtual Room Acoustic System Constellation™

Constellation™ by Meyer Sound Inc. is a multichannel regenerative system for reverberation enhancement. Its development is based on ideas already considered in the sixties of last century by Franssen when developing the above-mentioned MCR procedure. The principle is already rather old and was described by users. The biggest difference is that today Constellation™ uses, instead of the second reverberation room, an electronic reverberation processor which is more easily adaptable.

But modern electronic elements and DSPs have made it possible to design circuits which widely exclude timbre changes. This is achieved by coupling a primary room A (the theater or concert hall) with a secondary room B (the reverberant room processor). Simultaneously the number of reproduction channels is reduced along with the timbre change of sound events. An enhancement of the early reflections is obtained as well, cf. Fig. 7-64.

Contrary to other systems, Constellation™ uses a comparable number of microphones and loudspeakers in a room. To this effect the microphones are located in the reverberant or diffuse field of all sound sources within the room and connected via preamplifiers to a digital processor. Then the outputs of the processor are connected to power amplifiers and loudspeakers for reproduction of the signal.

With the Constellation™ system there is a multitude of small loudspeakers $L_1$ to $L_N$ (40 to 50) distributed in...
the room, which, of course, may also be used for panorama and effect purposes. Ten to fifteen strategically located and visually inconspicuous microphones $m_1$ to $m_N$ pick up the sound and transmit it to the effect processor $X(\omega)$ where the desired and adjustable reverberation takes place. The output signals thus obtained are fed back into the room. The advantage of this solution lies in the precise tuning of the reverberation processor enabling well-reproducible and thus also measurable results.

![Diagram 7-64](image1.png)

**Figure 7-64.** Principle of the Virtual Room Acoustic System, Constellation™.

7.4.2.3.7 CARMEN®

The underlying principle is that of an active wall whose reflection properties can be electronically modified. The system was called CARMEN® which is the French abbreviation of Active Reverberation Regulation through the Natural Effect of Virtual Walls. On the wall there are arranged so-called active cells forming a new virtual wall. The cells consist of a microphone, an electronic filter device, and a loudspeaker by which the picked-up signal is irradiated, Fig. 7-65. The microphones are typically located at 1 m distance from the loudspeaker of the respective cell, i.e. at approximately $\frac{1}{2}$ of the diffuse-field distance in typical halls. Therefore it might also be called a locally active system.

![Diagram 7-63](image2.png)

**Figure 7-63.** Active Field Control System (AFC) by Yamaha, Japan.
Every cell produces a desired decay of the artificial reflections, provided one does not choose an excessive cell gain liable to provoke feedback. To avoid feedback an adequate microphone directivity characteristic as well as internal echo canceling algorithms are used. In addition it is possible to delay the microphone signal electronically, a feature which allows the cell to be virtually shifted and the room volume to be apparently enlarged.

Since 1998 CARMEN® has been installed and tested in more than ten halls used by important orchestras. It has proven to be particularly effective in theaters which are also used for orchestra performances. In these rooms it best improves the acoustics in the distant areas under the balconies. In the Mogador Theater in Paris acoustics were significantly improved by installing CARMEN® cells in the side walls and in the ceiling of the balcony.

By means of twenty four cells in a room with a reverberation time of 1.2 s at 500 Hz, it was possible to enhance this reverberation time to 2.1 s. Additionally there resulted various spatial effects like a broadening of the sound source or an improved envelopment with lateral reflections, features often required for big orchestras, but also soloists.

### 7.4.3 Conclusions and Outlook

The above presented comparison shows that a large number of procedures exist for enhancing reverberation and spaciousness, part of which continue to be used today. Thanks to ever-increasing quality of the electronic transmission devices, the prejudices still existing especially among musicians against the electronic architecture will diminish, so that it will be increasingly possible to adapt concert halls even to the acoustical conditions characteristic of different creative and historic periods. Utilization in so-called multipurpose halls will, of course, prevail. The aim will have been achieved when musicians and audience perceive acoustical conditions established by means of electronic architecture as normal and natural. Simplicity of varying settings or security against acoustical feedback and unrelated timbre change will then be decisive factors in the choice of an enhancement system. Modern computer simulation will assist in banning the potential feedback risk.

Costly architectural measures for realizing the variable acoustic will be more and more discarded, particularly in view of their limited effectiveness.

8.1 Overview

Stadiums and outdoor venues present designers with a set of challenges which are not usually encountered in interior spaces. The leading challenge is the immense distance over which sound of an appreciable level must be projected. This is followed by the fact that the sound is not propagating in a stable medium—i.e., outdoors the air temperature and relative humidity are erratic variables and the air is hardly ever still. Lastly, in addition to the normal 6 dB loss for doubling of distance from a point source in a free field, there exists an additional attenuation from atmospheric absorption whose value is a function of frequency and depends on both temperature and relative humidity. These challenges will be addressed in turn.

8.2 Sound Projection Distances

The values of the distances required between reinforcement loudspeakers and observers in stadiums hinge on both the stadium geometry and on whether the reinforcement system is to be of the single source or distributed loudspeaker type. A distributed system avoids large throw distances and major atmospheric effects but is more expensive to install and maintain. The sound quality of distributed systems in stadiums is somewhat unnatural in that the nonlocal loudspeakers are sources of apparent echoes. A single source system is less expensive to install and maintain but requires special techniques to achieve adequate levels at large throw distances. Advocates exist for both system types. The problems associated with the single source system are more interesting and are the ones initially discussed here.

Throw distances for a central source system in a typical stadium range from 15 m to 200 m (50 ft to 650 ft). Sports stadiums, with the possible exception of baseball stadiums, have playing surfaces in the shape of elongated rectangles with audience seating being peripheral to the playing area. Single source loudspeakers are located at one end of an axis of symmetry along the long dimension of the playing surface as illustrated in Fig. 8-1. This allows the coverage of the seating spaces to fall into a number of zones for which the axial throw distances vary by no more than a factor of two. For example, in the stadium of Fig. 8-1, there is a near, intermediate, and far zone with axial distances of approximately 50 m, 100 m, and 200 m, respectively. Thus, the single source system is actually a splayed array of short, intermediate, and long throw devices.

8.3 Source Level Requirements

For a point source in a free field without atmospheric absorption, the acoustic pressure varies inversely with the distance measured from the source, i.e., there is a 6 dB loss for each doubling of the distance. The pressure level at 200 meters from such a source is 46 dB less than it is at one meter. If one assumes a noise level of 85 dB and a signal level at least 6 dB above the noise level, then the sound level at one meter must be at least $85 + 6 + 46$, or 137 dB, even without any headroom consideration. If one imposes a modest headroom requirement of 6 dB, an impressive 143 dB level is required even before considering atmospheric attenuation.

While this is not attainable from one loudspeaker, it is easily attainable by multiple loudspeakers.

8.4 Atmospheric Effects

Sound propagation is subject to the vagaries of the medium in which it exists. The air in outdoor venues has variable temperature, wind, and relative humidity. The effect of wind is twofold. Wind speed near to the ground is ordinarily less than at a higher elevation. This causes sound waves propagating in a direction into the wind to be diffracted upward while sound waves propagating in the same direction as the wind to be diffracted downward. Cross-winds shift the azimuth of the propagation direction towards that of the wind. Thus wind can cause shifts in apparent loudspeaker aiming points. Additionally, sound will propagate greater distances with the wind than against the wind. A gusting or variable wind introduces a temporal quality to these properties. The effect on a listener is that the sound intensity
appears to be modulated as the wind gust rises and falls, a layman’s description being “it fades in and out.”

Sound speed is influenced by air temperature with higher temperatures corresponding to increased sound speed. This relationship is given by

\[ c = 20.06 \sqrt{T} \]  \hspace{1cm} (8-1)

where,

- \( c \) is the sound speed in meters per second,
- \( T \) is the absolute temperature in degrees Kelvin.

A fixed air temperature has no influence on propagation direction, but thermal gradients can be a source of further diffraction effects. Normal thermal gradients correspond to a temperature decrease with increasing elevation. Such a condition diffracts sound waves upward such that the apparent direction of propagation is elevated. A temperature inversion gradient has just the opposite effect producing an apparent depressed direction of propagation. The severity of these effects obviously depends on the size of the thermal gradients. Typically encountered stadium situations can result in shifts of 5\(^\circ\) or more over a distance of 200 m (650 ft). These effects are illustrated in Fig. 8-2.

Atmospheric absorption of acoustical energy ultimately amounts to the conversion of the energy associated with a sound wave into heat energy associated with the random thermal motion of the molecular constituents of the air. Air is basically a gaseous mixture of nitrogen, oxygen, and argon with trace amounts of carbon dioxide, the noble gases, and water vapor. With the exception of argon and the other noble gases all of the constituent molecules are polyatomic and thus have complicated internal structures. There are three mechanisms contributing to the sound energy absorption process. Two of these, viscosity and thermal conductivity, are smooth functions of frequency and constitute what is called the classical absorption. The third or molecular effect involves transfer of acoustic energy into internal energy of vibration and rotation of polyatomic molecules and into the dissociation of molecular clusters. This third effect is by far the most dominant at audio frequencies and explains the complicated influence of water vapor on atmospheric absorption. The detailed behavior given in Fig. 8-3 is illustrative of these effects at a temperature of 20\(^\circ\)C whereas the approximate behavior given in Fig. 8-4 is more useful for general calculations.

Table 8-1 is extracted from Fig. 8-3 and illustrates the severity of the absorption effects.

Below 1 kHz the attenuation is not significant even for a 200 m (650 ft) path length. The relative humidities encountered in practice usually lie in the 10% to 100% range and it can be seen that for frequencies below 5 kHz that wetter air is preferable to drier air. High-frequency equalization to compensate for air losses is usually possible up to about 4 kHz with the amount of equalization required being dependent on the path length. Note that on a dry fall afternoon, the attenuation at 5 kHz over a 200 m path length is about 22 dB. No wonder that a marching brass band on such a day loses its sparkle. As a consequence, long throws in a single source outdoor system are limited to about a 4 kHz bandwidth.
8.5 Techniques for Achieving High Acoustic Pressures

In a previous calculation it was shown that for a 200 meter path length, the source must achieve a level of 143 dB at a distance of one meter even in the absence of atmospheric absorption. Including compensation for air losses, the required level can easily rise to 150 dB. Horn throat pressure leading to this level at one meter from the horn mouth would be significantly higher than 150 dB and would suffer from a serious amount of nonlinear distortion. Such pressures are usually achieved by using a coherent array of multiple devices. Typical medium and long throw devices have coverage angles of 40° vertical by 60° horizontal and 20° vertical by 40° horizontal, respectively, these being the angles between the half pressure points of the devices. The long throw angles required in a stadium are usually narrow in the vertical and wide in the horizontal so such devices are stacked to form a vertical array with the axes of the individual devices being parallel. This arrangement for two devices is depicted in Fig. 8-5.

Consider for the moment that the devices are identical point sources that are driven in phase with equal
strength electrical signals. In this circumstance, if the observation point, \( o \), is located in the median plane where \( \theta \) is zero, the acoustic pressure at any radial distance, \( r \), is just double that which would be produced by either source acting alone. This is true because the path lengths are equal so that the two pressure signals undergo the same inverse distance loss and phase lag and thus arrive with equal strength and in phase at the observation point. Now if one considers those observation points where \( r \) is always much larger than \( d \) and if \( d \) is small compared with the wavelength, then the amplitude difference between the two signals as well as the phase difference between the two signals will be insignificant at all such points and again the total pressure will be nearly twice that of a single source acting alone. Such observation points are located in the far field of the combined sources as would be the case in a stadium for all medium or long throw devices. This instance of pressure doubling at all far field observation points only occurs at low frequencies where the wavelength at the operating frequency is significantly larger than the device separation. Consider the case where the operating frequency is such that \( d = \lambda/2 \). In the far field the amplitude of the signal from each source is again essentially the same but now there will be a phase difference for all values of the angle \( \theta \) greater than zero. This is most obvious for distant points on the vertical axis where \( \theta = \pm 90^\circ \). At such points the phase difference between the two sources is 180° and the acoustic pressure is zero. The two sources are now exhibiting a frequency-dependent directivity function as a result of their physical placement one above the other. If the two sources are horns rather than point sources, then there is an additional directivity function associated with the horn behavior that is a function of both the azimuthal angle \( \phi \) as well as the vertical angle \( \theta \). The acoustic pressure amplitude for all points in the far field for both sources being driven equally and in phase can be calculated from

\[
p_m = \frac{2A}{r} \left| D_h(\theta, \phi)D_a(\theta) \right|
= \frac{2A}{r} \left| D_h(\theta, \phi) \cos \left( k \frac{d}{2} \sin(\theta) \right) \right|
\]

In the two equations for the pressure amplitude, \( p_m \), \( A \) is the source amplitude factor, \( D_h(\theta, \phi) \) is the horn directivity function, and \( D_a(\theta) \) is the directivity function brought about by arraying one source above the other. The vertical braces \( \vert \vert \) denote absolute magnitude of the enclosed quantity. This is necessary as the two directivity functions can independently each be positive or negative dependent upon the frequency and the pressure amplitude is always positive. The quantity, \( k \), is the propagation constant and is related to the wavelength through \( k = \frac{(2\pi)}{\lambda} = \frac{2\pi f}{c} \). It is important to note that the directivity behavior brought on by arraying one device above the other depends only on the angle \( \theta \) and that the horizontal directivity of the devices in the far field is not influenced by the physical placement of one above the other. This behavior in the vertical plane is depicted in Fig. 8-6A through E where the individual devices are 40° vertical by 60° horizontal horns having small mouths.

Figs. 8-6A through E illustrate both the desirable and undesirable attributes of arraying devices in a vertical line. A illustrates the directivity in the vertical plane for each device. The device directivity has a magnitude of 0.5 at \( \pm 20^\circ \) indicating that the vertical coverage angle is 40°. The minimum vertical spacing between the devices is limited by the mouth size and in this instance is 0.344 meter. This corresponds to \( \lambda/2 \) at a frequency of 500 Hz. As shown in Fig. 8-6B, the pressure on-axis is indeed doubled and the overall shape closely follows that of the horn directivity function with just a small narrowing of the vertical coverage angle. In Fig. 8-6C, where the operating frequency is now 1000 Hz, the on-axis pressure is again doubled but now the central lobe is noticeably narrower and small side lobes are in evidence. This trend continues in Fig. 8-6D where the operating frequency is now 2000 Hz. Side lobes are now much in evidence and the central lobe is narrowed even further. Finally, at 4000 Hz, as depicted in Fig. 8-6E, another pair of side lobes appear, the original side lobes, while having narrowed, are considerably stronger, and the central lobe is narrower still while maintaining double on-axis pressure. In all instances the overall envelope containing the vertical directivity behavior of the stacked pair has the same shape as that of the individual device directivity function.

One is not limited to stacking just two devices in a vertical line. Any number, \( N \), of identical devices can be so arranged and when several discrete devices are so arranged the combination is called a line array. The qualitative behavior of such an array as observed in the far field is quite similar to that of the stacked pair discussed above. Directional control does not appear until the length of the array becomes comparable to the wavelength, the on-axis pressure in the far field is \( N \) times as great as that of a single device, and as the operating frequency increases, side lobes appear and the central lobe becomes narrower and narrower as the operating frequency increases. This assumes that all of
Figure 8-6. Behavior in the vertical plane of stacking two 40° vertical by 60° horizontal small mouth horns.

- **A.** Vertical directivity of each device.
- **B.** Relative pressure at 500 Hz with \( d = \frac{L}{2} \).
- **C.** Relative pressure at 1000 Hz where \( d = \lambda \).
- **D.** Relative pressure at 2000 Hz where \( d = 2\lambda \).
- **E.** Relative pressure at 4000 Hz where \( d = 4\lambda \).
the devices are identical, have equal amplitude drive signals, and are driven in phase. When driven in this fashion, the array is said to be unprocessed. Modern line arrays are usually structured from enclosures that are each full range loudspeaker systems. Each such loudspeaker system usually divides the audio band into three or four separate bands. In effect then, one is dealing with not just a single line array, but rather three or four arranged parallel to each other. This technique allows optimization in each frequency band with regard to the number of devices, device spacing, and individual device directivity. Fig. 8-7A and B illustrates the performance of the low-frequency section of a straight line array consisting of ten 15 inch diameter woofers with a separation between woofers of 0.6 meter. Fig. 8-7A shows the pressure generated by the array relative to that produced by a single device when operating at 50 Hz, which is the bottom end of the woofer pass band. At this frequency the woofer itself is omnidirectional and the vertical directivity is that produced by the array structure itself. At 300 Hz, which is the upper end of the woofer pass band, the central lobe has been greatly narrowed and there are numerous side lobes as illustrated in Fig. 8-7B.

The operation in the other frequency bands of a full range line array that is unprocessed is qualitatively the same even though the number of devices and spacing between individual devices is, in general, different. The large increase of the pressure on-axis is the desirable attribute whereas the accompanying narrowing of the central lobe and the generation of side lobes are undesirable. The latter behavior can be mitigated to some extent by arraying on an arc rather than a straight line. The mounting hardware linking the devices in an array is structured so as to allow a splay between individual units with an adjustable angle in the range of 2° to 5°. This shapes the array into an arc of a circle rather than in a straight line. In such an arrangement, there is some reduction in the maximum pressure on axis, but the central lobe retains a more uniform width particularly at the upper ends of the various frequency bands. Mathematical details may be found in the first reference at the end of this chapter.

Another arraying technique worthy of mention is that of the Bessel array first introduced by the Dutch industrial giant Philips. The Bessel array in its simplest configuration employs five identical elements and although it only doubles the on-axis pressure in the far field, it does so while having a coverage pattern both vertically and horizontally that matches the coverage pattern of the individual elements from which it is constructed. The individual elements might be woofers, horns, or full range systems of any type. In the simplest configuration, five identical devices are arrayed along a straight line either horizontally or vertically as close together as possible with parallel axes. The unique properties of the array are brought about by weighting the voltage drive to the array in the sequence 0.5, 1, 1, −1, and 0.5. For example for a vertical array, one-half of the available voltage drive is applied to the top and bottom elements. This is easily accomplished in practice by connecting these two elements in series with each other. The interior elements are then connected together in parallel with the lowest interior element being operated in reverse polarity. This physical and electrical arrangement appears in Fig. 8-8.

When observed in the far field this arrangement produces twice the pressure of that of a single device
and has a directivity that is almost identical to that of a single structural element. The on-axis amplitude and phase response is also that of a single constituent device. For observation points off-axis, where $\theta$ is no longer zero, the amplitude response will exhibit a small ripple as the frequency changes throughout the pass band of the devices employed. The magnitude of this ripple is inconsequential as it amounts to less than 1.25 dB. Perhaps of more importance is the behavior of the phase response when observed off-axis. The phase response ripples between plus and minus 90° as the frequency changes throughout the pass band of the devices that are employed. This ripple in phase response is superimposed on the normal phase response of an individual device. The mathematical details describing the Bessel array behavior are given in the first reference given at the end of this chapter. The Bessel array, having preserved the coverage pattern of a single device, is relatively insensitive to aiming errors resulting from wind or thermal effects.

In recent years Meyer Sound Laboratories, Inc. has produced a number of well-designed self-powered loudspeaker systems that are well adapted for employment in stadiums and outdoor venues. Even though the concept of self-powered loudspeakers is an old one, Meyer took the concept several technical steps further by including not only the appropriate power amplification but also the necessary signal processing, amplifier, and loudspeaker protection circuitry as well, all within the confines of the loudspeaker enclosure. One such system that can be a real problem solver is Meyer’s SB-1 sound beam loudspeaker system that is depicted in Fig. 8-9.

The system of Fig. 8-9 is based on the properties of a parabolic reflector. A parabolic reflector is really a paraboloid, which is the shape generated when a parabola is rotated about its principal axis. Such shapes have been employed for many years as the basis for reflecting telescopes, radar antennas, and microphones. In the case of a telescope or microphone application the paraboloid focuses a beam of light or sound emanating from great distances to a common point known as the focal point of the paraboloid. In the instance of a radar antenna that is employed for both transmission and reception, radiation from a small element located at the focal point is formed into a parallel beam having small divergence during transmission and return signals traveling parallel to the system’s axis are focused on the small element at the focal point during reception. In the sound beam application of the SB-1 a 4 in compression driver fitted with an aspherical horn is mounted in a bullet-shaped pod and located at the focal point of the paraboloid. This assembly is aimed at a fiberglass parabolic reflector having a diameter of approximately
In order for such a reflector to form a well-defined beam it is necessary that the diameter of the reflector be considerably larger than the wavelength. This is true for this unit except at its low-frequency limit of 500 Hz. In the vicinity of 500 Hz diffraction produces some out-of-beam energy that is undesirable. This is compensated for through the placement of a 12 in diameter cone driver within the enclosure behind the reflector. This driver radiates through an opening at the center of the reflector. This driver’s electrical signal is band-pass limited in the vicinity of 500 Hz and is phased to cancel the diffracted out-of-beam signal produced by the compression driver. Separate power amplifier and processing circuitry is provided for the two drivers with all of the electronics and associated power supplies being located in the main enclosure. Once the system is assembled and aimed it is necessary only to supply the appropriate ac power and audio signal. The system is specified to produce a maximum SPL of 110 dB at 100 m in a pass band of 500 to 15,000 Hz with a coverage angle of 20°.

8.6 Single Source Location

Single source loudspeaker arrays are usually mounted at one end of an axis of symmetry of the stadium seating with the long axis being preferred. It is desirable to place the cluster at such an elevation that the components of the array are aimed down on the audience. This positioning minimizes the spill of sound into the surrounding community.

8.7 Covered Seating

Many stadiums feature double and occasionally triple decking such that a portion of the lower seating is obscured from a line-of-sight view of the single source point. In this instance the perception of a single source can be maintained while still providing direct sound to the covered seats by creating a stepped zone delay system. In this system, a distributed loudspeaker system is installed beneath the upper deck and arranged in a series of coverage zones such that the obscured seats in a given zone are all approximately the same distance from the single source point. The electrical signals to the loudspeakers in a given zone are delayed by an amount equal to the transit time of sound from the single source point to the given zone. If the zone loudspeakers radiate principally in the direction which would have been taken by the single source system had it not been obscured, one generates a traveling source of sound from one zone to the next that is in sync with sound from the single source system. Zonal boundaries at a linear spacing of about 20 m (65 ft) have been found to produce very intelligible apparently echo-free results.

8.8 Distributed Systems

Distributed systems are capable of producing full bandwidth sound throughout a stadium provided that the individual loudspeaker systems are installed with sufficient density such that the axial throw of any given unit is 50 m (165 ft) or less. A throw of 50 m will require variable equalization for air absorption if proper high-frequency balance is to be maintained. The uniformity of sound distribution is improved with an increasing loudspeaker density and hence an increasing expense.

The design of the individual sources in such a system is carried out as one would for an interior space that has a designated seating area. An array of loudspeakers is formed using conventional arraying techniques with the view toward providing uniformity of coverage and full bandwidth. The successive distributed areas are chosen such that the areas overlap at the −6 dB point of an individual area. This will provide quite uniform coverage throughout all of the seating areas. Psychoacoustically, the sound will appear more natural to the listeners if the source is elevated and in front of the audience. Weather proofing techniques must be employed in the loudspeaker manufacture and/or in the loudspeaker installation process.

A distributed system may be powered in a number of ways. All of the power amplifiers may be located at a single central point, in which case, long cable runs must be made on 70 V or 200 V lines to the distributed loudspeakers. This is convenient from the standpoint of monitoring or servicing the amplifiers, but is enormously expensive to install. Rather than locate all amplification at a single position, power amplifiers may be located at several subpoints throughout the stadium. Less costly low-level signal wiring connects the subpoints and high-level power runs are shortened and hence made less expensive. Alternatively, powered loudspeakers are available from which to construct the individual loudspeaker clusters. Less costly low-level signal wiring can now be run to each cluster. Ac power must be made available at each loudspeaker location under this option. This expense, however, is now shifted to the electrical contractor. This individually powered option is the least expensive initially but may present a servicing nightmare in the future. Regardless of the technique employed for installation, any reasonable design will include provisions for
monitoring the operation of the individual loudspeaker systems from a central point. The better, more sophisticated designs will also provide for individual system adjustments from the central monitoring point.

In summary, distributed systems are more expensive to install and considerably more expensive to maintain. They are capable of wider bandwidth than are single source systems and are less sensitive to atmospheric effects. Some listeners object to the apparent echoes produced by distributed systems whereas others maintain that is the way stadiums should sound.

8.9 Private Suite Systems

Practically all new stadium construction as well as renovation incorporate private suites in the stadium concept.

9.1 Introduction

As it is often the case with branches of engineering dealing with the understanding and the prediction of complex physical phenomena, *modeling* has rapidly become an integral part of the acoustical design process. When dealing with indoor sound propagation the use of a suitable model may allow the designer to assess the consequences that a change in parameters such as room shape, material selection, or source placement will have on variables like sound pressure, reverberation time, or reflection ratios at specific points inside the room. Acoustical models can also be developed for outdoor sound studies as one may inquire what shape and height a highway barrier needs to be in order to attenuate a specific level of unwanted noise from highway traffic over a given area. In these instances, the model is expected to provide the designer with the answer to the fundamental “what if?” question that is at the genesis of an engineered design—i.e., one that leaves little to chance in terms of the sensible selection of its parameters in order to achieve a specific result. The answers to the question allow the designer to assess the performance or the cost-effectiveness of a design, based on a specific set of criteria prior to committing to it.

Although an experienced designer may be able to achieve a substantial understanding of the acoustics of a given environment simply by looking at the data that results from the modeling phase of the design, the acoustical model may also be used to provide an auditory picture of the data so that a qualitative evaluation of the acoustics can be performed by trained and/or untrained listeners. This phase of the design—known as *auralization*—aims at doing for one’s ears what a picture does for one’s eyes: present a description of an environment in a way that is best suited to the most appropriate sensor. In this instance, the basic goal is to use sound to demonstrate what a specific environment will sound like, just like the fundamental purpose of an image is to illustrate what an environment may look like. The challenges associated with virtual representation that exist in the visual world, such as accuracy, context, and perception, are also present in the aural environment, and the old engineering school adage that “a picture is worth a thousand words, but only if it is a good picture” rings also true in the world of acoustical modeling and of auralization.

The aim of this chapter is to provide the reader with a basic understanding of the various methodologies that are used in acoustical modeling and auralization, and the emphasis is on models that can be used for the evaluation of room acoustics. The reader is referred to the bibliography for further in-depth reading on the topic.

9.2 Acoustical Modeling

This section will review various acoustical modeling techniques from the perspective of theory, implementation, and usage.* The categorization and grouping of the modeling techniques into three general families (physical models, computational models, and empirical models) and in further subgroups as presented in Fig. 9-1 is provided as a means to identify the specific issues associated with each technique in a fashion that is deemed effective by the author from the standpoint of clarity. A brief mention of hybrid models that combine various techniques will also be introduced. The sections of this chapter are written as independently from each other as possible so the reader can go to topics of specific interest without reading the preceding sections.

![Figure 9-1. General classification of acoustical modeling methodologies.](image)

9.2.1 Physical Models

This class of model uses a scaling approach to yield a 3D representation of typically large acoustical environments like theater or auditoria for the purpose of evaluation and testing. The models are constructed at geometrical scales ranging from 1:8 to 1:40, and an example of a 1:20 physical model is presented in Figs. 9-2 and 9-3. Physical modeling techniques became pop-

---

* Model (mäd’l) n. [Fr. modèle < It modello] 1. a) a small copy or imitation of an existing object made to scale b) a preliminary representation of something, serving as the plan from which the final, usually larger, object is to be constructed c) archetype d) a hypothetical or stylized representation e) a generalized, hypothetical description, often based on an analogy, used in analyzing or explaining something.

ular after WWII and are still used today by some designers when access to other modeling tools is limited and/or when a physical representation of the space under review is needed for the purpose of testing as well as visualization.

9.2.1.1 Frequency and Wavelength Considerations in Physical Models

The issues pertaining to frequency and wavelength in scale models are best presented with the use of an example. If a source of sound generating a frequency \( f = 1000 \text{ Hz} \) is placed inside a room, then under standard conditions of temperature \( t = 20^\circ \text{C} \) where the velocity of sound is found to be \( c = 344 \text{ m/s} \), the wavelength of the sound wave is obtained from

\[
\lambda = \frac{c}{f} \tag{9-1}
\]

or in this example

\[
\lambda = \frac{344 \text{ m/s}}{1000 \text{ Hz}} = 0.34 \text{ m}
\]

The wave number \( k \) can also be used to represent the wavelength since

\[
k = \frac{2\pi}{\lambda} \tag{9-2}
\]

so in our example we have

\[
k = \frac{2\pi}{0.34 \text{ m}} = 18.3 \text{ m}^{-1}
\]
In the absence of acoustical absorption, the relative size of the wavelength of a sound wave to the size of an object in the path of the wave dictates the primary physical phenomenon that takes place when the sound waves reach the object. If the object can be considered acoustically hard (i.e., having a low absorption coefficient) so that the energy of the wave is not significantly reduced by absorption and if the characteristic dimension of the object (its largest dimension in the path of the sound wave) is denoted by $a$ then the product $ka$ can be used to predict how the sound waves will be affected by the presence of the object.

Table 9-1 shows a range of products $ka$ and the resulting primary effect that the object will have on the sound waves.

### Table 9-1. Effect of Wave Number and Object Dimension on the Propagation of Sound Waves

<table>
<thead>
<tr>
<th>Value of $ka$</th>
<th>Primary Phenomenon Taking Place When the Sound Waves Reach the Object (Not Including Absorption)</th>
</tr>
</thead>
<tbody>
<tr>
<td>$ka \leq 1$</td>
<td>Diffraction: the sound waves travel around the object without being affected by its presence. The object can be considered invisible to the waves.</td>
</tr>
<tr>
<td>$1 &lt; ka &lt; 5$</td>
<td>Scattering: the sound waves are partially reflected by the object in many directions and in a complicated fashion. This scattering phenomenon is associated with the notion of acoustical diffusion.</td>
</tr>
<tr>
<td>$ka &gt; 5$</td>
<td>Reflection: the sound waves are deflected by the object in one or more specific direction(s) that can be predicted from application of basic geometry laws.</td>
</tr>
</tbody>
</table>

In our example if an acoustically hard object of dimension $a = 0.5$ m is placed inside a full-size room, then the sound waves will be reflected by the object since $ka = 9.1$, a value clearly above the lower limit of 5 at which reflections become the primary phenomenon.

If a 1:10 scale model of the room is now created and the object is scaled by the same amount its dimension has now become $a' = 0.05$ m. Under the earlier conditions where $f = 1000$ Hz the product $ka'$ now has a value of $ka' = 0.91$ and the conclusion that must be drawn from the guidelines presented in Table 9-1 is that the sound waves diffract around the object: in other words, the model has failed at predicting accurately the primary physical phenomenon of sound reflection that takes place when a 1000 Hz sound wave strikes an acoustically hard object of 0.5 m in size.

In order for the model to yield the proper conclusion—i.e., the sound waves are reflected by the object—the wavelength of the sound waves has to be scaled down by the same amount as the physical dimensions of the room, or looking at Eq. 9-1—and keeping the speed of sound a constant—the frequencies of the sound waves have to be scaled up by an amount equal to the inverse of the model’s physical scale. In our example, a 10 kHz frequency needs to be used in the model in order to assess the conditions that exist inside the full-size room under 1 kHz excitation. If data pertaining to the room needs to be available from 50 Hz to 20 kHz, the use of a 1:10 scale physical model will require that frequencies from 500 Hz to 200 kHz be used during the investigation.

#### 9.2.1.2 Time and Distance Considerations in Physical Models

A sound wave traveling at a velocity $c$ will take a time $t$ to cover a distance $x$ according to the relation

$$x = ct$$

(9-3)

In a physical model the dimensions are scaled down and as a consequence the time of travel of the waves inside the model is reduced by the same factor. If time-domain information with a specific resolution is required from the model, then the required resolution in the time data must increase by a factor equal to the inverse of the scale in order to yield the desired accuracy.

As an example, if a sound source is placed at the end of a room with a length $x = 30$ m and $c = 344$ m/s, the application of relation, Eq. 9-3, shows that the sound waves can be expected to reach the other end of the room in 87.2 ms. If an accuracy of $\pm 10$ cm is desired in the distance information, then a time resolution of $\pm 291$ $\mu$s is required for the time measurements.

In a 1:10 scale situation—and under the same conditions of sound velocity—the sound waves will now take 8.72 ms to travel the length of the model and a resolution of $\pm 29.1$ $\mu$s will be required in the time-measuring apparatus to yield the required distance resolution.

#### 9.2.1.3 Medium Considerations in Physical Models

As a sound wave travels through a gaseous medium like air it loses energy because of interaction with the molecules of the media in a phenomenon known as thermal relaxation. Energy is also lost via spreading of the wave as it travels away from the source. The absorption in the medium as a function of distance of travel $x$ and other parameters such as temperature and humidity can be represented by a loss factor $K$ that is given by:

$$K = e^{-mx}$$

(9-4)
where, $m$ is called the decay index, and it takes into account the temperature and the humidity of the air as a function of the frequency of the sound.

The value of $m$ has been determined both analytically and experimentally for various conditions of temperature and humidity over a range of frequencies extending from 100 Hz to 100 kHz and an examination of the data shows that the absorption of air increases with increased frequencies and that for a given frequency the maximum absorption takes place for higher relative humidity.

Since the distance $x$ traveled by sound waves in a physical model are scaled down in a linear fashion (i.e., by the scale factor), one cannot expect the attenuation of the waves inside the model to accurately reflect the absorption of the air since the loss factor $K$ follows an exponential decay that is dependent upon the term $m$ that is itself affected by the physical properties of the medium. In a scaled physical model this discrepancy is taken into account by either totally drying the air inside the model or achieving conditions of 100% relative humidity; in either case, the approach yields a simpler relation for $m$ that becomes solely dependent on temperature and frequency. For example, in the case of totally dry air the decay index becomes

$$m = (33 + 0.2T)10^{-12}f^2$$

(9-5)

and under these conditions, it is clear that the dominant term that dictates the loss of energy in the sound wave is the frequency $f$ since $m$ is proportional to $f^2$ and varies only slightly with the temperature $T$.

Another available option to account for the differences in the air absorption between a scaled physical model and its full-size representation is to use a different transmission medium in the model. Replacing the air inside the model with a simple molecular gas like nitrogen will yield a decay index similar to that of Eq. 9-5 up to frequencies of 100 kHz but this is a cumbersome technique that limits the usability of the scale model.

9.2.1.4 Source and Receiver Considerations in Physical Models

To account for the primary phenomena (defined in Table 9-1) that take place over a range of frequencies from 40 Hz to 15 kHz inside a full-size room, one needs to generate acoustic waves with frequencies extending from 400 Hz to 150 kHz if a 1:10 model is used, and the required range of test frequencies becomes 800 Hz to 300 kHz in the case of a 1:20 scale model. The difficulties associated with creating efficient and linear transducers of acoustical energy over such frequency ranges are a major issue associated with the use of physical scale models in acoustics.

Transducers of acoustical energy that can generate continuous or steady-state waves over the desired range of frequencies and that can also radiate the acoustical energy in a point-source fashion are difficult to design, thus physical scale models often use impulse sources for excitation; in these instances the frequency information is derived from application of transform functions to the time-domain results. One commonly used source of impulse is a spark generator as shown in Fig. 9-4 where a high voltage of short duration (typically ranging from less than 20 μs to 150 μs) is applied across two conductors separated by a short distance. A spark bridges the air gap and the resulting noise contains substantial high-frequency energy that radiates over an adequately spherical pattern.

Although the typical spark impulse may contain sufficient energy beyond 30 kHz, the frequency response of a spark generator is far from being regular and narrowing of the bandwidth of the received data is required in order to yield the most useful information. The bandwidth of the impulse $\Delta f_{\text{impulse}}$ and its duration $t_{\text{impulse}}$ are related by the uncertainty principle

$$\Delta f_{\text{impulse}}t_{\text{impulse}} = 1$$

(9-6)

When dealing with impulses created with a spark generator, the received data must be processed via a bandpass filter of order to eliminate distortion associated with the nonlinearity of the spark explosion, but the
filter must have a sufficient bandwidth \( \Delta f_{\text{filter}} \), to avoid limiting the response of the impulse.

\[
\Delta f_{\text{filter}} \geq \frac{4}{t_{\text{impulse}}} \quad (9-7)
\]

Steady-state sound waves can be generated over spherical (nondirectional) patterns up to frequencies of about 30 kHz by using specially designed electrostatic transducers. Gas nozzles can also be used to generate continuous high-frequency spectra although issues of linearity and perturbation of the medium must be taken into account for receiver locations that are close to the source.

Microphones are available with very good flatness (±2 dB) over frequency responses extending beyond 50 kHz. The main issues associated with the use of microphones in physical scale models are that the size of the microphone cannot be ignored when compared to the wavelength of the sound waves present in the model, and that microphones become directional at high frequencies. A typical half-inch microphone capsule with a 20 cm housing in a 1:20 scale model is equivalent to a 25 cm × 4 m obstacle in a real room and can hardly be ignored in term of its contribution to the measurement; furthermore its directivity can be expected to deviate substantially (>6 dB) from the idealized spherical pattern above 20 kHz. Using smaller capsules (\( \frac{1}{4} \) in or even \( \frac{1}{8} \) in) can improve the omnidirectionality of the microphone but it also reduces its sensitivity and yields a lower SNR during the measurements.

9.2.1.5 Surface Materials and Absorption
Considerations in Physical Models

Ideally, the surface materials used in a scale physical model should have absorption coefficients that closely match those of real materials planned for the full-size environment at the equivalent frequencies. For example, if a 1:20 scale model is used to investigate sound absorption from a surface at 1 kHz in the model (or 50 Hz in the real room) then the absorption coefficient \( a \) of the material used in the model at 1 kHz should match that of the planned full-size material at 50 Hz. In practice this requirement is never met since materials that have similar absorption coefficients over an extended range of frequencies are usually limited to hard reflectors where \( a < 0.02 \) and even under these condition, the absorption in the model will increase with frequency and deviate substantially from the desired value. The minimum value for the absorption coefficient of any surface in a model can be found from

\[
a_{\text{min}} = 1.8 \times 10^{-4} \sqrt{f}
\]

where,

\( f \) is the frequency of the sound wave at which the absorption is measured.

Thus at frequencies of 100 kHz, an acoustically hard surface like glass in a 1:20 scale model will have an absorption coefficient of \( a_{\text{min}} = 0.06 \), a value that is clearly greater than \( a < 0.03 \) or what can be expected of glass at the corresponding 5 kHz frequency in the full-size space.

The difference in level between the energy of the \( n \)th reflected wave to that of the direct wave after \( n \) reflections on surfaces with an absorption coefficient \( a \) is given by

\[
\Delta L_{\text{level}} = 10 \log(1 - a)^n \quad (9-9)
\]

Considering glass wherein the model \( a = a_{\text{min}} = 0.06 \), the application of Eq. 9-9 above shows that after two reflections the energy of the wave will have dropped by 0.54 dB. If the reflection coefficient is now changed to \( a = 0.03 \) then the reduction in level is 0.26 dB or a relative error of less than 0.3 dB. Even after five reflections, the relative error due to the discrepancies between \( a \) and \( a_{\text{min}} \) is still less than 0.7 dB, a very small amount indeed.

On the other hand, in the case of acoustically absorptive materials (\( \alpha > 0.1 \)) the issue of closely matching the absorption coefficients in the models to those used in the real environment becomes very important. The application of Eq. 9-9 to absorption coefficients \( \alpha \) in excess of 0.6 shows that even a slight mismatch of 10% in the absorption coefficients can result in differences of 1.5 dB after only two reflections. If the mismatch is increased to 20% then errors in the predicted level in excess of 10 dB can take place in the model.

Due to the difficulty in finding materials that are suitable for use in both the scaled physical model and in the real-size environment, different materials are used to match the absorption coefficient in the model (at the scaled frequencies) to that of the real-size environment at the expected frequencies. For example, a 10 mm layer of wool in a 1:20 scale model can be used to model rows of seats in the actual room, or a thin layer of polyurethane foam in a 1:10 scale model can be used to represent a 50 mm coating of acoustical plaster in the real space. Another physical parameter that is difficult to account for in scale physical model is stiffness, thus the evaluation of effects such as diaphragmatic
9.2.2 Computational Models

This section presents models that create a mathematical representation of an acoustical environment by using assumptions that are based on either a geometrical, analytical, numerical, or statistical description of the physical phenomena (or parameters) to be considered, or on any combination of the aforementioned techniques. In all instances, the final output of the modeling phase is the result of extensive mathematical operations that are usually performed by computers. With the development of powerful and affordable computers and of graphical interfaces these modeling tools have become increasingly popular with acoustical designers. To various degrees, the aim of computational models is to ultimately yield a form of the impulse response of the room at a specific receiver location from which data pertaining to time, frequency, and direction of the sound energy reaching the receiver can be derived. This information can then be used to yield specific quantifiers such as reverberation time, lateral reflection ratios, intelligibility, and so on.

The inherent advantage of computational models is flexibility: changes to variables can be made very rapidly and the effects of the changes are available at no hard cost, save for that of computer time. Issues related to source or receiver placement, changes in materials and/or in room geometry can be analyzed to an infinite extent. Another advantage of computational models is that scaling is not an issue since the models exist in a virtual world as opposed to a physical one.

Computational models are themselves divided into subgroups that are fundamentally based on issues of adequacy, accuracy, and efficiency. An adequate model uses a set of assumptions based on a valid (true) description of the physical reality that is to be modeled. An accurate model will further the cause of adequacy by providing data that is eminently useful because of the high confidence associated with it. An efficient model will aim at providing fast and adequate results but maybe to a lesser—yet justified—extent in accuracy. Although issues of accuracy and of efficiency will be considered in this portion of the chapter, the discussion of the various classes of computational models will be primarily based on their adequacy.

9.2.2.1 Geometrical Models

The primary assumption that is being made in all geometrical models applied to acoustics is that the wave can be seen as propagating in one or more specific directions, and that its reflection(s) as it strikes a surface is (are) also predictable in terms of direction; this is a very valid assumption when the wavelength can be considered small compared to the size of the surface and the condition \( ka > 5 \) presented in Table 9-1 quantifies the limit above which the assumption is valid. Under this condition, the propagating sound waves can be represented as straight lines emanating from the sources and striking the surfaces (or objects) in the room at specific points. The laws of optics involving angles of incidence and angles of reflection will apply and the term geometrical acoustics is used to describe the modeling technique.

The second assumption of relevance to geometrical acoustics models is that the wavelength of the sound waves impinging on the surfaces must be large compared to the irregularities in the surface, in other words the surface has to appear smooth to the wave and in this instance the irregularities in the surface will become invisible since the wave will diffract around them. If the characteristic dimension of the irregularities is denoted by \( b \), then the condition \( kb < 1 \) is required using the criteria outlined in Table 9-1. This is a necessary condition to assume that the reflection is specular, that is that all of its energy is concentrated in the new direction of propagation. Unless this condition is met in the actual room the energy of the reflected wave will be spread out in a diffuse fashion and the geometrical acoustics assumption of the model will rapidly become invalid, especially if many reflections are to be considered.

Image Models. In this class of geometrical acoustics models, the assumption that is being made is that the only sound reflections that the model should be concerned about are those reaching the receiver, so the methodology aims at computing such reflections within time and order constraints selected by the user of the model while ignoring the reflections that will not reach the receiver. To find the path of a first-order reflection a source of sound \( S_0 \) is assumed to have an image—a virtual source \( S_1 \)—located across the surface upon which the sound waves are impinging as presented in Fig. 9-5.

As long as the surface can be considered to be rigid, the image method allows for the prediction of the angles of reflections from the surface and can find all of the paths that may exist between a source and a receiver.\(^3\) It
also satisfies the boundary conditions that must take place at the surface, that is, the acoustical pressures have to be equal on both sides of the surface at the reflection point, and the velocity of the wave has to be zero at the interface. The image from the virtual source $S_1$ can also be used to determine where the second-order reflections from a second surface will be directed to since as far as the second surface is concerned, the wave that is impinging upon it emanated from $S_1$. A second order source $S_2$ can thus be created as shown in Fig. 9-6 and the process can be repeated as needed to investigate any order of reflections that constitutes a path between source and receiver.

It is thus possible to collect the amplitude and the direction of all of the reflections at a specific location as well as a map of where the reflections emanate from. Even the reflection paths from curved surfaces can be modeled by using tangential planes as shown in Fig. 9-7 and Fig. 9-8.

Since the speed of sound can be assumed to be a constant inside the room, the distance information pertaining to the travel of the reflections can be translated into time-domain information; the result is called a reflectogram (or sometimes an echogram) and it provides for a very detailed investigation of the reflections inside a space that reach a receiver at a specific location. A sample of a reflectogram is shown in Fig. 9-9.

![Figure 9-5](image1.png)  
**Figure 9-5.** A source and its virtual image located across a boundary define the direction of the first-order reflection.

![Figure 9-6](image2.png)  
**Figure 9-6.** Higher-order reflections can be created by adding virtual images of the source.

![Figure 9-7](image3.png)  
**Figure 9-7.** Image construction from a convex plane. Adapted from Reference 1.

![Figure 9-8](image4.png)  
**Figure 9-8.** Image construction from a concave plane. Adapted from Reference 1.

![Figure 9-9](image5.png)  
**Figure 9-9.** A reflectogram (or echogram) display of reflections at a specific point inside a room.

Although it was originally developed solely for the determination of the low-order specular reflections taking place in rectangular rooms due to the geometric increase in the complexity of the computations required, the technique was expanded to predict the directions of the specular reflections from a wide range of shapes. In the image method, the boundaries of the room are effectively...
being replaced by sources and there is no theoretical limit
to the order of reflection that can be handled by the
image methodology. From a practical standpoint, the
number of the computations that are required tends to
grow exponentially with the order of the reflections and
the number of surfaces as shown in Eq. 9-10, where \( N_{IS} \)
represents the number of images, \( N_W \) is the number of
surfaces that define the room, and \( i \) is the order of the
reflections.\(^5\)

\[
N_{IS} = \frac{N_W}{N_W - 2} \times (N_W - 1)^{i-1} - 1
\]  \hspace{1cm} (9-10)

Furthermore reflections must be analyzed properly in
terms of their visibility to the receiver in the case of
complicated room shapes where some elements may
block the reflections from the receiver as shown in
Fig. 9-10.

The model must also constantly check for the
validity of the virtual sources to insure that they actually
contribute to the real reflectogram by emulating reflec-
tions taking place inside the room and not outside its
physical boundaries. Fig. 9-11 illustrates such a
situation.

In Fig. 9-11 a real source \( S_0 \) creates a first-order
image \( S_1 \) across boundary 1. This is a valid virtual
source that can be used to determine the magnitude and
the direction of first-order specular reflections on the
boundary surface 1. If one attempts to create a
second-order virtual source \( S_2 \) from \( S_1 \) with respect to
boundary surface 2 to find the second order reflection,
the image of this virtual source \( S_2 \) with respect to
boundary 1 is called \( S_3 \) but it is contained outside the
boundary used to create it and it cannot represent a
physical reflection.

Once the map of all the images corresponding to the
reflection paths has been stored, the intensity of each
individual reflection can be computed by applying
Eq. 9-9 introduced earlier. Since the virtual sources do

![Figure 9-10](image1.png)

**Figure 9-10.** The reflection is not visible to the listener due
to the balcony obstruction.

represent the effect of the boundaries on the sound waves, the frequency dependence of the absorption
coefficients of the surfaces is modeled by changing the
power radiated by the virtual sources; thus, once the
image map is obtained the model can be used to rapidly
simulate an unlimited number of “what if” simulations
pertaining to material changes as long as the locations
of the sources and the receiver remain unchanged. A
further correction for the air absorption resulting from
the wave traveling over extended distances can also be
incorporated at this time in the simulation. The same
reasoning applies to the frequency distribution of the
source: since the image map (and the resulting location
of the reflections in the time domain) is a sole function
of source and receiver position, the image model can
rapidly perform “what if” simulations to yield reflecto-
grams at various frequencies.

The image methodology does not readily account for
variations in the absorption coefficient of the surfaces as
a function of the angle of incidence of the wave. When
taking into account all of the properties in the transmis-
sion medium, it can be shown that many materials will
exhibit a substantial dependence of their absorption
coefficient on the incidence angle of the wave, and in its
most basic implementation the image method can
misestimate the intensity of the reflections. It is
however, possible to incorporate the relationship
between angle of incidence and absorption coefficient
into a suitable image algorithm in order to yield more
accurate results, although at the expense of computa-
tional time.

In an image model the user can control the length of
the reflection path as well as the number of segments
(i.e., the order of the reflections) that comprise it. This
allows for a reduction in the computational time of the
process since virtual sources located beyond a certain distance from the receiver location can be eliminated while not compromising the fact that all of the reflections within a specific time frame are being recorded, and the image method can lead to very accurate results in the modeling of the arrival time of reflections at a specific location.

Efficient computer implementations of the image methodology have been developed\(^4\) to allow for a fast output of the reflections while also checking for the validity of the images and for the presence of obstacles. Still the method is best suited to the generation of very accurate reflectograms of short durations (500 ms or less) and limited number of reflections (fifth order maximum for typical applications). These factors do not negatively affect the application of the image method in acoustical modeling since in a typical large space—like an auditorium or a theater—the sound field will become substantially diffuse after only a few reflections and some of the most relevant perceived attributes of the acoustics of the space are correlated to information contained in the first 200 ms of the reflectogram.

Ray-Tracing Models. The ray-tracing methodology follows the assumptions of geometrical acoustics presented at the onset of this section, but in this instance the source is modeled to emit a finite number of rays representing the sound waves in either an omnidirectional pattern for the most general case of a point source, or in a specific pattern if the directivity of the source is known. Fig. 9-12 shows an example of a source \(S\) generating rays inside a space and how some of the rays are reflected and reach the receiver location \(R\).

![Figure 9-12](image.png)

Figure 9-12. Rays are generated by a source, \(S\). Some of the rays reach the receiver, \(R\).

In this instance, the goal is not to compute all of the reflection paths reaching the receiver within a given time frame but to yield a high probability that a specified density of reflections will reach the receiver (or detector usually modeled as a sphere with a diameter selected by the user) over a specific time window.

In the case of the image method, the boundaries of the room are replaced by virtual sources that dictate the angle of the reflections of the sound waves. In a similar fashion, the ray-tracing technique creates a virtual environment in which the rays emitted by the source can be viewed as traveling in straight paths across virtual rooms until they reach a virtual listener as presented in Fig. 9-13.

![Figure 9-13](image.png)

Figure 9-13. The rays can be seen as traveling in straight paths across virtual images of the room until they intercept a receiver. Adapted from Reference 4.

The time of travel and location of the ray are then recorded and can yield a reflectogram similar to that presented earlier in Fig. 9-9.

The main advantage of the ray-tracing technique is that since the model is not trying to find all of the reflection paths between source and receiver, the computational time is greatly reduced when compared to an image technique; for a standard ray-tracing algorithm, the computational time is found to be proportional to the number of rays and to the desired order of the reflections. Another advantage inherent to the technique is that multiple receiver locations may be investigated simultaneously since the source is emitting energy in all directions and the model is returning the number and the directions of rays that are being detected without trying to complete a specific path between source and receiver. On the other hand, since the source is emitting energy in many directions and one cannot dictate what the frequency content of a specific ray is versus that of another, the simulations pertaining to the assessment of frequency-dependent absorption must be performed independently and in their entirety for each frequency of interest.
One problem associated with the ray-tracing technique is that the accuracy of the detection is strongly influenced by size of the detector. A large spherical detector will record a larger number of hits from the rays than another spherical detector of smaller diameter, even if the respective centers of the spheres are located at the exact same point in space. Furthermore, the ray-tracing method may lead to an underestimation of the energy reaching the detector (even if its size is considered adequate) unless large numbers of rays are used since the energy is sampled via rays that diverge as they spread from the source thus increasing the possibility that low-order reflections may miss the detector.

Techniques combining the image methodology and the ray-tracing approach have been developed. The algorithms aim at reducing the number of images to be considered by using the more computationally efficient ray-tracing technique to conduct the visibility test required by the image method.

**Beam-Tracing Models.** The triangular area that is defined between two adjacent rays emanating from a source is called a 2D ray; more than two rays can also be used to define a 3D pyramidal or conical region of space in which the acoustical energy is traveling away from the source. In these instances, the source is viewed at emitting beams of energy, and the associated modeling techniques are known as *beam-tracing* methods. Figure 9-14 shows an example of a beam and its reflection path from a surface.

![Figure 9-14. A 3D beam is emitted by a source S and reflects at a surface.](image)

The beam-tracing technique offers the advantage of guaranteeing that the entire space defining the model will receive energy since the directions of propagations are not sampled as in the case of the traditional ray-tracing approach. Virtual source techniques are used to locate the points that define the reflection zones across the boundaries of the room. On the other hand, the technique requires very complex computations to determine the reflection patterns from the surfaces since the reflection cannot be viewed as a single point as in the case of the ray-tracing technique: when 2D beams are used, the reflections from the surfaces must be considered as lines, while 3D beams define their reflections as areas. Care must also be taken to account for overlapping of the beams by each other or truncation of the beams by obstacles in the room.

Although the computational complexity of the model is substantially increased when it comes to assessing the direction of the reflections, the departure from the single point reflection model presents numerous advantages over the traditional image and/or ray-tracing technique. The issues associated with the divergence of the reflections as a function of increased distance from the source are naturally handled by the beam-tracing approach. Furthermore, the effects of acoustical diffusion can be modeled—at least in an estimated fashion—since the energy contained in the beams can be defined as having a certain distribution over either the length of the intersecting lines (for 2D beams) or areas (for 3D beams). For example, an adaptive beam-tracing model that controls the cross-sectional shape of the reflecting beam as a function of the shape of the reflecting surfaces also allows for an evaluation of the diffuse and specular energy contained inside a reflecting beam. If the energy contained inside the incident beam is \( E_B \) and the energy reflected from a surface is \( E_R \), then one can write

\[
E_R = E_B (1 - \alpha) (1 - \delta)
\]  

where,

- \( \alpha \) is the surface’s absorption coefficient,
- \( \delta \) is the surface’s diffusion coefficient.

The energy \( E_D \) that is diffused by the surface is found to be proportional to the area of illumination \( A \) and inversely proportional to the square of an equivalent distance \( L \) between the source and the reflection area

\[
E_D \propto \frac{E_B A \delta (1 - \alpha)}{4 \pi L^2}
\]  

(9-12)

The adaptive algorithm allows for a separate assessment of the specular and of the diffuse reflections from the same geometrical data set that represents the travel map of the beams inside the space. In this instance the diffused energy from a given surface is redirected to other surfaces in a recursive fashion via radiant exchange, a technique also used in light rendering applications. The diffuse and the specular portions of the
response can then be recombined to yield a reflectogram that presents a high degree of accuracy, especially when compared to traditional ray-tracing techniques. Fig. 9-15 shows a comparative set of impulse response reflectograms obtained by the adaptive beam tracing, the image, the ray-tracing, and the nonadaptive beam-tracing techniques in a model of a simple performance space containing a stage and a balcony.

The adaptive model is able to yield a reflectogram that is extremely close to that obtained with an image method—i.e., it is able to generate all of the possible reflections paths at a single point in space. From the perspective of computing efficiency, the adaptive-beam tracing methodology compares favorably with the image methodology especially when the complexity of the room and/or the order of the reflections is increased.

A note on diffusion: The issue of diffusion has been of prime interest to the developers of computer models since commercially available or custom-made diffusers are often integrated into room designs, sometimes at a high cost. Although diffusion is an essential qualitative part of the definition of a sound field, the quantitative question of “how much diffusion is needed?” is often answered using considerations that have little foundation in scatter theory and/or general acoustics. A concept as elementary as reverberation finds its classical quantitative representation (the Sabine/Eyring equation and associated variants) rooted into the notion that the sound field is assumed to be diffuse, and unless this condition is met in reality, one will encounter substantial errors in predicting the reverberation time. Today’s advanced large room computer acoustic simulation software products incorporate the ability to model diffused reflections using either a frequency dependence function or an adaptive geometry that spreads out the incident energy of the sound ray over a finite area. This allows for a much more accurate correlation between predicted and test data especially in rooms that have geometry involving shapes and aspect ratios that are out of the ordinary, noneven distribution of absorptive surfaces, and/or coupled volumes. Under these conditions the incorporation of diffusion parameters into the model is necessary and a specular-only treatment of the reflections (even when using an efficient ray-tracing technique) will lead to errors.

9.2.2.2 Wave Equation Models

Wave equation models are based on an evaluation of the fundamental wave equation, which in its simplest form relates the pressure $p$ of a wave at any point in space to its environment via the use of the 3D Laplacian operator $\nabla^2$ and the wave number $k$:

$$\nabla^2 p + k^2 p = 0$$  (9-13)
Solving the fundamental wave equation allows for an exact definition of the acoustic pressure at any specific point since appropriate boundary conditions defining the physical properties of the environment (surfaces, medium) can be used whenever required. As an example, in a model based on the wave equation the materials that comprise the environment (like the room) can be defined in terms of their "acoustical impedance" $z$ given by

$$ z = \frac{p}{U} \quad (9-14) $$

where,

- $p$ refers to the pressure of the wave,
- $U$ to its velocity in the medium.

When using the wave equation, issues having to do with diffraction, diffusion, and reflections are automatically handled since the phenomena are assessed from a fundamental perspective without using geometrical simplifications. The main difficulty associated with the method is found in the fact that the environment (surfaces and materials) must be described accurately in order for the wave equation to be applied: either an analytical or a numerical approach can be used to achieve this goal.

### 9.2.2.2.1 Analytical Model: Full-Wave Methodology.

An analytical model aims at providing a mathematical expression that describes a specific phenomenon in an accurate fashion based on underlying principles and/or physical laws that the phenomenon must obey. Because of this requirement the analytical expression governing the behavior of a model must be free of correction terms obtained from experiments and of parameters that cannot be rigorously derived from—or encountered in—other analytical expressions.

The complexity of the issues associated with sound propagation has prevented the development of a single and unified model that can be applied over the entire range of frequencies and surfaces that one may encounter in acoustics; most of the difficulties are found in trying to obtain a complete analytical description of the scattering effects that take place when sound waves impinge on a surface. In the words of J.S. Bradley, one of the seminal researchers in the field of architectural acoustics:

*Without the inclusion of the effects of diffraction and scattering, it is not possible to accurately predict values of conventional room acoustics parameters [...]. Ideally, approxima-

tions to the scattering effects of surfaces, or of diffraction from finite size wall elements should be derived from more complete theoretical analyses. Much work is needed to develop room acoustics models in this area.*

In this section, we present the full-wave methodology, one analytical technique that can be used for the modeling of the behavior of sound waves as they interact with nonidealized surfaces, resulting in some of the energy being scattered, reflected, and/or absorbed as in the case of a real space. Due to the complexity of the mathematical foundation associated with this analytical technique, only the general approach is introduced here and the reader is referred to the bibliography and reference section for more details.

The full-wave approach (originally developed for electromagnetic scattering problems) meets the important condition of acoustic reciprocity requiring that the position of the source and of the receiver can be interchanged without affecting the physical parameters of the environment like transmission and reflection coefficients of the room’s surfaces. In other words if the environment remains the same, interchanging the position of a source and of a receiver inside a room will result in the same sound fields being recorded at the receiver positions. The full-wave method also allows for exact boundary conditions to be applied at any point on the surfaces that define the environment, and it accounts for all scattering phenomena in a consistent and unified manner, regardless of the relative size of the wavelength of the sound wave with that of the objects in its path. Thus the surfaces do not have to be defined by general (and less than accurate) coefficients to represent absorption or diffusion, but they can be represented in terms of their inherent physical properties like density, bulk modulus, and internal sound velocity.

The full-wave methodology computes the pressure at every point in the surface upon which the waves are impinging, and follows the shape of the surface. The coupled equations involving pressure and velocity are then converted into a set of equations that separate the forward (in the direction of the wave) and the backward components of the wave from each other, thus allowing for a detailed analysis of the sound field in every direction. Since the full-wave approach uses the fundamental wave equation for the derivation of the sound field, the model can return variables such as sound pressure or sound intensity as needed.

The main difficulty associated with the full-wave method is that the surfaces must also be defined in an analytical fashion. This is possible for simple (i.e.,
planar, or curved) surfaces for which equations are readily available, but for more complicated surfaces—such as those found in certain shapes of diffusers—an analytical description is more difficult to achieve, and the methodology becomes restricted to receiver locations that are located at a minimum distance from the surfaces upon which the sound waves are impinging. Still for many problems the full-wave methodology is a very accurate and efficient way to model complicated scattering phenomena.

9.2.2.3 Numerical Model: Boundary Element Methodology

The boundary element analysis (BEA) techniques are numerical methods that yield a quantitative value of the solution to the problem under investigation. BEA techniques\(^{11,12,13,14}\) can be used in solving a wide range of problems dealing with the interaction of energy (in various forms) with media such as air and complex physical surfaces, and they are well suited to the investigation of sound propagation in a room. Although the method is based on solving the fundamental differential wave equation presented earlier, the BEA methodology makes use of an equivalent set of much simpler algebraic equations valid over a small part of the geometry, and then expands the solution to the entire geometry by solving the resulting set of algebraic equations simultaneously. In essence, the BEA technique replaces the task of solving one very complex equation over a single complicated surface by that of solving a large quantity of very simple equations over a large quantity of very simple surfaces. In a BEA implementation the surface is described using a meshing approach as shown in Fig. 9-16.

Figure 9-16. A mesh describes a boundary in the BEA method.

In the BEA method the analytical form of the solution over the small domain (area) of investigation is not directly accessible for modification. The use exercises control over the solution by properly specifying the domain (geometry) of the problem, its class (radiation or scattering), the parameters of the source (power, directivity, location), and, of course, the set of boundary conditions that must be applied at each area defined by the mesh. It is thus possible to assign individual material properties at every location in the mesh of the model in order to handle complex scattering and absorption scenarios, if needed. Although it can be adapted to solving acoustical problems in the time domain the BEA technique is better suited to providing solutions in the frequency domain since the characteristics of the materials are considered to be time-invariant but frequency dependent.

The main issue that is associated with the use of BEA methodology for the investigation of acoustical spaces is that the size of the elements comprising the mesh representing the surfaces dictates the accuracy of the solution. A small mesh size will, of course, allow for a very accurate description of the surfaces, both geometrically and in terms of its materials, but it will also drastically affect the computational time required to yield a solution. On the other hand, a large mesh size will yield very fast results that may be inaccurate because the algebraic equations that are used in lieu of the fundamental wave equation improperly being applied over large surfaces. A comparison of the accuracy yielded by BEA techniques over very simple geometries indicates that a minimum ratio of seven to one (7:1) must exist between the wavelength of the sound and the element size in order to bind the dependence of the BEA analysis on the size of its element to less than a ±0.5 dB resolution. In other words, the wavelengths considered for analysis must be at least seven times larger than the largest mesh element in order for the methodology to be accurate. For this reason the BEA methodology is very efficient and accurate to model sound propagation at low frequencies (below 1000 Hz), but it becomes tedious and cumbersome at higher frequencies since in this instance the mesh must be modeled with better than a 50 mm resolution. Still the technique can be shown to yield excellent results when correlating modeled projection and actual test data from complicated surfaces such as diffusers.\(^{13}\)
Numeric Model: Finite Difference Time-Domain Methodology. As mentioned earlier, the BEA techniques are best suited to yielding data in the frequency domain, although they can be adapted to provide time-domain information albeit at a cost in computing efficiency. Another numerical methodology that uses a discrete representation of the acoustical environment is known as Finite-Difference Time-Domain (FDTD) and it is very efficient in terms of computational speed and storage while also offering excellent resolution in the time domain. It has been demonstrated\textsuperscript{15} that the technique can be used to effectively model low-frequency problems in room acoustics simulations and the results are suitable for the generation of reflectograms.

In the finite difference (FD) approach instead of describing the surface with a mesh (as with the BEA technique), a grid is used and the algebraic equations are solved at the points of the grid as shown in Fig. 9-17.

![Figure 9-17](image)

**Figure 9-17.** A grid describes a surface in the FD method.

In this instance the size of the grid can be made as small as needed to provide a high degree of resolution when needed and the grid points can be defined using the most effective coordinate system for the application. For example, a flat surface could be defined with a \((x, y, z)\) Cartesian grid system while cylinders (for pillars) and spheres (for audience’s heads) could be expressed with cylindrical and spherical systems respectively.

9.2.2.4 Statistical Models

The use of statistics in acoustical modeling is primarily reserved for the study of the behavior of sound in rectangular and rigid rooms where the dominant phenomena that are taking place are related to modes. The issues of modal frequencies, modal density, and mode distributions are presented, along with the appropriate descriptive equations in Chapter 5—Small Room Acoustics.

Another application of statistics in acoustical modeling can be found in situations where resonance effects take place at high frequencies, as opposed to the traditionally low frequencies associated with room modes. A technique known as Statistical Energy Analysis\textsuperscript{16} (SEA) can be used to accurately account for the effect of modal resonance effects that take place in systems such as partitions and walls, by analyzing the kinetic energy and the strain energy associated with vibrating structures. An SEA model will describe a vibrating system (such as a wall) with mass and spring equivalents and will allow for the analysis of the effect that adding damping materials will have on the vibration spectrum. SEA techniques are optimized for frequency-domain analysis and the output cannot be used for time-domain applications to add information to the impulse response of a room, or to yield a reflectogram; still, the main advantage of SEA is that real materials such as composite partitions with different degrees of stiffness, construction beams, and acoustical sprays can be modeled in a precise manner (i.e., not only in terms of a unique physical coefficient) over an extended range of frequency.

9.2.2.5 Small Room Models

A room that is acoustically small can be defined as one in which classically defined reverberation phenomena (using the assumption of a diffuse sound field) do not take place, but rather that the sound decays in a nonuniform manner that is a function of where the measurement is taken. The use of diffusion algorithms in large room models that rely on either ray-tracing, image source, or adaptive algorithms has vastly improve the reliability of the prediction models in a wide range of spaces, however accurate predictions of the sound field can be made in small rooms considering the interference patterns that result from modal effects. Figs. 9-18 and 9-19 shows the mapping\textsuperscript{17} of the interference patterns resulting from modal effects in an 8 m \(\times\) 6 m room where two loudspeakers are located at B1 and B2. In the first instance, a modal effect at 34.3 Hz creates a large dip in the response at about 5.5 m, while the second case shows a very different pattern at 54.4 Hz. Such models are very useful to determine the placement of low-frequency absorbers into a room in order to minimize the impact of modal effects at a specific listening location, and they are a good complement to the large
room models that typically do not investigate the distribution of the sound field at the very low frequencies.

9.2.3 Empirical Models

Empirical models are derived from experiments and are described by equations that typically follow curve-fitting procedures of the data obtained in the observations. No analytical, geometrical, and/or statistical expression is developed to fully explain the interdependence of variables and parameters in the model, but a general form of a descriptive expression may be constructed from underlying theories. Empirical models have been extensively used for many years in acoustical modeling due to the large quantity of variables and parameters that are often present when dealing with issues of sound propagation in a complicated environment, and this section will present only a couple of examples.

9.2.3.1 Gypsum Cavity Wall Absorption

There is numerous test data available pertaining to the sound transmission class (STC) of various wall constructions, but little has been investigated regarding the sound absorption of walls constructed of gypsum (drywall) panels. The absorption of a composite wall panel is partly diaphragmatic (due to the mounting), partly adiabatic (due to the porosity of the material and the air), and some energy is lost inside the cavity via resonance. The complicated absorption behavior of gypsum walls has been described using an empirical model that takes into account absorption data acquired in reverberation chamber experiments. The mathematical model is fitted to the measured data to account for the resonant absorption of the cavity by assuming that the mechanical behavior of the wall can be modeled by a simple mechanical system.

In this model, the resonance frequency at which the maximum cavity absorption takes place is given by

$$f_{MAM} = P \left(\frac{m_1 + m_2}{d} \right)$$

where,

- $m_1$ and $m_2$ are the mass of the gypsum panels comprising the sides of the wall in kg/m²,
- $d$ is the width of the cavity expressed in millimeters,
- $P$ is a constant with the following values:
  - If the cavity is empty (air), $P = 1900$,
  - If the cavity contains porous or fibrous sound-absorptive materials, $P = 1362$.

The empirical model combines the maximum absorption $\alpha_{MAM}$ taking place at the resonant frequency given by Eq. 9-15 with the high-frequency absorption $\alpha_S$ into a form that fits data obtained experimentally, to give an equation that allows for the prediction of the absorption coefficient of the wall as a function of frequency:

$$\alpha(f) = \alpha_{MAM} \left(\frac{f_{MAM}}{f} \right)^2 + \alpha_{MAM}$$

Although it does not take into account all of the construction variables (stud spacing, bonding between layers) the model still provides accurate prediction of the sound absorption parameters of various gypsum wall constructions.
9.2.3.2 Absorption from Trees and Shrubs

When dealing with issues related to outdoor noise propagation one may need to predict the anticipated noise reduction that can be expected from vegetation. In this instance, some of the general attributes of a tree-barrier such as height and width can be modeled from geometry, but others like leaf density, wind resistance, or diffraction effects from trunks may prove very difficult to describe either analytically or geometrically. In this instance an empirical model that fits experimental data to polynomial equations based on statistical regression is the most appropriate to yield the sound pressure level at various distances from a sound source while taking into account tree height, width of the tree barrier, wind velocity, and tree type. An example of such an equation is presented below, and it is shown to give excellent (±1 dB) accuracy between predicted and observed levels for distances extending 150 ft to 400 ft from the source that is assumed to be truck noise on an interstate highway. The receiver is shielded from the traffic by a belt of conifer trees planted along the interstate.

\[
L_{dB} = 81.65 - 0.2257H - 0.0229W + 0.728V - 0.0576D
\]  

(9-17)

where,

- \( L_{dB} \) is the predicted sound level behind the tree belt,
- \( H \) is the height of the tree belt, expressed in feet,
- \( W \) is the width of the tree belt, expressed in feet,
- \( V \) is the wind velocity component in the direction of the sound propagation, expressed in mph,
- \( D \) is the distance from the receiver to the tree belt.

Other equations are available for different sources and different types of trees. In this class of empirical models, no attempt is made to support the equation by analytical expressions but this does not affect the usefulness or the accuracy of the model.

9.2.4 Hybrid Models

As the name implies hybrid models use a combination of techniques to yield results and the choice of the technique may be based on a specific need such as fast output, accuracy, range of applicability, etc. A hybrid model can combine the inherent accuracy of the image method for the determination of reflection arrival time in the specular case, with an adaptive beam-tracing approach when diffusion is required, and may also incorporate some BEM computations for complicated materials wherever required. A hybrid model can also rely on empirical approaches to provide a confidence factor for results obtained from physical scale models or from statistical approaches.

An example of hybrid techniques can be found in models that are aimed at assessing outdoor noise propagation. In this instance, the objects that are in the path of the sound waves are typically buildings or large natural obstacles and can be considered to be much larger than the wavelength, except for the lowest frequencies, and as such, the geometrical acoustics assumptions apply very well; as such, the image method is very appropriate to compute reflection paths between obstacles. On the other hand one cannot ignore the fact that outdoor noise may contain a lot of low frequencies and that diffraction effects will take place; in this instance the model must use an appropriate description of diffraction such as the one presented in Chapter 4—Acoustical Treatment of Rooms and the model may also be refined from empirical data table to represent complicated sources such as car traffic, aircraft, and trains since point source assumptions become invalid and the sources are also moving. Figs. 9-20 and 9-21 shows the type of noise prediction maps that can be obtained from such a model; in the first instance the noise sources are a combination of street traffic and large mechanical systems, and the model takes into account the diffraction effects of various buildings. In the second instance, the model is used to assess the difference in expected noise levels between different types of pavements (asphalt vs. concrete) based on traffic data on a segment of road that is surrounded by residences.

Hybrid models are also found in construction applications, where they combine analytical techniques based on specific equations with databases of test results obtained in the laboratory and in the field. As an example, a simple model could be developed using the Mass Law in order to predict the sound transmission between two spaces and yield an estimate of the Sound Transmission Class (STC) of the partition, however, the results would not be very useful because they would extensively be influenced by the construction technique and the presence of flanking paths. With a model that takes into account the construction techniques of the partition, the results are much more accurate and provide the designer with valuable insight on the weak links of the construction as they pertain to noise transmission.
9.3 Auralization

Auralization is the process of rendering audible, by physical or mathematical modeling, the sound field of a source in a space, in such a way as to simulate the binaural listening experience at a given position in the modeled space.²²

Auralization systems have been in existence since the 1950s.²³ During the early experiments, researchers used a physical 1:10 scale model in which a tape containing speech and music samples was played back at scaled-up speed through a scaled omnidirectional source while also taking into account the air absorption and scaling the reverberation time of the model. A recording of the sound was made at the desired receiver locations using a scaled dummy head and the results were played back at a scaled-down speed under anechoic conditions using two speakers. The sound of the model was then subjectively assessed and compared to that perceived in the real room.

The technique—or variants of it—was used for the prediction of the acoustics of both large and small rooms throughout the 1970s, however, with computer systems becoming increasingly faster and more affordable auralization techniques based on computational models have been developed to yield an audible repre-
sentation of the sound field at any specified receiver location by using the results of the acoustical modeling phase. Various implementations of auralization have been put into place\textsuperscript{24,25,26,27} at the time of this writing but because of the tremendous developments that are taking place in the field of auralization this section will only explore the general concepts associated with the topic of auralization since it is safe to say that specific implementations of auralization techniques will be subject to changes and additions dictated by new technological advances and/or by market demands.

9.3.1 The Basic Auralization Process

The basic auralization process associated with an acoustical model is illustrated in Fig. 9-22.

The process starts with the reflectograms representing the impulse response (IR) of the model obtained at a specific receiver location for various frequencies. The reflectograms contain the information pertaining to the intensity and the direction of arrival of the reflections over a period of time that is deemed suitable to record the desired order and length of the reflections, and they are obtained from any of the methodologies presented in the modeling portion of this chapter. The reflectograms are then convolved—or mixed—with a dry (anechoic) recording of speech or music that can be played back under controlled conditions, using either headphones or loudspeakers, for the purpose of subjective evaluation.

9.3.2 Implementation

The energy reaching the listener is comprised of the direct sound, of the early reflections, and of the late reflections as shown in Fig. 9-23.

The direct sound is easily found and modeled accurately in the reflectogram since it represents the energy traveling from source to receiver in a direct line of sight. The only concern for the accurate auralization of the direct sound is to insure that the attenuation follows the inverse-distance spreading law as dictated by the source configuration and directivity. The early reflections are also obtained from the modeling phase but the reflectogram must be limited in length—or in the order of the reflections—because of computational constraints. The late portion of the reflectogram is usually modeled from a dense and random pattern of reflections with a smooth decay and a frequency content patterned after the reverberation time of the room estimated at various frequencies.

Since the reflectogram typically represents the impulse response at a single point (or within a small volume) in the modeled space, it must be modified in order to represent the binaural sound that would be reaching the eardrums of a listener by and at this point, two separate approaches are available.

9.3.2.1 Binaural Reproduction Using Loudspeakers

The impulse response is divided into its left and right components corresponding to the vertical left and right planes crossing the receiver location, and thus yielding the binaural impulse response (BIR) of the room for a listener at the receiver location. The anechoic signal is convolved separately for the left and the right channel, and the result is presented under anechoic and/or near field conditions to a listener using loudspeakers as shown in Fig. 9-24.

This technique has the advantage of being efficient from a computational standpoint since the process is limited to the separation of the IR into the BIR and the resulting convolution into left and right channels for the playback system. The drawback of the technique is that the playback requires a controlled environment where the listener has to maintain a fixed position with respect to the playback system and the crosstalk between the loudspeakers must be very small in order to yield the proper sense of spatial impression.

9.3.2.2 Binaural Reproduction Using Headphones

In this approach, the BIR is further modified by the application of head-related transfer functions (HRTF) that represent the effects that the head, torso, shoulders, and ears will have on the sound that reaches the eardrums of the listener. It has been shown\textsuperscript{28,29} that these parameters have a drastic influence on the localization of the sound and on its overall subjective assessment. As shown in Fig. 9-25, the reproduction system must now use headphones since the effects of the body and head shape of the listener have already been taken into account. The advantage of this approach is that the playback system is very simple; good quality headphones are readily available and no special setup is required. The drawback is that the implementation of the modified BIR takes time due to the computational requirements for the application of the HRTF. It must also be noted that the HRTF may not accurately describe the specific parameters that a given listener experiences, although current HRTF research has yielded accurate
composite data for a wide segment of the test results. Another issue of concern when using headphone reproduction is that the apparent source location will move with the listener’s head movements, something that does not take place in the real world.

### 9.3.2.3 Multichannel Reproduction Using Loudspeakers

In this instance, the impulse response of the room is divided into components that correspond to the general locations in space from where the reflections originate as shown in Fig. 9-26. Various systems have been developed throughout the years ranging from just a few speakers to hundreds of units driven by dozens of separate channels. The advantage of the technique is that the system relies on the listener’s own HRTF while also allowing for head tracking effects. From the perspective of efficiency the approach can be implemented with minimal hardware and software since the reflections can be categorized in terms of their direction of arrival while the IR is being generated. The multichannel reproduction technique can actually be implemented from a physical scale model without the need for computer tools by using delay lines and an analog matrix system. The reproduction system is, of course, rather complicated since it requires substantial hardware and an anechoic environment.

### 9.3.3 Real-Time Auralization and Virtual Reality

A real-time auralization system allows the user to actually move within the room and to hear the resulting changes in the sound as they actually happen. This approach requires the near-instantaneous computation of the impulse response so that all parameters pertaining to the direct sound and to the reflections can be computed. In a recent implementation the space is modeled using an enhanced image method approach in which a fast ray-tracing preprocessing step is taken to check the visibility of the reflections at the receiver location. The air absorption and the properties of the surface materials are modeled using efficient digital filters, and the late reverberation is described using techniques that give a smooth and dense reflection pattern.

---

**Figure 9-22.** The basic auralization process.

**Figure 9-23.** An example of a complete reflectogram at 1000 Hz.
that follows the statistical behavior of sound in a bounded space. The technique yields a parametric room impulse response (PRIR) in which a combination of real-time and nonreal-time processes performs a model-
Acoustical Modeling and Auralization

In this approach, known as dynamic auralization, the presentation of the sound field can be done either via binaural headphones or by multi-channel speaker techniques and the auralization parameters must be updated at a fast rate (typically more than ten times per second) in order for the rendering to be of high quality. The impulse response that is used for the convolutions can be a combination of an accurate set of binaural responses (that map head-tracking movements) to account for the early portion of the reflections with a simpler static impulse response that provides the foundation for the calculation of the late part of the sound field. This approach is moderately efficient in terms of computational time and memory consumption and recent developments\textsuperscript{33} have been aimed at making use of an efficient means to process the impulse response of a space. Using an approach known as Ambisonics B-format\textsuperscript{34} the sound information is encoded into four separate channels labeled W, X, Y and Z. The W channel would be equivalent to the mono output from an omnidirectional microphone while the X, Y and Z channels are the directional components of the sound in front-back (X), left-right (Y), and up-down (Z) directions. This allows a single B-format file to be stored for each location to account for all head motions at this specific location and to produce a realistic and fast auralization as the user can move from one receiver location to the other and experience a near-seamless simulation even while turning his/her head in the virtual model.

9.4 Conclusion

Acoustical modeling and auralization are topics of ongoing research and development. Originally planned for the evaluation of large rooms, the techniques have also been used in small spaces\textsuperscript{35} and in outdoor noise propagation studies\textsuperscript{36} and one can expect to witness the standard use of these representation tools in a wide range of applications aimed at assessing complex acoustical quantifiers. Even simple digital processing systems such as those offered as plug-ins for audio workstations can be used to illustrate the effect of frequency-dependent transmission loss from various materials using simple equalization and level settings corresponding to octave or third-octave band reduction data.

Further work is needed in the representation and modeling of complicated sources such as musical instruments, automobiles, trains, and other forms of transportation; work is also ongoing in the definition of materials and surfaces so that the effect of vibrations and stiffness is accounted for. Still, the models are rapidly becoming both very accurate and very efficient and they are demonstrating their adequacy at illustrating the complicated issues that are associated with sound propagation and, eventually, sound perception.

10.1 Resistors

Resistance is associated with the phenomenon of energy dissipation. In its simplest form, it is a measure of the opposition to the flow of current by a piece of electric material. Resistance dissipates energy in the form of heat; the best conductors have low resistance and produce little heat, whereas the poorest conductors have high resistance and produce the most heat. For example, if a current of 10 A flowed through a resistance of 1 Ω, the heat would be 100 W. If the same current flowed through 100 Ω, the heat would be 10,000 W, which is found with the equation

\[ P = I^2R \]  
(10-1)

where,

- \( P \) is the power in watts,
- \( I \) is the current in amperes,
- \( R \) is the resistance in ohms.

In a pure resistance—i.e. one without inductance or capacitance—the voltage and current phase relationship remains the same. In this case the voltage drop across the resistor is

\[ V = IR \]  
(10-2)

where,

- \( V \) is the voltage in volts,
- \( I \) is the current in amperes,
- \( R \) is the resistance in ohms.

All resistors have one by-product in common when put into a circuit, they produce heat because power is dissipated any time a voltage, \( V \), is impressed across a resistance \( R \). This power is calculated from Eq. 10-1 or

\[ P = \frac{V^2}{R} \]  
(10-3)

where,

- \( P \) is the power in watts,
- \( V \) is the voltage in volts,
- \( R \) is the resistance in ohms.

Changing the voltage, while holding the resistance constant, changes the power by the square of the voltage. For instance, a voltage change from 10 V to 12 V increases the power 44%. Changing the voltage from 10 V to 20 V increases the power 400%.

Changing the current while holding the resistance constant has the same effect as a voltage change. Changing the current from 1 A to 1.2 A increases the power 44%, whereas changing from 1 A to 2 A increases the power 400%.

Changing the resistance while holding the voltage constant changes the power linearly. If the resistance is decreased from 1 kΩ to 800 Ω and the voltage remains the same, the power will increase 20%. If the resistance is increased from 500 Ω to 1 kΩ, the power will decrease 50%. Note that an increase in resistance causes a decrease in power.

Changing the resistance while holding the current constant is also a linear power change. In this example, increasing the resistance from 1 kΩ to 1.2 kΩ increases the power 20%, whereas increasing the resistance from 1 kΩ to 2 kΩ increases the power 100%.

It is important in sizing resistors to take into account changes in voltage or current. If the resistor remains constant and voltage is increased, current also increases linearly. This is determined by using Ohm’s Law, Eq. 10-1 or 10-3.

Resistors can be fixed or variable, have tolerances from 0.5% to 20%, and power ranges from 0.1 W to hundreds of watts.

10.1.1 Resistor Characteristics

Resistors will change value as a result of applied voltage, power, ambient temperature, frequency change, mechanical shock, or humidity.

The values of the resistor are either printed on the resistor, as in power resistors, or are color coded on the resistor, Fig. 10-1. While many of the resistors in Fig. 10-1 are obsolete, they are still found in grandma’s old radio you are asked to repair.

**Voltage Coefficient.** The voltage coefficient is the rate of change of resistance due to an applied voltage, given in percent parts per million per volt (%ppm/V). For most resistors the voltage coefficient is negative—that is, the resistance decreases as the voltage increases. However, some semiconductor devices increase in resistance with applied voltage. The voltage coefficient of very high valued carbon-film resistors is rather large and for wirewound resistors is usually negligible. Varistors are resistive devices designed to have a large voltage coefficient.

**Temperature Coefficient of Resistance.** The temperature coefficient of resistance (TCR) is the rate of change in resistance with ambient temperature, usually stated as parts per million per degree Celsius (ppm/°C). Many types of resistors increase in value as the temperature increases, while others, particularly hot-molded carbon types, have a maximum or minimum in their resistance.
curves that gives a zero temperature coefficient at some temperature. Metal film and wirewound types have temperature coefficient values of less than 100 ppm/°C. Thermistors are resistance devices designed to have a large temperature coefficient.

The percent temperature coefficient of resistance is

\[ TCR = \frac{(R - r)100}{(R - T)R} \]  

where,

- \( TCR \) is the temperature coefficient in percent per °C,
- \( R \) is the resistance at reference temperature,
- \( r \) is the resistance at test temperature,
- \( TR \) is the reference temperature in °C,
- \( TT \) is the test temperature in °C.

It is better to operate critical resistors with a limited temperature rise.

**Noise.** Noise is an unwanted voltage fluctuation generated within the resistor. The total noise of a resistor always includes Johnson noise, which depends only on resistance value and the temperature of the resistance element. Depending on the type of element and its construction, total noise may also include noise caused by current flow and by cracked bodies and loose end caps or leads. For adjustable resistors, noise is also caused by the jumping of the contact over turns of wire and by an imperfect electrical path between the contact and resistance element.

**Hot-Spot Temperature.** The hot-spot temperature is the maximum temperature measured on the resistor due to both internal heating and the ambient operating temperature. The maximum allowable hot-spot temperature is predicated on the thermal limits of the materials and the resistor design. The maximum hot-spot temperature may not be exceeded under normal operating conditions, so the wattage rating of the resistor must be lowered if it is operated at an ambient temperature higher than that at which the wattage rating was established. At zero dissipation, the maximum ambient temperature around the resistor may be its maximum hot-spot temperature. The ambient temperature for a resistor is affected by surrounding heat-producing devices. Resistors stacked together do not experience the actual ambient temperature surrounding the outside of the stack except under forced cooling conditions.

Carbon resistors should, at most, be warm to touch, 40°C (140°F), while wirewound or ceramic resistors are designed to operate at temperatures up to 140°C (284°F). Wherever power is dissipated, it is imperative that adequate ventilation is provided to eliminate
thermal destruction of the resistor and surrounding components.

**Power Coefficient.** The *power coefficient* is the product of the temperature coefficient of resistance and the temperature rise per watt. It is given in percent per watt (%/W), and is the change in value resulting from applied power.

**Ac Resistance.** The *ac resistance* value changes with frequency because of the inherent inductance and capacitance of the resistor plus the skin effect, eddy current losses, and dielectric loss.

**Ambient Temperature Effect.** When operating a resistor in free air at high ambient temperature, the power capabilities must be derated, Fig. 10-2. Free air is operation of a resistor suspended by its terminals in free space and still air with a minimum clearance of one foot in all directions to the nearest object.

**Grouping.** Mounting a number of resistors in close proximity can cause excessive temperature rise requiring derating the power capabilities, Fig 10-3. The curves are for operation at maximum permissible hot spot temperature with spacing between the closest points of the resistors. Derating could be less if operated at less than permissible hot spot temperature.

**Enclosure.** Enclosures create a rise in temperature due to the surface area, size, shape, orientation, thickness, material and ventilation. Fig. 10-4 indicates the effects on a resistor enclosed in an unpainted steel sheet metal box, 0.32 inches thick without vents. Determining the derating is often by trial and error.
Forced Air Cooling. Resistors and components can be operated at higher than rated wattage with forced air cooling, Fig. 10-5. The volume of cooling air required to keep the resistor temperature within limits can be found with the equation

\[
Volume\ of\ air = \frac{3170}{\Delta T} KW
\]  

(10-5)

where,

- Volume of air is in cubic feet per minute,
- \(\Delta T\) is the permissible temperature rise in degrees F,
- \(KW\) is the power dissipated inside the enclosure in kilowatts.

Air density at high altitudes causes less heat to be dissipated by convection so more forced air would be required.

Pulse Operation. A resistor can usually be operated with a higher power in the pulse mode than in a continuous duty cycle. The actual increase allowed depends on the type of resistor. Fig. 10-6 is the percent of continuous duty rating for pulse operation for a wirewound resistor. Fig. 10-7 is the percent of continuous duty rating for pulse operation of small and medium size vitreous enameled resistors. Fig. 10-8 shows the percent of continuous duty rating for pulse operation of a 160 W vitreous enameled resistor.

10.1.2 Combining Resistors

Resistors can be combined in series or parallel or series/parallel.

Resistors in series. The total resistance of resistors connected in series is the summation of the resistors.

\[
R_T = R_1 + R_2 + \ldots + R_n
\]  

(10-6)

The total resistance is always greater than the largest resistor.
Resistors in Parallel. The total resistance of resistors in parallel is

\[ R_T = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \cdots + \frac{1}{R_n}} \]  

(10-7)

If two resistors are in parallel use:

\[ R_T = \frac{R_1 \times R_2}{R_1 + R_2} \]  

(10-8)

When all of the resistors are equal, divide the value of one resistor by the number of resistors to determine the total resistance. The total resistance is always less than the smallest resistor.

To determine the value of one of the resistors when two are in parallel and the total resistance and one resistor in known, use

\[ R_2 = \frac{R_T \times R_1}{R_1 - R_T} \]  

(10-9)

10.1.3 Types of Resistors

Every material that conducts electrical current has resistivity, which is defined as the resistance of a material to electric current. Resistivity is normally defined as the resistance, in ohms, of a 1 cm per side cube of the material measured from one surface of the cube to the opposite surface. The measurement is stated in ohms per centimeter cubed (\(\Omega/cm^3\)). The inverse of resistivity is conductivity. Good conductors have low resistivity, and good insulators have high resistivity. Resistivity is important because it shows the difference between materials and their opposition to current, making it possible for resistor manufacturers to offer products with the same resistance but differing electrical, physical, mechanical, or thermal features.

Following is the resistivity of various materials:

<table>
<thead>

Carbon-Composition Resistors. Carbon-composition resistors are the least expensive resistors and are widely used in circuits that are not critical to input noise and do not require tolerances better than ±5%.

The carbon-composition, hot-molded version is basically the same product it was more than 50 years ago. Both the hot- and cold-molded versions are made from a mixture of carbon and a clay binder. In some versions, the composition is applied to a ceramic core or armature, while in the inexpensive version, the composition is a monolithic rigid structure. Carbon-composition resistors may be from 1 \(\Omega\) to many megohms and 0.1–4 W. The most common power rating is \(\frac{1}{4}\) W and \(\frac{1}{2}\) W with resistance values from 2 \(\Omega\)–22 M\(\Omega\).

Carbon-composition resistors can withstand higher surge currents than carbon-film resistors. Resistance values, however, are subject to change upon absorption of moisture and increase rapidly at temperatures much above 60°C (140°F). Noise also becomes a factor when carbon-composition resistors are used in audio and communication applications. A carbon-core resistor, for example, generates electrical noise that can reduce the readability of a signal or even mask it completely.

Carbon-Film Resistors. Carbon-film resistors are leaded ceramic cores with thin films of carbon applied. Carbon film resistors offer closer tolerances and better temperature coefficients than carbon composition resistors. Most characteristics are virtually identical for many general purpose, noncritical applications where high reliability, surge currents, or noise are not crucial factors.

Metal Film Resistors. Metal film resistors are discrete devices formed by depositing metal or metal oxide films on an insulated core. The metals are usually either nichrome sputtered on ceramic or tin oxide on ceramic or glass. Another method of production is to screen or paint powdered metal and powdered glass that is mixed in an ink or pastelike substance on a porous ceramic substrate. Firing or heating in an oven bonds the materials together. This type of resistor technology is called cermet technology.

Metal film resistors are most common in the 10 \(\Omega\) to 1 M\(\Omega\) range and \(\frac{1}{8}\) W to 1 W with tolerances of ±1%.

The TCR is in the ±100 ppm/°C range for all three technologies. Yet there are subtle differences:

- Cermet covers a wider resistance range and handles higher power than nichrome deposition.
- Nichrome is generally preferred over tin oxide in the upper and lower resistance ranges and can provide TCRs that are lower than 50 ppm/°C.
- Tin oxide is better able to stand higher power dissipation than nichrome.
Wirewound Resistors. *Wirewound resistors* have resistive wire wound on a central ceramic core. One of the oldest technologies, wirewounds provide the best known characteristics of high temperature stability and power handling ability. Nichrome, Manganin, and Evanohm are the three most widely used wires for wirewound resistors.

Wirewound resistors are usually in the 0.1 Ω–250 kΩ range. Tolerance is ±2% and TCR is ±10 ppm/°C.

Wirewound resistors are generally classed as power or instrument-grade products. Power wirewounds, capable of handling as much as 1500 W, are wound from uninsulated coarse wire to provide better heat dissipation. Common power ratings are 1.5 W, 3 W, 5 W, 8 W, 10 W, 20 W, 25 W, 50 W, 100 W, and 200 W.

Instrument-grade precision wirewound resistors are made from long lengths of finely insulated wire. After winding, they are usually coated with a ceramic material.

All wirewound resistors are classed as air-core inductors and the inductive reactance alters the high frequency resistive value. This problem is directly proportional with frequency. Special windings are useful to cancel reactance at audio frequencies. Because of the severity of the problem, these resistors cannot be used at high frequencies.

Noninductive Resistors. Non-inductive resistors are used for high frequency applications. This is accomplished by utilizing the Ayton-Perry type of wiring, i.e. two windings connected in parallel and wound in opposite directions. This keeps the inductance and distributed capacitance at a minimum. Table 10-1 is a comparison of MEMCOR-TRUOHM type FR10, FR50, VL3 and VL5 resistors.

Resistor Networks. With the advent of printed circuit boards and integrated circuits, *resistor networks* became popular. The resistive network may be mounted in a single-in-line package (SIP) socket or a dual-in-line package (DIP) socket—the same as the ones used for integrated circuits. The most common resistor network has 14 or 16 pins and includes 7 or 8 individual resistors or 12 to 15 resistors with a common terminal. In most resistor networks the value of the resistors are the same. Networks may also have special value resistors and interconnections for a specific use, as shown in Fig. 10-9.

The individual resistors in a thick-film network can have a resistance value ranging from 10 Ω to 2.2 MΩ and are normally rated at 0.125 W per resistor. They have normal tolerances of ±2% or better and a temperature coefficient of resistance ±100 ppm/°C from –55°C to +125°C (–67°F to +257°F).

*Thin-film resistors* are almost always specialized units and are packaged as DIPs or flatpacks. (Flatpacks are soldered into the circuit.) Thin-film networks use nickel chromium, tantalum nitride, and chromium cobalt vacuum depositions.

Variable Resistors. *Variable resistors* are ones whose value changes with light, temperature, or voltage or through mechanical means.

Photocells (Light-Sensitive Resistors). *Photocells* are used as off–on devices when a light beam is broken or as audio pickups for optical film tracks. In the latter, the sound track is either a variable density or variable area. Whichever, the film is between a focused light source and the photocell. As the light intensity on the photocell varies, the resistance varies.
Photocells are rated by specifying their resistance at low and high light levels. These typically vary from 600 Ω–110 kΩ (bright), and from 100 kΩ–200 MΩ (dark). Photocell power dissipation is between 0.005 W and 0.75 W.

**Thermistors.** Thermistors, thermal-sensitive resistors, may increase or decrease their resistance as temperature rises. If the coefficient of resistance is negative, the resistance decreases as the temperature increases; if positive, the resistance increases with an increase in temperature. Thermistors are specified by how their resistance changes for a 1°C change in temperature. They are also rated by their resistance at 25°C and by the ratio of resistance at 0°C and 50°C. Values vary from 2.5 Ω–1 MΩ at room temperature with power ratings from 0.1–1 W.

Thermistors are normally used as temperature-sensing devices or transducers. When used with a transistor, they can be used to control transistor current with a change in temperature. As the transistor heats up, the emitter-to-collector current increases. If the power supply voltage remains the same, the power dissipation in the transistor increases until it destroys itself through thermal runaway. The change in resistance due to temperature change of the thermistor placed in the base circuit of a transistor can be used to reduce base voltage and, therefore, reduce the transistor emitter to collector current. By properly matching the temperature coefficients of the two devices, the output current of the transistor can be held fairly constant with temperature change.

**Varistors.** Varistors (voltage-sensitive resistors) are voltage-dependent, nonlinear resistors which have symmetrical, sharp breakdown characteristics similar to back-to-back Zener diodes. They are designed for transient suppression in electrical circuits. The transients can result from the sudden release of previously stored energy—i.e., electromagnetic pulse (EMP)—or from extraneous sources beyond the control of the circuit designer, such as lightning surges. Certain semiconductors are most susceptible to transients. For example, LSI and VLSI circuits, which may have as many as 20,000 components in a 0.25 inch × 0.25 inch area, have damage thresholds below 100 μJ.

The varistor is mostly used to protect equipment from power-line surges by limiting the peak voltage across its terminals to a certain value. Above this voltage, the resistance drops, which in turn tends to reduce the terminal voltage. Voltage-variable resistors or varistors are specified by power dissipation (0.25–1.5 W) and peak voltage (30–300 V).

**Thermocouples.** While not truly a resistor, thermocouples are used for temperature measurement. They operate via the Seebeck Effect which states that two dissimilar metals joined together at one end produce a voltage at the open ends that varies as the temperature at the junction varies. The voltage output increases as the temperature increases. Thermocouples are rugged, accurate, and have a wide temperature range. They don’t require an excitation source and are highly responsive. Thermocouples are tip sensitive so they measure the temperature at a very small spot. Their output is very small (tens to hundreds of microvolts, and is nonlinear, requiring external linearization in the form of cold-junction compensation.

Never use copper wire to connect a thermocouple to the measuring device as that constitutes another thermocouple.

**Resistance Temperature Detectors.** RTDs are very accurate and stable. Most are made of platinum wire wound around a small ceramic tube. They can be thermally shocked by going from 100°C to −195°C 50 times with a resulting error less than 0.02°C.

RTDs feature a low resistance-value change to temperature (0.1 Ω/1°C). RTDs can self heat, causing
inaccurate readings, therefore the current through the unit should be kept to 1 mA or less. Self heating can also be controlled by using a 10% duty cycle rather than constant bias or by using an extremely low bias which can reduce the SNR. The connection leads may cause errors if they are long due to the wire resistance.

Potentiometers and Rheostats. The resistance of potentiometers (pots), and rheostats is varied by mechanically varying the size of the resistor. They are normally three terminal devices, two ends and one wiper, Fig. 10-10. By varying the position of the wiper, the resistance between either end and the wiper changes. Potentiometers may be wirewound or nonwirewound. The nonwirewound resistors usually have either a carbon or a conductive plastic coating. Potentiometers or pots may be 300° single turn or multiple turn, the most common being 1080° three turn and 3600° ten turn.

Potentiometers also come in combinations of two or more units controlled by a single control shaft or controlled individually by concentric shafts. Switches with various contact configurations can also be assembled to single or ganged potentiometers and arranged for actuation during the first few degrees of shaft rotation.

A wirewound potentiometer is made by winding resistance wire around a thin insulated card, Fig. 10-12A. After winding, the card is formed into a circle and fitted around a form. The card may be tapered, Fig. 10-12B, to permit various rates of change of resistance as shown in Fig 10-11. The wiper presses along the wire on the edge of the card.

Wirewound pots offer TCRs of ±50 ppm/°C and tolerances of ±5%. Resistive values are typically 10 Ω–100 kΩ, with power ratings from 1 W to 200 W.

Carbon pots have TCRs of ±400 ppm/°C to ±800 ppm/°C and tolerances of ±20%. The resistive range spans 50 Ω–2 MΩ, and power ratings are generally less than 0.5 W.

Potentiometers may be either linear or nonlinear, as shown in Fig. 10-11. The most common nonlinear pots are counterclockwise semilog and clockwise semilog. The counterclockwise semilog pot is also called an audio taper pot because when used as a volume control, it follows the human hearing equal loudness curve. If a linear pot is used as a simple volume control, only about the first 20% of the pot rotation would control the usable volume of the sound system. By using an audio taper pot as in Fig. 10-11 curve C2, the entire pot is used. Note there is only a 10%–20% change in resistance value between the common and wiper when the pot is 50% rotated.

Potentiometers are also produced with various taps that are often used in conjunction with loudness controls.

Contact Resistance. Noisy potentiometers have been a problem that has plagued audio circuits for years. Although pots have become better in tolerance and construction, noise is still the culprit that forces pots to be replaced. Noise is usually caused by dirt or, in the case of wirewound potentiometers, oxidation. Many circuits have gone up in smoke because bias-adjusting resistors, which are wirewound for good TCR, oxidize and the contact resistance increases to a point where it is more than the value of the pot. This problem is most
noticeable when trying to adjust a bias voltage with an old oxidized pot.

Sometimes the pot can be cleaned by spraying it with a contact cleaner or silicone and then vigorously rotating it. Usually, however, it is best to replace it because anything else is only temporary.

Any dc voltage present on the pot is also a source of noise. Such voltage is often produced by leaky coupling capacitors at the input connector or output circuit of the wiper, allowing dc voltage to appear at the wiper contact. If there is a resistance between the resistor and the wiper, the dc current flowing through the wiper contact to the output stage will create a voltage drop. Because the wiper is moving, the contact resistance constantly changes creating what looks like a varying ac voltage. Using Fig. 10-13, the value at $V_{Load}$, whether ac or dc, can be calculated with Eqs. 10-10 and 10-11. If the wiper resistance is 0—i.e., a perfect pot—the output voltage $V_{Load}$ is

$$V_{Load} = V_1 \frac{R_y}{R_1 + R_y} \quad (10-10)$$

where,

$$R_y = \frac{R_2 R_{Load}}{R_2 + R_{Load}}$$

If a pot wiper has a high resistance, $R_w$, the output voltage $V_{Load}$ is

$$V_{Load} = V_w \frac{R_{Load}}{R_w + R_{Load}} \quad (10-11)$$

where,

$$V_w = V_1 \frac{R_2 (R_w + R_{Load})}{R_2 + R_w + R_{Load}}.$$
$V_a$ is the applied voltage in volts,
$C_X$ is the capacitance of the individual capacitor under consideration in farads,
$C_T$ is the sum of all of the capacitors in series.

When used in an ac circuit, the capacitive reactance, or the impedance the capacitor injects into the circuit, is important to know and is found with the equation:

$$X_C = \frac{1}{2\pi fC}$$  \hspace{1cm} (10-15)

where,
$X_C$ is the capacitive reactance in ohms,
$f$ is the frequency in hertz,
$C$ is the capacitance in farads.

To determine the impedance of circuits with resistance, capacitance, and inductance, see Section 10.4.

Capacitance is the concept of energy storage in an electric field. If a potential difference is found between two points, an electric field exists. The electric field is the result of the separation of unlike charges, therefore, the strength of the field will depend on the amounts of the charges and their separator. The amount of work necessary to move an additional charge from one point to the other will depend on the force required and therefore upon the amount of charge previously moved. In a capacitor, the charge is restricted to the area, shape, and spacing of the capacitor electrodes, sometimes known as plates, as well as the property of the material separating the plates.

When electrical current flows into a capacitor, a force is established between two parallel plates separated by a dielectric. This energy is stored and remains even after the input current flow ceases. Connecting a conductor across the capacitor provides a plate-to-plate path by which the charged capacitor can regain electron balance, that is, discharge its stored energy. This conductor can be a resistor, hard wire, or even air. The value of a parallel plate capacitor can be found with the equation

$$C = \frac{x\varepsilon[(N-1)A]}{d} \times 10^{-13}$$ \hspace{1cm} (10-16)

where,
$C$ is the capacitance in farads,
$x$ is 0.0885 when $A$ and $d$ are in cm, and 0.225 when $A$ and $d$ are in inches,
$\varepsilon$ is the dielectric constant of the insulation,
$N$ is the number of plates,
$A$ is the area of the plates,
$d$ is the spacing between the plates.

The work necessary to transport a unit charge from one plate to the other is

$$e = kg$$ \hspace{1cm} (10-17)

where,
$e$ is the volts expressing energy per unit charge,
$k$ is the proportionality factor between the work necessary to carry a unit charge between the two plates and the charge already transported and is equal to $1/C$
$g$ is the coulombs of charge already transported.

The value of a capacitor can now be calculated from the equation

$$C = \frac{q}{e}$$ \hspace{1cm} (10-18)

where,
$q$ is the charge in coulombs,
$e$ is found with Eq. 10-17.

The energy stored in a capacitor is found with the equation

$$W = \frac{CV^2}{2}$$ \hspace{1cm} (10-19)

where,
$W$ is the energy in joules,
$C$ is the capacitance in farads,
$V$ is the applied voltage in volts.

**Dielectric Constant (K).** The dielectric constant is the property of a given material that determines the amount of electrostatic energy that may be stored in that material per unit volume for a given voltage. The value of K expresses the ratio of a capacitor in a vacuum to one using a given dielectric. The K of air is 1 and is the reference unit employed for expressing K of other materials. If K of the capacitor is increased or decreased, the capacitance will increase or decrease respectively if other quantities and physical dimensions are kept constant. Table 10-2 is a listing of K for various materials.

<table>
<thead>

</tbody>
</table>
The dielectric constant of materials is generally affected by both temperature and frequency, except for quartz, Styrofoam, and Teflon, whose dielectric constants remain essentially constant. Small differences in the composition of a given material will also affect the dielectric constant.

**Force.** The equation for calculating the force of attraction between the two plates is

\[
F = \frac{AV^2}{K(1504S)^2}
\]

(10-20)

where,
- \(F\) is the attractive force in dynes,
- \(A\) is the area of one plate in square centimeters,
- \(V\) is the potential energy difference in volts,
- \(K\) is the dielectric constant,
- \(S\) is the separation between the plates in centimeters.

### 10.2.1 Time Constants

When a dc voltage is impressed across a capacitor, a time \(t\) is required to charge the capacitor to a voltage. This is determined with the equation:

\[
t = RC
\]

(10-21)

where,
- \(t\) is the time in seconds,
- \(R\) is the resistance in ohms,
- \(C\) is the capacitance in farads.

In a circuit consisting of only resistance and capacitance, the time constant \(t\) is defined as the time it takes to charge the capacitor to 63.2% of the maximum voltage. During the next time constant, the capacitor is charged or the current builds up to 63.2% of the remaining difference of full value, or to 86.5% of the full value. Theoretically, the charge on a capacitor or the current through a coil can never actually reach 100% but is considered to be 100% after five time constants have passed. When the voltage is removed, the capacitor discharges and the current decays 63.2% per time constant to zero.

These two factors are shown graphically in Fig. 10-14. Curve A shows the voltage across a capacitor when charging. Curve B shows the capacitor voltage when discharging. It is also the voltage across the resistor on charge or discharge.

### 10.2.2 Network Transfer Function

Network transfer functions are the ratio of the output to input voltage (generally a complex number) for a given type of network containing resistive and reactive elements. The transfer functions for networks consisting of resistance and capacitance are given in Fig. 10-15.

The expressions for the transfer functions of the networks are:

- \(A\) is \(jZ\) or \(j2\pi f S\),
- \(B\) is \(RC\),
- \(C\) is \(R_1 C_1\),
- \(D\) is \(R_2 C_2\),
- \(n\) is a positive multiplier,
- \(f\) is the frequency in hertz,
- \(C\) is in farads,
- \(R\) is in ohms.

### 10.2.3 Characteristics of Capacitors

The operating characteristics of a capacitor determine what it was designed for and therefore where it is best used.

**Capacitance (C).** The capacitance of a capacitor is normally expressed in microfarads (\(\mu F\) or \(10^{-6}\) farads)

Figure 10-15. Resistance-capacitance network transfer functions.
or picofarads (pF or $10^{-12}$ farads) with a stated accuracy or tolerance. Tolerance is expressed as plus or minus a certain percentage of the nominal or nameplate value. Another tolerance rating is GMV (guaranteed minimum value), sometimes referred to as MRV (minimum rated value). The capacitance will never be less than the marked value when used under specified operating conditions but the capacitance could be more than the named value.

**Equivalent Series Resistance (ESR).** All capacitors have an equivalent series resistance expressed in ohms or milliohms. This loss comes from lead resistance, termination losses, and dissipation in the dielectric material.

**Equivalent Series Inductance (ESL).** The equivalent series inductance can be useful or detrimental. It does reduce the high-frequency performance of the capacitor. However, it can be used in conjunction with the capacitors capacitance to form a resonant circuit.

**Dielectric Absorption (DA).** Dielectric absorption is a reluctance on the part of the dielectric to give up stored electrons when the capacitor is discharged. If a capacitor is discharged through a resistance, and the resistance is removed, the electrons that remained in the dielectric will reconvene on the electrode, causing a voltage to appear across the capacitor. This is also called *memory*.

When an ac signal, such as sound, with its high rate of attack is impressed across the capacitor, time is required for the capacitor to follow the signal because the free electrons in the dielectric move slowly. The result is compressed signal. The procedure for testing DA calls for a 5 min capacitor charging time, a 5 s discharge, then a 1 min open circuit, after which the recovery voltage is read. The percentage of DA is defined as the ratio of recovery to charging voltage times 100.

**Insulation Resistance.** Insulation resistance is basically the resistance of the dielectric material, and determines the period of time a capacitor, once charged with a dc voltage, will hold its charge by a specified percentage. The insulation resistance is generally very high. In electrolytic capacitors, the leakage current should not exceed

$$I_L = 0.04C + 0.30$$  \hspace{1cm} (10-22)

where,

- $I_L$ is the leakage current in microamperes,
- $C$ is the capacitance in microfarads.

**Maximum Working Voltage.** All capacitors have a maximum working voltage that should not be exceeded. The capacitors working voltage is a combination of the dc value plus the peak ac value that may be applied during operation. For instance, if a capacitor has 10 V$_{dc}$ applied to it, and an ac voltage of 10 V$_{rms}$ or 17 V$_{peak}$ is applied, the capacitor will have to be capable of withstanding 27 V.

**Quality Factor ($Q$).** The quality factor of a capacitor is the ratio of the capacitors reactance to its resistance at a specified frequency. $Q$ is found by the equation

$$Q = \frac{1}{2\pi fCR}$$  \hspace{1cm} (10-23)

where,

- $f$ is the frequency in hertz,
- $C$ is the value of capacitance in farads,
- $R$ is the internal resistance in ohms.

**Dissipation Factor (DF).** The dissipation factor is the ratio of the effective series resistance of a capacitor to its reactance at a specified frequency and is given in percent. It is also the reciprocal of $Q$. It is, therefore, a similar indication of power loss within the capacitor and, in general, should be as low as possible.

**Power Factor (PF).** The power factor represents the fraction of input volt-amperes or power dissipated in the capacitor dielectric and is virtually independent of the capacitance, applied voltage, and frequency. $PF$ is the preferred measurement in describing capacitive losses in ac circuits.

### 10.2.4 Types of Capacitors

The uses made of capacitors become more varied and more specialized each year. They are used to filter, tune, couple, block dc, pass ac, shift phase, bypass, feed through, compensate, store energy, isolate, suppress noise, and start motors, among other things. While doing this, they frequently have to withstand adverse conditions such as shock, vibration, salt spray, extreme temperatures, high altitude, high humidity, and radiation. They must also be small, lightweight, and reliable.

Capacitors are grouped according to their dielectric material and mechanical configuration. Because they may be hardwired or mounted on circuit boards, capacitors come with leads on one end, two ends, or they may be mounted in a dual-in-line (DIP) or single in-line (SIP) package. Figs. 10-16 and 10-17 show the various types of capacitors, their characteristics, and their color codes.
**Film Capacitors**

Film capacitors consist of alternate layers of metal foil, and one or more layers of a flexible plastic insulating...
material (dielectric) in ribbon form rolled and encapsulated.

10.2.4.2 Paper Foil-Filled Capacitors

*Paper foil-filled capacitors* consist of alternate layers of aluminum foil and paper rolled together. The paper may be saturated with oil and the assembly mounted in an oil-filled, hermetically sealed metal case. These capacitors are often used as motor capacitors and are rated at 60 Hz.

10.2.4.3 Mica Capacitors

Two types of *mica capacitors* are in use. In one type, alternate layers of metal foil and mica insulation, are stacked together and encapsulated. In the silvered-mica type, a silver electrode is screened on the mica insulators that are then assembled and encapsulated. Mica capacitors have small capacitance values and are usually used in high frequency circuits.

10.2.4.4 Ceramic Capacitors

*Ceramic capacitors* are the most popular capacitors for bypass and coupling applications because of their variety of sizes, shapes, and ratings.

Ceramic capacitors also come with a variety of $K$ values or dielectric constant. The higher the $K$ value, the smaller the size of the capacitor. However, high $K$-value capacitors are less stable. High-$K$ capacitors have a dielectric constant over 3000, are very small, and have values between 0.001 μF to several microfarads.

When temperature stability is important, capacitors with a $K$ in the 10–200 region are required. If a high $Q$ capacitor is also required, the capacitor will be physically larger. Ceramic capacitors can be made with a zero capacitance/temperature change. These are called *negative-positive-zero* (NPO). They come in a capacitance range of 1.0 pF–0.033 μF.

A temperature-compensated capacitor with a designation of N750 is used when temperature compensation is required. The 750 indicates that the capacitance will decrease at a rate of 75 ppm/°C with a temperature rise or the capacitance value will decrease 1.5% for a 20°C (68°F) temperature increase. N750 capacitors come in values between 4.0 pF and 680 pF.

10.2.4.5 Electrolytic Capacitors

The first electrolytic capacitor was made in Germany in about 1895 although its principle was discovered some 25 years earlier. It was not until the late 1920s when power supplies replaced batteries in radio receivers, that aluminum electrolytics were used in any quantities. The first electrolytics contained liquid electrolytes. These *wet* units disappeared during the late 1930s when the *dry gel* types took over.

Electrolytic capacitors are still not perfect. Low temperatures reduce performance and can even freeze electrolytes, while high temperatures can dry them out and the electrolytes themselves can leak and corrode the equipment. Also, repeated surges over the rated working voltage, excessive ripple currents, and high operating temperature reduce performance and shorten capacitor life. Even with their faults, electrolytic capacitors account for one-third of the total dollars spent on capacitors, probably because they provide high capacitance in small volume at a relatively low cost per microfarad-volt.

During the past few years, many new and important developments have occurred. Process controls have improved performance. Better seals have assured longer life, improved etching has given a tenfold increase in volume efficiencies, and leakage characteristics have improved one hundredfold.

Basic to the construction of electrolytic capacitors is the electrochemical formation of an oxide film on a metal surface. Intimate contact is made with this oxide film by means of another electrically conductive material. The metal on which the oxide film is formed serves as the anode or positive terminal of the capacitor; the oxide film is the dielectric, and the cathode or negative terminal is either a conducting liquid or a gel. The most commonly used basic materials are aluminum and tantalum.

**Aluminum Electrolytic Capacitors.** *Aluminum electrolytic capacitors* use aluminum as the base material. The surface is often etched to increase the surface area as much as 100 times that of unetched foil, resulting in higher capacitance in the same volume.

The type of etch pattern and the degree to which the surface area is increased involve many carefully controlled variables. If a fine etch pattern is desired to achieve high capacitance per unit area of foil for low voltage devices, the level of current density and time the foil is exposed to the etching solution will be far different from that required for a coarse etch pattern. The foil is then electrochemically treated to form a layer of aluminum oxide on its surface. Time and current density determine the amount of power consumed in the
process. The oxide film dielectric is thin, usually about 15 Å/V. When formed on a high purity aluminum foil, it has a dielectric constant between 7 and 10 and an equivalent dielectric strength of 25 million volts per inch (25 × 10^6 V/inch).

The thickness of the oxide coating dielectric is determined by the voltage used to form it. The working voltage of the capacitor is somewhat less than this formation voltage. Thin films result in low voltage, high capacitance units; thicker films produce higher voltage, lower capacitance units for a given case size.

As a capacitor section is wound, a system of paper spacers is put in place to separate the foils. This prevents the possibility of direct shorts between anode and cathode foils that might result because of rough surfaces or jagged edges on either foil. The spacer material also absorbs the electrolyte with which the capacitor is impregnated, and thus assures uniform and intimate contact with all of the surface eccentricities of the etched anode foil throughout the life of the capacitor. The cathode foil serves only as an electrical connection to the electrolyte which is in fact the true cathode of the electrolytic capacitor.

The electrolyte commonly used in aluminum electrolytic capacitors is an ionogen that is dissolved in and reacts with glycol to form a pastelike mass of medium resistivity. This is normally supported in a carrier of high purity craft or hemp paper. In addition to the glycol electrolyte, low resistivity nonaqueous electrolytes are used to obtain a lower ESR and wider operating temperatures.

The foil-spacer-foil combination is wound into a cylinder, inserted into a suitable container, impregnated, and sealed.

- **Electrical Characteristics.** The equivalent circuit of an electrolytic capacitor is shown in Fig. 10-18. A and B are the capacitor terminals. The shunt resistance, $R_s$, in parallel with the effective capacitance, $C$, accounts for the dc leakage current through the capacitor. Heat is generated in the ESR if there is ripple current and heat is generated in the shunt resistance by the voltage. In an aluminum electrolytic capacitor, the ESR is due mainly to the spacer-electrolyte-oxide system. Generally it varies only slightly except at low temperatures where it increases greatly. $L$ is the self-inductance of the capacitor caused by terminals, electrodes, and geometry.

- **Impedance.** The impedance of a capacitor is frequency dependent, as shown in Fig. 10-19. Here, ESR is the equivalent series resistance, $X_C$ is the capacitive reactance, $X_L$ is the inductive reactance, and $Z$ is the impedance. The initial downward slope is a result of the capacitive reactance. The trough (lowest impedance) portion of the curve is almost totally resistive, and the rising upper or higher frequency portion of the curve is due to the capacitor’s self-inductance. If the ESR were plotted separately, it would show a small ESR decrease with frequency to about 5–10 kHz, and then remain relatively constant throughout the remainder of the frequency range.

- **Leakage Current.** Leakage current in an electrolytic capacitor is the direct current that passes through a capacitor when a correctly polarized dc voltage is applied to its terminals. This current is proportional to temperature and becomes increasingly important when capacitors are used at elevated ambient temperatures. Imperfections in the oxide dielectric film cause high leakage currents. Leakage current decreases slowly after a voltage is applied and usually reaches steady-state conditions after 10 minutes.

  If a capacitor is connected with its polarity backward, the oxide film is forward biased and offers very little resistance to current flow, resulting in high current, which, if left unchecked, will cause overheating and self destruction of the capacitor.

  The total heat generated within a capacitor is the sum of the heat created by the $I^2R$ losses in the ESR and that created by the $I_{Leakage} \times V_{applied}$.

- **Ac Ripple Current.** The ac ripple current rating is one of the most important factors in filter applications, because excessive current produces a greater than permissible temperature rise, shortening capacitor life. The maximum permissible rms ripple
current for any capacitor is limited by the temperature within the capacitor and the rate of heat dissipation from the capacitor. Lower ESR and longer cans or enclosures increase the ripple current rating.

**Reverse Voltage.** Aluminum electrolytic capacitors can withstand a reverse voltage of up to 1.5 V without noticeable effect from its operating characteristics. Higher reverse voltages, when applied over extended periods, will lead to some loss of capacitance. Excess reverse voltages applied for short periods will cause some change in capacitance but may not lead to capacitor failure during the reverse voltage application or during subsequent operation in the normal polarity direction.

A major use of large value capacitors is for filtering in dc power supplies. After a capacitor is fully charged, when the rectifier conduction decreases, the capacitor discharges into the load until the next half cycle, Fig. 10-20. Then on the next cycle the capacitor recharges again to the peak voltage. The $\Delta e$ shown in the illustration is equal to the total peak-to-peak ripple voltage. This is a complex wave which contains many harmonics of the fundamental ripple frequency and is the ripple that causes the noticeable heating of the capacitor.

![Figure 10-20. Capacitor charge and discharge on a full-wave rectifier output.](image)

This can be mathematically determined or the ripple current through the capacitor can be measured by inserting a low impedance true rms ammeter in series with the capacitor. It is very important that the impedance of the meter be small compared with that of the capacitor, otherwise, a large measurement error will result.

**Standard Life Tests.** Standard life tests at rated voltage and maximum rated temperatures are usually the criteria for determining the quality of an electrolytic capacitor. These two conditions rarely occur simultaneously in practice. Capacitor life expectancy is doubled for each 10°C (18°F) decrease in operating temperature, so a capacitor operating at room temperature will have a life expectancy 64 times that of the same capacitor operating at 85°C (185°F).

**Surge Voltage.** The surge voltage specification of a capacitor determines its ability to withstand the high transient voltages that occur during the start up period of equipment. Standard tests specify a short on and long off period for an interval of 24 hours or more; the allowable surge voltage levels are usually 10% above the rated voltage of the capacitor. Fig. 10-21 shows how temperature, frequency, time, and applied voltage affect electrolytic capacitors.

![Figure 10-21. Variations in aluminum electrolytic characteristics caused by temperature, frequency, time, and applied voltage. Courtesy of Sprague Electric Company.](image)

**Tantalum Capacitors.** Tantalum electrolytics have become the preferred type where high reliability and long service life are paramount considerations.

Most metals form crystalline oxides that are nonprotecting, such as rust on iron or black oxide on
copper. A few metals form dense, stable, tightly adhering, electrically insulating oxides. These are the so-called valve metals and include titanium, zirconium, niobium, tantalum, hafnium, and aluminum. Only a few of these permit the accurate control of oxide thickness by electrochemical means. Of these, the most valuable for the electronics industry are aluminum and tantalum.

The dielectric used in all tantalum electrolytic capacitors is tantalum pentoxide. Although wet foil capacitors use a porous paper separator between their foil plates, its function is merely to hold the electrolyte solution and to keep the foils from touching.

The tantalum pentoxide compound possesses high dielectric strength and a high dielectric constant. As capacitors are being manufactured, a film of tantalum pentoxide is applied to their electrodes by an electrolytic process. The film is applied in various thicknesses and at various voltages. Although transparent at first, it takes on different colors as light refracts through it. This coloring occurs on the tantalum electrodes of all three types of tantalum capacitors.

Rating for rating, tantalum capacitors tend to have as much as three times better capacitance/volume efficiency than aluminum electrolytic capacitors, because tantalum pentoxide has a dielectric constant of 26, some three times greater than that of aluminum oxide. This, in addition to the fact that extremely thin films can be deposited during manufacturing, makes the tantalum capacitor extremely efficient with respect to the number of microfarads available per unit volume.

The capacitance of any capacitor is determined by the surface area of the two conducting plates, the distance between the plates, and the dielectric constant of the insulating material between the plates.

The distance between the plates in tantalum electrolytic capacitors is very small since it is only the thickness of the tantalum pentoxide film. The dielectric constant of the tantalum pentoxide is high, therefore, the capacitance of a tantalum capacitor is high.

Tantalum capacitors contain either liquid or solid electrolytes. The liquid electrolyte in wet-slug and foil capacitors, usually sulfuric acid, forms the cathode or negative plate. In solid-electrolyte capacitors a dry material, manganese dioxide, forms the cathode plate.

The anode lead wire from the tantalum pellet consists of two pieces. A tantalum lead is embedded in, or welded to, the pellet, which is welded, in turn, to a nickel lead. In hermetically sealed types, the nickel lead is terminated to a tubular eyelet. An external lead of nickel or solder-coated nickel is soldered or welded to the eyelet. In encapsulated or plastic-encased designs, the nickel lead, which is welded to the basic tantalum lead, extends through the external epoxy resin coating or the epoxy end fill in the plastic outer shell.

**Foil Tantalum Capacitors.** Foil tantalum capacitors are made by rolling two strips of thin foil, separated by a paper saturated with electrolyte, into a convolute roll. The tantalum foil, which is to be the anode, is chemically etched to increase its effective surface area, providing more capacitance in a given volume. This is followed by anodizing in a chemical solution under direct voltage. This produces the dielectric tantalum pentoxide film on the foil surface.

Foil tantalum capacitors can be manufactured in dc working voltage values up to 300 V. However, of the three types of tantalum electrolytic capacitors, the foil design has the lowest capacitance per unit volume. It is also the least often encountered since it is best suited for the higher voltages primarily found in older designs of equipment and requires more manufacturing operations than do the two other types. Consequently, it is more expensive and is used only where neither a solid electrolyte nor a wet-slug tantalum capacitor can be employed.

Foil tantalum capacitors are generally designed for operation over the temperature range of \(-55^\circ\text{C}\) to \(+125^\circ\text{C}\) (\(-67^\circ\text{F}\) to \(+257^\circ\text{F}\)) and are found primarily in industrial and military electronics equipment.

**Wet-Electrolyte Sintered Anode Tantalum Capacitors.** Wet-electrolyte sintered anode tantalum capacitors, often called wet-slug tantalum capacitors, use a pellet of sintered tantalum powder to which a lead has been attached. This anode has an enormous surface area for its size because of its construction. Tantalum powder of suitable fineness, sometimes mixed with binding agents, is machine-pressed into pellets. The second step is a sintering operation in which binders, impurities, and contaminants are vaporized and the tantalum particles are sintered into a porous mass with a very large internal surface area. A tantalum lead wire is attached by welding the wire to the pellet. (In some cases, the lead is embedded during pressing of the pellet before sintering.)

A film of tantalum pentoxide is electrochemically formed on the surface areas of the fused tantalum particles. The oxide is then grown to a thickness determined by the applied voltage.

Finally the pellet is inserted into a tantalum or silver container that contains an electrolyte solution. Most liquid electrolytes are gelled to prevent the free movement of the solution inside the container and to keep the...
electrolyte in intimate contact with the capacitor cathode. A suitable end seal arrangement prevents the loss of the electrolyte.

Wet-slug tantalum capacitors are manufactured in a working voltage range up to 150 Vdc.

**Solid-Electrolyte Sintered Anode Tantalum Capacitors.** Solid-electrolyte sintered anode tantalum capacitors differ from the wet versions in their electrolyte. Here, the electrolyte is manganese dioxide, which is formed on the tantalum pentoxide dielectric layer by impregnating the pellet with a solution of manganous nitrate. The pellets are then heated in an oven and the manganous nitrate is converted to manganese dioxide.

The pellet is next coated with graphite followed by a layer of metallic silver, which provides a solderable surface between the pellet and its can.

The pellets, with lead wire and header attached, are inserted into the can where the pellet is held in place by solder. The can cover is also soldered into place.

Another variation of the solid-electrolyte tantalum capacitor encases the element in plastic resins, such as epoxy materials. It offers excellent reliability and high stability for consumer and commercial electronics with the added feature of low cost.

Still other designs of solid tantalum capacitors, as they are commonly known, use plastic film or sleeving as the encasing material and others use metal shells which are back filled with an epoxy resin. And, of course, there are small tubular and rectangular molded plastic encasements as well.

**Tantalum Capacitors.** In choosing between the three basic types of tantalum capacitors, the circuit designer customarily uses foil tantalum capacitors only where high voltage constructions are required or where there is substantial reverse voltage applied to a capacitor during circuit operation.

Wet-electrolyte sintered anode capacitors, or wet-slug tantalum capacitors, are used where the lowest dc leakage is required. The conventional silver can design will not tolerate any reverse voltages. However, in military or aerospace applications, tantalum cases are used instead of silver cases where utmost reliability is desired. The tantalum-cased wet-slug units will withstand reverse voltages up to 3 V, will operate under higher ripple currents, and can be used at temperatures up to 200°C (392°F).

Solid-electrolyte designs are the least expensive for a given rating and are used in many applications where their very small size for a given unit of capacitance is important. They will typically withstand up to 15% of the rated dc working voltage in a reverse direction.

They also have good low temperature performance characteristics and freedom from corrosive electrolytes.

### 10.2.4.6 Suppression Capacitors

Suppression capacitors are used to reduce interference that comes in or out through the power line. They are effective because they are frequency dependent in that they become a short circuit at radio frequencies, without affecting low frequencies. Suppression capacitors are identified as X capacitors and Y capacitors. Fig. 10-22 shows two examples of radio interference suppression. Fig. 10-22A is for protection class I which would include drills and hair dryers. Fig.10-22B is for protection class II where no protective conductor is connected to the metal case G.

![Figure 10-22. Radio frequency suppression with X and Y capacitors. Courtesy of Vishay Roederstein.](image-url)

**X Capacitors.** X capacitors are used across the mains to reduce symmetrical interference where a failure in the capacitor—i.e., the capacitor shorts out—will not cause injury, shock or death.

**Y Capacitors.** Y capacitors are used between a live conductor and a cabinet or case to reduce asymmetrical
interference. Y capacitors have high electrical and mechanical specifications so they are much less likely to fail.

**XY Capacitors.** When used together they are called XY capacitors.

### 10.2.4.7 Supercapacitors

Supercapacitors, Ultracapacitors, more technically known as electrochemical double-layer capacitors, are one more step beyond the electrolytic capacitors. The charge-separation distance in ultracapacitors has been reduced to literally the dimensions of the ions within the electrolyte. In supercapacitors, the charges are not separated by millimeters or micrometers (microns) but by a few nanometers or from electrostatic capacitors to electrolytic capacitors to ultracapacitors. The charge-separation distance has in each instance dropped by three orders of magnitude, from $10^{-3}$ m to $10^{-6}$ m to $10^{-9}$ m.

- **How a Supercapacitor Works.** An supercapacitor or ultracapacitor, also known as a double-layer capacitor, polarizes an electrolytic solution to store energy electrostatically. Though it is an electrochemical device, no chemical reactions are involved in its energy storage mechanism. This mechanism is highly reversible and allows the ultracapacitor to be charged and discharged hundreds of thousands of times.

An ultracapacitor can be viewed as two nonreactive porous plates, or collectors, suspended within an electrolyte, with a voltage potential applied across the collectors. In an individual ultracapacitor cell, the applied potential on the positive electrode attracts the negative ions in the electrolyte, while the potential on the negative electrode attracts the positive ions. A dielectric separator between the two electrodes prevents the charge from moving between the two electrodes.

Once the ultracapacitor is charged and energy stored, a load can use this energy. The amount of energy stored is very large compared to a standard capacitor because of the enormous surface area created by the porous carbon electrodes and the small charge separation of 10 angstroms created by the dielectric separator. However, it stores a much smaller amount of energy than does a battery. Since the rates of charge and discharge are determined solely by its physical properties, the ultracapacitor can release energy much faster (with more power) than a battery that relies on slow chemical reactions.

Many applications can benefit from ultracapacitors, whether they require short power pulses or low-power support of critical memory systems. Using an ultracapacitor in conjunction with a battery combines the power performance of the former with the greater energy storage capability of the latter. It can extend the life of a battery, save on replacement and maintenance costs, and enable a battery to be downsized. At the same time, it can increase available energy by providing high peak power whenever necessary. The combination of ultracapacitors and batteries requires additional dc/dc power electronics, which increases the cost of the circuit.

Supercapacitors merged with batteries (hybrid battery) will become the new superbattery. Just about everything that is now powered by batteries will be improved by this much better energy supply. They can be made in most any size, from postage stamp to hybrid car battery pack. Their light weight and low cost make them attractive for most portable electronics and phones, as well as for aircraft and automobiles.

- **Advantages of a Supercapacitor**
  1. Virtually unlimited life cycle—cycles millions of times—10 to 12 year life.
  2. Low internal impedance.
  3. Can be charged in seconds.
  4. Cannot be overcharged.
  5. Capable of very high rates of charge and discharge.
  6. High cycle efficiency (95% or more).

- **Disadvantages of a Supercapacitor:**
  1. Supercapacitors and ultra capacitors are relatively expensive in terms of cost per watt.
  2. Linear discharge voltage prevents use of the full energy spectrum.
  3. Low energy density—typically holds one-fifth to one-tenth the energy of an electrochemical battery.
  4. Cells have low voltages; therefore, serial connections are needed to obtain higher voltages, which require voltage balancing if more than three capacitors are connected in series.
  5. High self-discharge—the self-discharge rate is considerably higher than that of an electrochemical battery.
  6. Requires sophisticated electronic control and switching equipment.

A supercapacitor by itself cannot totally replace the battery. But, by merging a supercapacitor and a battery together—like a hybrid battery, it will be possible for
Resistors, Capacitors, and Inductors

supercapacitors to replace the battery as we know it today.

Presently supercapacitors need batteries to store the energy and are basically used as a buffer between the battery and the device. Supercapacitors can be charged and discharged hundreds of thousands of times where a battery cannot do that.

- **Calculating Backup Time.** To calculate the desired backup time the supercapacitor will provide if the power goes off, the starting and ending voltage on the capacitor, the current draw from the capacitor, and the capacitor size must be known.

  Assuming that the load draws a constant current while running from $V_{\text{BACKUP}}$ then the worst-case backup time in hours would use the equation:

  $\frac{C(V_{\text{BACKUPSTART}} - V_{\text{BACKUPMIN}})}{I_{\text{BACKUPMAX}}} \frac{3600}{3600} = \frac{10^6}{300} = 111.1 \, \text{h}$

  where,

  $C$ is the capacitor value in farads,

  $V_{\text{BACKUPSTART}}$ is the initial voltage in volts. The voltage applied to $V_{\text{CC}}$, less the voltage drop from the diodes, if any, used in the charging circuit,

  $V_{\text{BACKUPMIN}}$ is the ending voltage in volts,

  $I_{\text{BACKUPMAX}}$ is the maximum $V_{\text{BACKUP}}$ current in amperes.

  For example, to determine how long the backup time will be under the following conditions:

  - 0.2 F capacitor
  - $V_{\text{BACKUPSTART}}$ is 3.3 V
  - $V_{\text{BACKUPMIN}}$ is 1.3 V
  - $I_{\text{BACKUPMAX}}$ is 1000 nA, then:

    $\frac{0.2(3.3 - 1.3)}{10^{-6}} \frac{3600}{3600} = \frac{10^6}{300} = 111.1 \, \text{h}$

10.3 Inductors

**Inductance** is used for the storage of electrical energy in a magnetic field, called magnetic energy. Magnetic energy is stored as long as current keeps flowing through the inductor. The current of a sine wave lags the voltage by 90° in a perfect inductor. Figure 10-23 shows the color code for small inductors.
Ceramic has a low thermal coefficient of expansion allowing high inductance stability over a high operating temperature range.

10.3.1.5 Epoxy-Coated Inductor

Epoxy-coated inductors usually have a smooth surface and edges. The coating provides insulation.

10.3.1.6 Ferrite Core

Ferrite cores can be easily magnetized. The core consists of a mixture of oxide of iron and other elements such as manganese and zinc (MnZn) or nickel and zinc (NiZn). The general composition is $xx\text{Fe}_2\text{O}_4$ where $xx$ is one of the other elements.

10.3.1.7 Laminated Cores

Laminated cores are made by stacking insulated laminations on top of each other. Some laminations have the grains oriented to minimize core losses, giving higher permeability. Laminated cores are more common in transformers.

10.3.1.8 Molded Inductor

A molded inductor has its case formed via a molding process, creating a smooth, well-defined body with sharp edges.

10.3.1.9 MPP Core

MPP, or moly perm alloy powder, is a magnetic material with a inherent distributed air gap, allowing it to store higher levels of magnetic flux compared to other materials. This allows more dc to flow through the inductor before the core saturates.

The core consists of 80% nickel, 2–3% molybdenum, and the remaining percentage iron.

10.3.1.10 Multilayer Inductor

A multilayer inductor consists of layers of coil between layers of core material. The coil is usually bare metal and is sometimes referred to as nonwirewound.

10.3.1.11 Phenolic Core

Phenolic cores are often called air cores and are often used in high frequency applications where low inductance values, low core losses, and high Q values are required.

Phenolic has no magnetic properties so there is no increase in permeability due to the core material. Phenolic cores provide high strength, high flammability ratings, and high temperature characteristics.

10.3.1.12 Powdered Iron Core

Powdered iron is a magnetic material with an inherent distributed air gap that allows the core to have high

---

**Figure 10-24.** Various inductor core types.
levels of magnetic flux. This allows a high level of dc to flow through the core before saturation.

Powdered iron cores are close to 100% iron whose particles are insulated and mixed with a binder such as epoxy or phenolic. They are pressed into a final shape and cured by baking.

10.3.1.13 Radial Inductor

A radial inductor is constructed on a core with leads on the same side, Fig. 10-24C. This allows for easy mounting on circuit boards, etc.

10.3.1.14 Shielded Inductor

A shielded inductor has its core designed to contain the majority of the magnetic field. Some are self shielding such as toroids, e-cores, and pot cores. Bobbin and slug cores require a magnetic sleeve for shielding.

10.3.1.15 Slug Core

Slug cores have the shape of a cylindrical rod and come with or without leads, Fig. 10-24D. They have higher flux density characteristics than other core shapes as most of the magnetic energy is stored in the air around the core.

10.3.1.16 Tape Wound Core

Tape wound cores are made by rolling insulated and precisely controlled thickness strips of alloy iron into a toroidal shape. The finished cores have an outside coating for protection.

Tape wound cores are capable of storing high amounts of energy and contain a high permeability.

10.3.1.17 Toroidal Inductor

Toroidals are constructed by placing the winding on a donut-shaped core, Fig. 10-24E. Toroidal cores may be ferrite, powdered iron, tape wound, or alloy and high flux.

Toroidals are self shielding and have efficient energy transfer, high coupling between windings, and early saturation.

10.3.2 Impedance Characteristics

Impedance. The impedance or inductive reactance \( X_L \) of an inductor to an ac signal is found with the equation

\[
X_L = 2\pi f L
\]

where,

- \( f \) is the frequency in hertz,
- \( L \) is the inductance in henrys.

The inductance of a coil is only slightly affected by the type of wire used for its construction. The \( Q \) of the coil will be governed by the ohmic resistance of the wire. Coils wound with silver or gold wire have the highest \( Q \) for a given design.

To increase the inductance, inductors can be connected in series. The total inductance will always be greater than the largest inductor

\[
L_T = L_1 + L_2 + \cdots + L_n \tag{10-26}
\]

To reduce the total inductance, place the inductors in parallel. The total inductance will always be less than the value of the lowest inductor

\[
L_T = \frac{1}{1/L_1 + 1/L_2 + \cdots + 1/L_n} \tag{10-27}
\]

To determine the impedance of circuits with resistance, capacitance, and inductance, see Section 10.4.

Mutual Inductance. Mutual inductance is the property that exists between two conductors that are carrying current when the magnetic lines of force from one conductor link with the magnetic lines of force of the other. The mutual inductance of two coils with fields interacting can be determined by

\[
M = \frac{L_A - L_B}{4} \tag{10-28}
\]

where,

- \( M \) is the mutual inductance of \( L_A \) and \( L_B \) in henrys,
- \( L_A \) is the total inductance of coils \( L_1 \) and \( L_2 \) with fields aiding in henrys,
- \( L_B \) is the total inductance of coils \( L_1 \) and \( L_2 \) with fields opposing in henrys.

The coupled inductance can be determined by the following equations.

In parallel with fields aiding
In parallel with fields opposing

\[ L_T = \frac{1}{\frac{1}{L_1} + \frac{M}{L_2}} \]  \hspace{1cm} (10-29)

In series with fields aiding

\[ L_T = L_1 + L_2 + 2M \]  \hspace{1cm} (10-31)

In series with fields opposing

\[ L_T = L_1 + L_2 - 2M \]  \hspace{1cm} (10-32)

where,
- \( L_t \) is the total inductance in henrys,
- \( L_1 \) and \( L_2 \) are the inductances of the individual coils in henrys,
- \( M \) is the mutual inductance in henrys.

When two coils are inductively coupled to give transformer action, the coupling coefficient is determined by

\[ K = \frac{M}{\sqrt{L_1 \times L_2}} \]  \hspace{1cm} (10-33)

The maximum voltage induced in a conductor moving in a magnetic field is proportional to the number of magnetic lines of force cut by the conductor moving in the field. A conductor moving parallel to the lines of force cuts no lines of force so no current is generated in the conductor. A conductor moving at right angles to the lines of force will cut the maximum number of lines per inch per second; therefore, the voltage will be at the maximum.

A conductor moving at any angle to the lines of force cuts a number of lines of force proportional to the sine of the angles.

\[ V = \beta L v \sin \theta \times 10^{-8} \]  \hspace{1cm} (10-35)

where,
- \( V \) is the voltage produced,
- \( \beta \) is the flux density,
- \( L \) is the length of the conductor in centimeters,
- \( v \) is the velocity in centimeters per second of the conductor moving at an angle \( \theta \).

The direction of the induced electromotive force (emf) is in the direction in which the axis of a right-hand screw, when turned with the velocity vector, moves through the smallest angle toward the flux density vector. This is called the right-hand rule.

The magnetomotive force produced by a coil is derived by

\[ \text{ampere turns} = TI \]  \hspace{1cm} (10-36)

where,
- \( T \) is the number of turns,
- \( V \) is the voltage in volts,
- \( R \) is the resistance of the wire in ohms.
$I$ is the current in amperes.

The inductance of single-layer, spiral, and multilayer coils can be calculated by using either Wheeler’s or Nagaoka’s equations. The accuracy of the calculation will vary between 1% and 5%. The inductance of a single-layer coil, Fig. 10-25A, may be found using Wheeler’s equation

$$L = \frac{B^2 N^2}{9B + 10A}$$  \hspace{1cm} (10-37)

For the multilayer coil, Fig. 10-25B, the calculations are

$$L = \frac{0.8B^2 N^2}{6B + 9A + 10C}$$  \hspace{1cm} (10-38)

For the spiral coil, Fig. 10-25C, the calculations are:

$$L = \frac{B^2 N^2}{8B + 11C}$$  \hspace{1cm} (10-39)

where,

$B$ is the radius of the winding,

$N$ is the number of turns in the coil,

$A$ is the length of the winding,

$C$ is the thickness of the winding,

$L$ is in μH.

The $Q$ of the coil can be measured as follows. Using the circuit of Fig. 10-26, $Q$ of a coil may be easily measured for frequencies up to 1 MHz. Since the voltage across an inductance at resonance equals $Q \times V$, where $V$ is the voltage developed by the oscillator, it is necessary only to measure the output voltage from the oscillator and the voltage across the inductance.

![Figure 10-26. Circuit for measuring the $Q$ of a coil.](image)

The voltage from the oscillator is introduced across a low value of resistance $R$, about 1% of the anticipated radiofrequency resistance of the $LC$ combination, to assure that the measurement will not be in error by more than 1%. For average measurements, resistor $R$ will be on the order of 0.10 Ω. If the oscillator cannot be operated into an impedance of 0.10 Ω, a matching transformer may be employed. It is desirable to make $C$ as large as convenient to minimize the ratio of the impedance looking from the voltmeter to the impedance of the test circuit. The voltage across $R$ is made small, on the order of 0.10 V. The $LC$ circuit is then adjusted to resonate and the resultant voltage measured. The value of $Q$ may then be equated

$$Q = \frac{\text{Resonant voltage across } C}{\text{Voltage across } R}.$$  \hspace{1cm} (10-41)

The $Q$ of a coil may be approximated by the equation

$$Q = \frac{2\pi fL}{R}$$  \hspace{1cm} (10-42)

where,

$f$ is the frequency in hertz,

$L$ is the inductance in henrys,

$R$ is the resistance in ohms as measured by an ohmmeter,

$X_L$ is the inductive reactance of the coil.

**Time Constant.** When a dc voltage is applied to an $RL$ circuit, a certain amount of time is required to change the voltage. In a circuit containing inductance and resis-
tance, the time constant is defined as the time it takes for the current to reach 62.3% of its maximum value. The time constant can be determined with the following equation:

\[
T = \frac{L}{R}
\]

(10-43)

where,
\(T\) is the time in seconds,
\(L\) is the inductance in henrys,
\(R\) is the resistance in ohms.

See Section 10.2.1 for a further discussion of time constants. The effect of an inductor is the same as for a capacitor and resistor. Also, curve A in Fig. 10-14 shows the current through an inductor on buildup and curve B shows the current decay when the voltage is removed.

**Right-Hand Rule.** The *right-hand rule* is a method devised for determining the direction of a magnetic field around a conductor carrying a direct current. The conductor is grasped in the right hand with the thumb extended along the conductor. The thumb points in the direction of the current. If the fingers are partly closed, the fingertips will point in the direction of the magnetic field.

Maxwell’s rule states, “If the direction of travel of a right-handed corkscrew represents the direction of the current in a straight conductor, the direction of rotation of the corkscrew will represent the direction of the magnetic lines of force.”

10.3.3 **Ferrite Beads**

The original ferrite beads were small round ferrites with a hole through the middle where a wire passed through. Today they come as the original style plus as multiple apertures and surface mount configurations.

The ferrite bead can be considered a frequency-dependent resistor whose equivalent circuit is a resistor in series with an inductor. As the frequency increases, the inductive reactance increases and then decreases, and the complex impedance of the ferrite material increases the overall impedance of the bead, Fig. 10-27.

At frequencies below 10 MHz, the impedance is less than 10 \(\Omega\). As the frequency increases, the impedance increases to about 100 \(\Omega\) and becomes mostly resistive at 100 MHz.

Once the impedance is resistive, resonance does not occur as it would using an LC network. Ferrite beads do not attenuate low frequencies or dc so are useful for reducing EMI/EMC in audio circuits.

10.3.4 **Skin Effect**

Skin effect is the tendency of ac to flow near the surface of a conductor rather than flowing through the conductor’s entire cross sectional area. This increases the resistance of the conductor because the magnetic field caused by the current creates eddy currents near the center of the conductor. The eddy currents oppose the normal flow of current near the center, forcing the main current flow out toward the surface as the frequency of the ac current increases.

To reduce this problem, a wire made up of separately insulated strands woven and/or bunched together is used. Commonly called Litz wire, the current is equally divided between all of the individual strands which equalizes the flux linkage and reactance of the individual strands, reducing the ac losses compared to solid wire.

10.3.5 **Shielded Inductor**

Some inductor designs are self-shielding. Examples are toroid, pot core, and E-core inductors. Slug cores and bobbins may require shielding, depending on the application. It is impossible to completely shield an inductor.

10.4 **Impedance**

The total impedance created by resistors, capacitors, and inductors in circuits can be determined with the following equations.
Parallel circuits

\[ Z = \frac{RX}{\sqrt{R^2 + X^2}} \quad (10-44) \]

Series circuits

\[ Z = \sqrt{R^2 + X^2} \quad (10-45) \]

Resistance and inductance in series

\[ Z = \sqrt{R^2 + X_L^2} \quad (10-46) \]
\[ \theta = \tan^{-1}\frac{X_L}{R} \quad (10-47) \]

Resistance and capacitance in series

\[ Z = \sqrt{R^2 + X_C^2} \quad (10-48) \]
\[ \theta = \tan^{-1}\frac{X_C}{R} \quad (10-49) \]

Inductance and capacitance in series when \( X_L \) is larger than \( X_C \)

\[ Z = X_L - X_C \quad (10-50) \]

Inductance and capacitance in series when \( X_C \) is larger than \( X_L \)

\[ Z = X_C - X_L \quad (10-51) \]

Resistance, inductance, and capacitance in series

\[ Z = \sqrt{R^2 + (X_L - X_C)^2} \quad (10-52) \]
\[ \theta = \tan^{-1}\frac{X_L - X_C}{R} \quad (10-53) \]

Resistance and inductance in parallel

\[ Z = \frac{RX_L}{\sqrt{R^2 + X_L^2}} \quad (10-54) \]

Capacitance and inductance in parallel when \( X_L \) is larger than \( X_C \)

\[ Z = \frac{RX_C}{\sqrt{R^2 + X_C^2}} \quad (10-55) \]

Capacitance and inductance in parallel when \( X_C \) is larger than \( X_L \)

\[ Z = \frac{X_L \times X_C}{X_L - X_C} \quad (10-56) \]

Inductance, capacitance, and resistance in parallel

\[ Z = \frac{RX_LX_C}{\sqrt{X_L^2X_C^2 + R^2(X_L - X_C)^2}} \quad (10-58) \]
\[ \theta = \tan^{-1}\frac{R(X_L - X_C)}{X_LX_C} \quad (10-59) \]

Inductance and series resistance in parallel with resistance

\[ Z = R_2\sqrt{\frac{R_1^2 + X_L^2}{(R_1 + R_2)^2 + X_L^2}} \quad (10-60) \]
\[ \theta = \tan^{-1}\frac{R_2X_L}{R_1^2 + X_L^2 + R_1R_2} \quad (10-61) \]

Inductance and series resistance in parallel with capacitance

\[ Z = X_C\sqrt{\frac{R^2 + X_L^2}{R^2 + (X_L - X_C)^2}} \quad (10-62) \]
\[ \theta = \tan^{-1}\frac{X_L(X_C - X_L) - R^2}{RX_C} \quad (10-63) \]

Capacitance and resistance in parallel

\[ Z = \frac{R(X_C - X_L)}{X_CX_L} \quad (10-57) \]
where,
\[ Z = \frac{(R_1^2 + X_L^2)(R_2^2 + X_C^2)}{k'(R_1 + R_2)^2 + (X_L - X_C)^2} \] (10-64)

\[ Z = \tan \frac{X_L(R_2^2 + X_C^2) - X_C(R_1^2 + X_L^2)}{R_1(R_2^2 + X_C^2) + R_2(R_1^2 + X_L^2)} \] (10-65)

where,
\( Z \) is the impedance in ohms,
\( R \) is the resistance in ohms,
\( L \) is the inductance in henrys,
\( X_L \) is the inductive reactance in ohms,
\( X_C \) is the capacitive reactance in ohms.

\( \theta \) is the phase angle in degrees by which the current leads the voltage in a capacitive circuit or lags the voltage in an inductive circuit. \( 0^\circ \) indicates an in-phase condition.

### 10.5 Resonant Frequency

When an inductor and capacitor are connected in series or parallel, they form a resonant circuit. The resonant frequency can be determined from the equation

\[ f = \frac{1}{2\pi \sqrt{LC}} \]

\[ = \frac{1}{2\pi CX_C} \]

\[ = \frac{X_L}{2\pi L} \] (10-66)

where,
\( L \) is the inductance in henrys,
\( C \) is the capacitance in farads,
\( X_L \) and \( X_C \) are the impedance in ohms.

The resonant frequency can also be determined through the use of a reactance chart developed by the Bell Telephone Laboratories, Fig. 10-28. This chart can be used for solving problems of inductance, capacitance, frequency, and impedance. If two of the values are known, the third and fourth values may be found with its use. As an example, what is the value of capacitance and inductance required to resonate at a frequency of 1000 Hz in a circuit having an impedance of 500 \( \Omega \)? Entering the chart on the 1000 Hz vertical line and following it to the 500 \( \Omega \) line (impedance is shown along the left-hand margin), the value of inductance is indicated by the diagonal line running upward as 0.08 H (80 mH), and the capacitance indicated by the diagonal line running downward at the right-hand margin is 0.3 \( \mu F \).

11.1 Audio Transformer Basics

Since the birth of audio electronics, the audio transformer has played an important role. When compared to modern miniaturized electronics, a transformer seems large, heavy, and expensive but it continues to be the most effective solution in many audio applications. The usefulness of a transformer lies in the fact that electrical energy can be transferred from one circuit to another without direct connection (e.g., isolation from ground loops), and in the process the energy can be readily changed from one voltage level to another (e.g., impedance matching). Although a transformer is not a complex device, considerable explanation is required to properly understand how it operates. This chapter is intended to help the audio system engineer properly select and apply transformers. In the interest of simplicity, only basic concepts of their design and manufacture will be discussed.

11.1.1 Basic Principles and Terminology

11.1.1.1 Magnetic Fields and Induction

As shown in Fig. 11-1, a magnetic field is created around any conductor (wire) in which current flows. The strength of the field is directly proportional to current. These invisible magnetic lines of force, collectively called flux, are set up at right angles to the wire and have a direction, or magnetic polarity, that depends on the direction of current flow. Note that although the flux around the upper and lower wires have different directions, the lines inside the loop aid because they point in the same direction. If an alternating current flows in the loop, the instantaneous intensity and polarity of the flux will vary at the same frequency and in direct proportion to Fig. 11-2, as expanding, contracting, and reversing in polarity with each cycle of the ac current. The law of induction states that a voltage will be induced in a conductor exposed to changing flux and that the induced voltage will be proportional to the rate of the flux change. This voltage has an instantaneous polarity which opposes the original current flow in the wire, creating an apparent resistance called inductive reactance. Inductive reactance is calculated according to the formula

\[ X_L = 2\pi f L \]  (11-1)

where,

- \( X_L \) is inductive reactance in ohms,
- \( f \) is the frequency in hertz,
- \( L \) is inductance in Henrys.

According to the law of induction, a voltage will be induced in any conductor (wire) that cuts flux lines.
Therefore, if we place two coils near each other as shown in Fig. 11-4, an ac current in one coil will induce an ac voltage in the second coil. This is the essential principle of energy transfer in a transformer. Because they require a changing magnetic field to operate, transformers will not work at dc. In an ideal transformer, the magnetic coupling between the two coils is total and complete, i.e., all the flux lines generated by one coil cut across all the turns of the other. The coupling coefficient is said to be unity or 1.00.

11.1.1.2 Windings and Turns Ratio

The coil or winding that is driven by an electrical source is called the primary and the other is called the secondary. The ratio of the number of turns on the primary to the number of turns on the secondary is called the turns ratio. Since essentially the same voltage is induced in each turn of each winding, the primary to secondary voltage ratio is the same as the turns ratio. For example, with 100 turns on the primary and 50 turns on the secondary, the turns ratio is 2:1. Therefore, if 20 V were applied to the primary, 10 V would appear at the secondary. Since it reduces voltage, this transformer would be called a step-down transformer. Conversely, a transformer with a turns ratio of 1:2 would be called a step-up transformer since its secondary voltage would be twice that of the primary. Since a transformer cannot create power, the power output from the secondary of an ideal transformer can only equal (and in a real transformer can only be less than) the power input to the primary. Consider an ideal 1:2 step-up transformer. When 10 V is applied to its primary, 20 V appears at its secondary. Since no current is drawn by the primary (this is an ideal transformer—see “11.1.1.3, Excitation Current,” its impedance appears to be infinite or an open circuit.

However, when a 20 Ω load is connected to the secondary, a current of 1 A flows making output power equal 20 W. To do this, a current of 2 A must be drawn by the primary, making input power equal 20 W. Since the primary is now drawing 2 A with 10 V applied, its impedance appears to be 5 Ω. In other words, the 20 Ω load impedance on the secondary has been reflected to the primary as 5 Ω. In this example, a transformer with a 1:2 turns ratio exhibited an impedance ratio of 1:4. Transformers always reflect impedances from one winding to another by the square of their turns ratio or, expressed as an equation

$$\frac{Z_p}{Z_s} = \left(\frac{N_p}{N_s}\right)^2$$

(11-2)

where,

- $Z_p$ is primary impedance,
- $Z_s$ is secondary impedance,
- $N_p/N_s$ is turns ratio, which is the same as the voltage ratio.

When a transformer converts voltage, it also converts impedance—and vice versa.

The direction in which coils are wound—i.e., clockwise or counterclockwise—and/or the connections to the start or finish of each winding determines the instantaneous polarity of the ac voltages. All windings that are wound in the same direction will have the same polarity between start and finish ends. Therefore, relative to the primary, polarity can be inverted by either (1) winding the primary and secondary in opposite directions, or (2) reversing the start and finish connections to either winding. In schematic symbols for transformers, dots are generally used to indicate which ends of windings have the same polarity. Observing polarity is essential when making series or parallel connections to transformers with multiple windings. Taps are connections made at any intermediate point in a winding. For example, if 50 turns are wound, an electrical connection brought out, and another 50 turns completes the winding, the 100 turn winding is said to be center-tapped.

11.1.1.3 Excitation Current

While an ideal transformer has infinite primary inductance, a real transformer does not. Therefore, as shown in Fig. 11-5, when there is no load on the secondary and an ac voltage is applied to the primary, an excitation current will flow in the primary, creating magnetic excitation flux around the winding. In theory, the current is due only to the inductive reactance of the primary winding. In accordance with Ohm’s Law and the equation for inductive reactance,
where,

\[ I_E = \frac{E_p}{2\pi f L_p} \]  \hspace{1cm} (11-3)

\( I_E \) is excitation current in amperes,
\( E_p \) is primary voltage in volts,
\( f \) is frequency in hertz,
\( L_p \) is primary inductance in henrys.

**Figure 11-5.** Excitation current.

Obviously, if primary inductance were infinite, excitation current would be zero. As shown in Fig. 11-6, when a load is connected, current will flow in the secondary winding. Because secondary current flows in the opposite direction, it creates magnetic flux which opposes the excitation flux. This causes the impedance of the primary winding to drop, resulting in additional current being drawn from the driving source. Equilibrium is reached when the additional flux is just sufficient to completely cancel that created by the secondary. The result, which may surprise some, is that flux density in a transformer is not increased by load current. This also illustrates how load current on the secondary is reflected to the primary.

**Figure 11-6.** Cancellation of flux generated by load current.

Fig. 11-7 illustrates the relationships between voltage, excitation current, and flux in a transformer as frequency is changed. The horizontal scale is time. The primary voltage \( E_p \) is held constant as the frequency is changed (tripled and then tripled again). For example, the left waveform could represent one cycle at 100 Hz, the middle 300 Hz, and the right 900 Hz. Because of the primary inductance, excitation current \( I_p \) will decrease linearly with frequency—i.e., halving for every doubling in frequency or decreasing at 6 dB per octave. The magnitude of the magnetic flux will likewise decrease exactly the same way. Note that the inductance causes a 90° phase lag between voltage and current as well. Since the slew rate of a constant amplitude sine wave increases linearly with frequency—i.e., doubling for every doubling in frequency or increasing at 6 dB per octave—the resultant flux rate of change remains constant. Note that the slope of the \( I_p \) and flux waveforms stays constant as frequency is changed. Since, according to the law of induction, the voltage induced in the secondary is proportional to this slope or rate of change, output voltage also remains uniform, or flat versus frequency.

**Figure 11-7.** Excitation current and flux vary inversely with frequency.

### 11.1.2 Realities of Practical Transformers

Thus far, we have not considered the unavoidable parasitic elements which exist in any practical transformer. Even the design of a relatively simple 60 Hz power transformer must take parasitics into account. The design of an audio transformer operating over a 20 Hz to 20 kHz frequency range is much more difficult because these parasitics often interact in complex ways. For example, materials and techniques that improve low-frequency performance are often detrimental to high-frequency performance and vice versa. Good transformer designs must consider both the surrounding electronic circuitry and the performance ramifications of internal design tradeoffs.

A schematic representation of the major low frequency parasitic elements in a generalized transformer is shown in Fig. 11-8. The IDEAL TRANSFORMER represents a perfect transformer having a turns ratio of 1:N and no parasitic elements of any kind.
The actual transformer is connected at the PRI terminals to the driving voltage source, through its source impedance $R_G$, and at the SEC terminals to the load $R_L$.

One of the main goals in the design of any transformer is to reduce the excitation current in the primary winding to negligible levels so as not to become a significant load on the driving source. For a given source voltage and frequency, primary excitation current can be reduced only by increasing inductance $L_p$. In the context of normal electronic circuit impedances, very large values of inductance are required for satisfactory operation at the lowest audio frequencies. Of course, inductance can be raised by using a very large number of coil turns but, for reasons discussed later, there are practical limits due to other considerations. Another way to increase inductance by a factor of 10,000 or more is to wind the coil around a highly magnetic material, generally referred to as the core.

11.1.2.1 Core Materials and Construction

Magnetic circuits are quite similar to electric circuits. As shown in Fig. 11-11, magnetic flux always takes a closed path from one magnetic pole to the other and, like an electric current, always favors the paths of highest conductivity or least resistance. The equivalent of applied voltage in magnetic circuits is magnetizing force, symbolized $H$. It is directly proportional to ampere-turns (coil current $I$ times its number of turns $N$) and inversely proportional to the flux path length $l$ in the magnetic circuit. The equivalent of electric current flow is flux density, symbolized $B$. It represents the number of magnetic flux lines per square unit of area. A graphic plot of the relationship between field intensity and flux density is shown in Fig. 11-9 and is referred to as the “B-H loop” or “hysteresis loop” for a given material. In the United States, the most commonly used units for magnetizing force and flux density are the Oersted and Gauss, respectively, which are CGS (centimeter, gram, second) units. In Europe, the SI (Système Internationale) units amperes per meter and tesla, respectively, are more common. The slope of the B-H loop indicates how an incremental increase in applied magnetizing force changes the resulting flux density. This slope is effectively a measure of conductivity in the magnetic circuit and is called permeability, symbolized $\mu$. Any material inside a coil, which can also serve as a form to support it, is called a core. By definition, the permeability of a vacuum, or air, is 1.00 and common nonmagnetic materials such as aluminum, brass, copper, paper, glass, and plastic also have a permeability of 1 for practical purposes. The permeability of some common ferromagnetic materials is about 300 for ordinary steel, about 5000 for 4% silicon transformer steel, and up to about 100,000 for some nickel-iron-molybdenum alloys. Because such materials concentrate magnetic flux, they greatly increase the inductance of a coil. Audio transformers must utilize both high-permeability cores and the largest practical number of coil turns to create high primary inductance. Coil inductance increases as the square of the number of turns and in direct proportion to the permeability of the core and can be approximated using the equation

$$L = \frac{3.2N^2\mu A}{10^8l}$$

(11-4)

where,
$L$ is the inductance in henrys,
$N$ is the number of coil turns,
$\mu$ is the permeability of core,
$A$ is the cross-section area of core in square inches,
$l$ is the mean flux path length in inches.

The permeability of magnetic materials varies with flux density. As shown in Fig. 11-9, when magnetic field intensity becomes high, the material can saturate, essentially losing its ability to conduct any additional
flux. As a material saturates, its permeability decreases until, at complete saturation, its permeability becomes that of air or 1. In audio transformer applications, magnetic saturation causes low-frequency harmonic distortion to increase steadily for low-frequency signals as they increase in level beyond a threshold. In general, materials with a higher permeability tend to saturate at a lower flux density. In general, permeability also varies inversely with frequency.

Magnetic hysteresis can be thought of as a magnetic memory effect. When a magnetizing force saturates material that has high-hysteresis, it remains strongly magnetized even after the force is removed. High-hysteresis materials have wide or square B-H loops and are used to make magnetic memory devices and permanent magnets. However, if we magnetically saturate zero-hysteresis material, it will have no residual magnetism (flux density) when the magnetizing force is removed. But virtually all high-permeability core materials have some hysteresis, retaining a small memory of their previous magnetic state. Hysteresis can be greatly reduced by using certain metal alloys that have been annealed or heat-treated using special processes. In audio transformers, the nonlinearity due to magnetic hysteresis causes increased harmonic distortion for low-frequency signals at relatively low signal levels. Resistor $R_C$ in Fig. 11-8 is a nonlinear resistance that, in the equivalent circuit model, represents the combined effects of magnetic saturation, magnetic hysteresis, and eddy-current losses.

The magnetic operating point, or zero signal point, for most transformers is the center of the B-H loop shown in Fig. 11-9, where the net magnetizing force is zero. Small ac signals cause a small portion of the loop to be traversed in the direction of the arrows. Large ac signals traverse portions farther from the operating point and may approach the saturation end points. For this normal operating point at the center, signal distortions (discussed in detail later) caused by the curvature of the loop are symmetrical—i.e., they affect the positive and negative signal excursions equally. Symmetrical distortions produce odd-order harmonics such as third and fifth. If dc current flows in a winding, the operating point will shift to a point on the loop away from the center. This causes the distortion of a superimposed ac signal to become nonsymmetrical. Nonsymmetrical distortions produce even-order harmonics such as second and fourth. When a small dc current flows in a winding, under say 1% of the saturation value, the effect is to add even-order harmonics to the normal odd-order content of the hysteresis distortion, which affects mostly low level signals. The same effects occur when the core becomes weakly magnetized, as could happen via the brief accidental application of dc to a winding, for example. However, the narrow B-H loop indicates that only a weak residual field would remain even if a magnetizing force strong enough to saturate the core were applied and then removed.

When a larger dc current flows in a winding, the symmetry of saturation distortion is also affected in a similar way. For example, enough dc current might flow in a winding to move the operating point to 50% of the core saturation value. Only half as much ac signal could then be handled before the core would saturate and, when it did, it would occur only for one direction of the signal swing. This would produce strong second-harmonic distortion. To avoid such saturation effects, air gaps are sometimes intentionally built into the magnetic circuit. This can be done, for example, by placing a thin paper spacer between the center leg of the E and I cores of Fig. 11-10. The magnetic permeability of such a gap is so low—even though it may be only a few thousandths of an inch—compared to the core material, that it effectively controls the flux density in the entire magnetic circuit. Although it drastically reduces the inductance of the coil, gapping is done to prevent flux density from reaching levels that would otherwise saturate the core, especially when substantial dc is present in a winding.

Because high-permeability materials are usually electrical conductors as well, small voltages are also induced in the cross-section of the core material itself, giving rise
to *eddy currents*. Eddy currents are greatly reduced when the core consists of a stack of thin sheets called *laminations*, as shown in Fig. 11-10. Because the laminations are effectively insulated from each other, eddy currents generally become insignificant. The E and I shaped laminations shown form the widely used shell or double-window, core construction. Its parallel magnetic paths are illustrated in Fig. 11-11. When cores are made of laminations, care must be taken that they are flat and straight to avoid tiny air gaps between them that could significantly reduce inductance.

![Figure 11-11. Magnetic circuits in shell core.](image)

A *toroidal core* is made by rolling a long thin strip of core material into a coiled ring shape that looks something like a donut. It is insulated with a conformal coating or tape and windings are wound around the core through the center hole using special machines. With a toroidal core, there are no unintended air gaps that can degrade magnetic properties. Audio transformers don’t often use toroidal cores because, especially in high bandwidth designs where multiple sections or Faraday shields are necessary, physical construction becomes very complex. Other core configurations include the ring core, sometimes called *semitoroidal*. It is similar to core of Fig. 11-11 but without the center section and windings are placed on the sides. Sometimes a solid—not laminations—metal version of a ring core is cut into two pieces having polished mating faces. These two *C-cores* are then held together with clamps after the windings are installed.

11.1.2.2 Winding Resistances and Auto-Transformers

If zero-resistance wire existed, some truly amazing transformers could be built. In a 60 Hz power transformer, for example, we could wind a primary with tiny wire on a tiny core to create enough inductance to make excitation current reasonable. Then we could wind a secondary with equally tiny wire. Because the wire has no resistance and the flux density in the core doesn’t change with load current, this postage-stamp-sized transformer could handle unlimited kilowatts of power—and it wouldn’t even get warm! But, at least until practical superconducting wire is available, real wire has resistance. As primary and secondary currents flow in the winding resistances, the resulting voltage drops cause signal loss in audio transformers and significant heating in power transformers. This resistance can be reduced by using larger—lower gauge—wire or fewer turns, but the required number of turns and the tolerable power loss (or resulting heat) all conspire to force transformers to become physically larger and heavier as their rated power increases. Sometimes silver wire is suggested to replace copper, but since its resistance is only about 6% less, its effect is minimal and certainly not cost-effective. However, there is an alternative configuration of transformer windings, called an *auto-transformer*, which can reduce the size and cost in certain applications. Because an auto-transformer electrically connects primary and secondary windings, it can’t be used where electrical isolation is required! In addition, the size and cost advantage is maximum when the required turns ratio is very close to 1:1 and diminishes at higher ratios, becoming minimal in practical designs at about 3:1 or 1:3.

For example, in a hypothetical transformer to convert 100 V to 140 V, the primary could have 100 turns and the secondary 140 turns of wire. This transformer, with its 1:1.4 turns ratio, is represented in the upper diagram of Fig. 11-12. If 1 A of secondary (load) current $I_S$ flows, transformer output power is 140 W and 1.4 A of primary current $I_P$ will flow since input and output power must be equal in the ideal case. In a practical transformer, the wire size for each winding would be chosen to limit voltage losses and/or heating.

An auto-transformer essentially puts the windings in series so that the secondary voltage adds to (boosting) or subtracts from (bucking) the primary input voltage. A step-up auto-transformer is shown in the middle diagram of Fig. 11-12. Note that the dots indicate ends of the windings with the same instantaneous polarity. A 40 V secondary (the upper winding) series connected, as shown with the 100 V primary, would result in an output of 140 V. Now, if 1 A of secondary load current $I_S$ flows, transformer output power is only 40 W and only 0.4 A of primary current $I_P$ will flow. Although the total power delivered to the load is still 140 W, 100 W have come directly from the driving source and only 40 W have been transformed and added by the auto-transformer. In the auto-transformer, 100 turns of smaller wire can be used for the primary and only 40
turns of heavier wire is needed for the secondary. Compare this to the total of 240 turns of heavier wire required in the transformer.

A step-down auto-transformer is shown in the bottom diagram of Fig. 11-12. Operation is similar except that the secondary is connected so that its instantaneous polarity subtracts from or bucking the input voltage. For example, we could step down U.S. 120 Vac power to Japanese 100 Vac power by configuring a 100 V to 20 V step-down transformer as an auto-transformer. Thus, a 100 W load can be driven using only a 20 W rated transformer.

The windings of low level audio transformers may consist of hundreds or even many thousands of turns of wire, sometimes as small as #46 gauge, whose 0.0015 inch diameter is comparable to a human hair. As a result, each winding may have a dc resistance as high as several thousand ohms. Transformer primary and secondary winding resistances are represented by $R_p$ and $R_s$, respectively, in Fig. 11-8.

### 11.1.2.3 Leakage Inductance and Winding Techniques

In an ideal transformer, since all flux generated by the primary is linked to the secondary, a short circuit on the secondary would be reflected to the primary as a short circuit. However, in real transformers, the unlinked flux causes a residual or leakage inductance that can be measured at either winding. Therefore, the secondary would appear to have residual inductance if the primary were shorted and vice-versa. The leakage inductance is shown as $L_L$ in the model of Fig. 11-13. Note that leakage inductance is reflected from one winding to another as the square of turns ratio, just as other impedances are.

The degree of flux coupling between primary and secondary windings depends on the physical spacing between them and how they are placed with respect to each other. The lowest leakage inductance is achieved by winding the coils on a common axis and as close as possible to each other. The ultimate form of this technique is called multi-filar winding where multiple wires are wound simultaneously as if they were a single strand. For example, if two windings—i.e. primary and secondary—are wound as one, the transformer is said to be bi-filar wound. Note in the cross-section view of Fig. 11-14 how the primary and secondary windings are side-by-side throughout the entire winding. Another technique to reduce leakage inductance is to use layering, a technique in which portions or sections of the primary and/or secondary are wound in sequence over each other to interleave them. For example, Fig. 11-15 shows the cross-section of a three-layer transformer where half the primary is wound, then the secondary, followed by the other half of the primary. This results in considerably less leakage inductance than just a secondary over primary two-layer design. Leakage
inductance decreases rapidly as the number of layers is increased.

11.1.2.4 Winding Capacitances and Faraday Shields

To allow the maximum number of turns in a given space, the insulation on the wire used to wind transformers is very thin. Called magnet wire, it is most commonly insulated by a thin film of polyurethane enamel. A transformer winding is made, in general, by spinning the bobbin shown in Fig. 11-10 on a machine similar to a lathe and guiding the wire to form a layer one wire thick across the length of the bobbin. The wire is guided to traverse back and forth across the bobbin to form a coil of many layers as shown in Fig. 11-15, where the bobbin cross-section is the solid line on three sides of the winding. This simple side-to-side, back-and-forth winding results in considerable layer-to-layer capacitance within a winding or winding section. More complex techniques such as universal winding are sometimes used to substantially reduce winding capacitances. These capacitances within the windings are represented by $C_p$ and $C_s$ in the circuit model of Fig. 11-13. Additional capacitances will exist between the primary and secondary windings and are represented by capacitors $C_w$ in the model. Sometimes layers of insulating tape are added to increase the spacing, therefore reducing capacitance, between primary and secondary windings. In the bi-filar windings of Fig. 11-14, since the wires of primary and secondary windings are side by side throughout, the inter-winding capacitances $C_w$ can be quite high.

In some applications, interwinding capacitances are very undesirable. They are completely eliminated by the use of a Faraday shield between the windings. Sometimes called an electrostatic shield, it generally takes the form of a thin sheet of copper foil placed between the windings. Obviously, transformers that utilize multiple layers to reduce leakage inductance will require Faraday shields between all adjacent layers. In Fig. 11-15 the dark lines between the winding layers are the Faraday shields. Normally, all the shields surrounding a winding are tied together and treated as a single electrical connection. When connected to circuit ground, as shown in Fig. 11-16, a Faraday shield intercepts the capacitive current that would otherwise flow between transformer windings.

Faraday shields are nearly always used in transformers designed to eliminate ground noise. In these applications, the transformer is intended to respond only to the voltage difference or signal across its primary and have no response to the noise that exists equally (or common-mode) at the terminals of its primary. A Faraday shield is used to prevent capacitive coupling, via $C_p$ in Fig. 11-13, of this noise to the secondary. For any winding connected to a balanced line, the matching of capacitances to ground is critical to the rejection of
common-mode noise, or CMRR, as discussed in Chapter 37. In Fig. 11-16, if the primary is driven by a balanced line, $C_1$ and $C_2$ must be very accurately matched to achieve high CMRR. In most applications, such as microphone or line input transformers, the secondary is operated unbalanced—i.e., one side is grounded. This relaxes the matching requirements for capacitances $C_3$ and $C_4$. Although capacitances $CC_1$ and $CC_2$ are generally quite small—a few pF—they have the effect of diminishing CMRR at high audio frequencies and limiting rejection of RF interference.

11.1.2.5 Magnetic Shielding

A magnetic shield has a completely different purpose. Devices such as power transformers, electric motors, and television or computer monitor cathode-ray tubes generate powerful ac magnetic fields. If such a field takes a path through the core of an audio transformer, it can induce an undesired voltage in its windings—most often heard as hum. If the offending source and the victim transformer have fixed locations, orientation of one or both can sometimes nullify the pickup. In Fig. 11-11 note that an external field that flows vertically through the core will cause a flux gradient across the length of the coil, inducing a voltage in it, but a field that flows horizontally through the core will not. Such magnetic pickup is usually worse in input transformers (discussed later) because they generally have more turns. It should also be noted that higher permeability core materials are more immune to external fields. Therefore, an unshielded output transformer with a high nickel core will be more immune than one with a steel core.

Another way to prevent such pickup is to surround the core with a closed—no air gap—magnetic path. This magnetic shield most often takes the form of a can or box with tight-fitting lid and is made of high permeability material. While the permeability of ordinary steel, such as that in electrical conduit, is only about 300, special-purpose nickel alloys can have permeability as high as 100,000. Commercial products include Mumetal®️, Permalloy®, HyMu®️ and Co-Netic®️.1,2

Since the shield completely surrounds the transformer, the offending external field will now flow through it instead of the transformer core. Generally speaking, care must be taken not to mechanically stress these metals because doing so will significantly decrease their permeability. For this reason, most magnetic shield materials must be re-annealed after they are fabricated.

The effectiveness of magnetic shielding is generally rated in dB. The transformer is placed in an external magnetic field of known strength, generally at 60 Hz. Its output without and with the shield is then compared. For example, a housing of $\frac{1}{4}$ inch thick cast iron reduces pickup by about 12 dB, while a 0.030 inch thick Mumetal can reduces it by about 30 dB. Where low-level transformers operate near strong magnetic fields, several progressively smaller shield cans can be nested around the transformer. Two or three Mumetal cans can provide 60 dB and 90 dB of shielding, respectively. In very strong fields, because high permeability materials might saturate, an iron or steel outer can is sometimes used.

Toroidal power transformers can have a weaker radiated magnetic field than other types. Using them can be an advantage if audio transformers must be located nearby. However, a toroidal transformer must be otherwise well designed to produce a low external field. For example, every winding must completely cover the full periphery of the core. The attachment points of the transformer lead wires are frequently a problem in this regard. To gain size and cost advantages, most commercial power transformers of any kind are designed to operate on the verge of magnetic saturation of the core. When saturation occurs in any transformer, magnetic field radiation dramatically increases. Power transformers designed to operate at low flux density will prevent this. A standard commercial power transformer, when operated at reduced primary voltage, will have a very low external field—comparable to that of a standard toroidal design.

11.1.3 General Application Considerations

For any given application, a number of parameters must be considered when selecting or designing an appropriate audio transformer. We will discuss how the performance of a transformer can be profoundly affected by its interaction with surrounding circuitry.

11.1.3.1 Maximum Signal Level, Distortion, and Source Impedance

Because these parameters are inextricably interdependent, they must be discussed as a group. Although transformer operating level is often specified in terms of power such as dBm or watts, what directly affects distortion is the equivalent driving voltage. Distortion is caused by excitation current in the primary winding which is proportional to primary voltage, not power. Referring to Fig. 11-8, recall that nonlinear resistance $R_p$ represents the distortion-producing mechanisms of the core material. Consider that, if both $R_G$ the driving source impedance, and $R_p$, the internal winding resis-
tance, were zero, the voltage source—by definition zero impedance—would effectively short out $R_C$, resulting in zero distortion! But in a real transformer design there is a fixed relationship between signal level, distortion, and source impedance. Since distortion is also a function of magnetic flux density, which increases as frequency decreases, a maximum operating level specification must also specify a frequency. The specified maximum operating level, maximum allowable distortion at a specified low frequency, and maximum allowable source impedance will usually dictate the type of core material that must be used and its physical size. And, of course, cost plays a role, too.

The most commonly used audio transformer core materials are M6 steel (a steel alloy containing 6% silicon) and 49% nickel or 84% nickel (alloys containing 49% or 84% nickel plus iron and molybdenum). Nickel alloys are substantially more expensive than steel. Fig. 11-17 shows how the choice of core material affects low-frequency distortion as signal level changes. The increased distortion at low levels is due to magnetic hysteresis and at high levels is due to magnetic saturation. Fig. 11-18 shows how distortion decreases rapidly with increasing frequency. Because of differences in their hysteresis distortion, the falloff is most rapid for the 84% nickel and least rapid for the steel. Fig. 11-19 shows how distortion is strongly affected by the impedance of the driving source. The plots begin at 40 $\Omega$ because that is the resistance of the primary winding. Therefore, maximum operating levels predicated on higher frequencies, higher distortion, and lower source impedance will always be higher than those predicated on lower frequencies, lower distortion, and lower source impedance.

As background, it should be said that THD, or total harmonic distortion, is a remarkably inadequate way to describe the perceived awfulness of distortion. Distortion consisting of low-order harmonics, 2nd or 3rd for example, is dramatically less audible than that consisting of high order harmonics, 7th or 13th for example. Consider that, at very low frequencies, even the finest loudspeakers routinely exhibit harmonic distortion in the range of several percent at normal listening levels. Simple distortion tests whose results correlate well with the human auditory experience simply don’t exist. Clearly, such perceptions are far too complex to quantify with a single figure.

One type of distortion that is particularly audible is intermodulation or IM distortion. Test signals generally combine a large low-frequency signal with a smaller high-frequency signal and measure how much the amplitude of the high frequency is modulated by the lower frequency. Such intermodulation creates tones at new, nonharmonic frequencies. The classic SMPTE (Society of Motion Picture and Television Engineers)
IM distortion test mixes 60 Hz and 7 kHz signals in a 4:1 amplitude ratio. For virtually all electronic amplifier circuits, there is an approximate relationship between harmonic distortion and SMPTE IM distortion. For example, if an amplifier measured 0.1% THD at 60 Hz at a given operating level, its SMPTE IM distortion would measure about three or four times that, or 0.3% to 0.4% at an equivalent operating level. This correlation is due to the fact that electronic non-linearities generally distort audio signals without regard to frequency. Actually, because of negative feedback and limited gain bandwidth, most electronic distortions become worse as frequency increases.

Distortion in audio transformers is different in a way that makes it sound unusually benign. It is caused by the smooth symmetrical curvature of the magnetic transfer characteristic or B-H loop of the core material shown in Fig. 11-9. The nonlinearity is related to flux density that, for a constant voltage input, is inversely proportional to frequency. The resulting harmonic distortion products are nearly pure third harmonic. In Fig. 11-18, note that distortion for 84% nickel cores roughly quarters for every doubling of frequency, dropping to less than 0.001% above about 50 Hz. Unlike that in amplifiers, the distortion mechanism in a transformer is frequency selective. This makes its IM distortion much less than might be expected. For example, the Jensen JT-10KB-D line input transformer has a THD of about 0.03% for a +26 dBu input at 60 Hz. But, at an equivalent level, its SMPTE IM distortion is only about 0.01%—about a tenth of what it would be for an amplifier having the same THD.

**11.1.3.2 Frequency Response**

The simplified equivalent circuit of Fig. 11-20 shows the high-pass RL filter formed by the circuit resistances and transformer primary inductance $L_p$. The effective source impedance is the parallel equivalent of $R_G + R_p$ and $R_S + R_L$. When the inductive reactance of $L_p$ equals the effective source impedance, low-frequency response will fall to 3 dB below its mid-band value. For example, consider a transformer having an $L_p$ of 10 henrys and winding resistances $R_p$ and $R_S$ of 50 $\Omega$ each. The generator impedance $R_G$ is 600 $\Omega$ and the load $R_L$ is 10 k$\Omega$. The effective source impedance is then 600 $\Omega$ + 50 $\Omega$ in parallel with 10 k$\Omega$ + 50 $\Omega$, which computes to about 610 $\Omega$. A 10 henry inductor will have 610 $\Omega$ of reactance at about 10 Hz, making response 3 dB down at that frequency. If the generator impedance $R_G$ were made 50 $\Omega$ instead, response would be −3 dB at 1.6 Hz. Lower source impedance will always extend low-frequency bandwidth. Since the filter is single pole, response falls at 6 dB per octave. As discussed earlier, the permeability of most core material steadily increases as frequency is lowered and typically reaches its maximum somewhere under 1 Hz. This results in an actual roll-off rate less than 6 dB per octave and a corresponding improvement in phase distortion—deviation from linear phase. Although a transformer cannot have response to 0 Hz or dc, it can have much less phase distortion than a coupling capacitor chosen for the same cutoff frequency. Or, as a salesperson might say, “It’s not a defect, it’s a feature.”

![Figure 11-20. Simplified low frequency transformer equivalent circuit.](image)

The simplified equivalent schematic of Fig. 11-21 shows the parasitic elements that limit and control high-frequency response.

![Figure 11-21. Simplified high-frequency transformer equivalent circuit.](image)
Except in bi-filar wound types discussed below, leakage inductance \( L_L \) and load capacitance are the major limiting factors. This is especially true in Faraday shields because of the increase in leakage inductance. Note that a low-pass filter is formed by series leakage inductance \( L_L \) with shunt winding capacitance \( C_S \) plus external load capacitance \( C_L \). Since this filter has two reactive elements, it is a two-pole filter subject to response variations caused by damping. Resistive elements in a filter provide damping, dissipating energy when the inductive and capacitive elements resonate. As shown in the figure, if damping resistance \( R_D \) is too high, response will rise before it falls and if damping resistance is too low, response falls too early. Optimum damping results in the widest bandwidth with no response peak. It should be noted that placing capacitive loads \( C_L \) on transformers with high leakage inductance not only lowers their bandwidth but also changes the resistance required for optimum damping. For most transformers, \( R_L \) controls damping. In the time domain, under-damping manifests itself as ringing on square-waves as shown in Fig. 11-22. When loaded by its specified load resistance, the same transformer responds as shown in Fig. 11-23. In some transformers, source impedance also provides significant damping.

In bi-filar wound transformers, leakage inductance \( L_L \) is very low but interwinding capacitance \( C_W \) and winding capacitances \( C_P \) and \( C_S \) are quite high. Leakage inductance must be kept very small in applications such as line drivers because large cable capacitances \( C_L \) would otherwise be disastrous to high-frequency response. Such transformers are generally referred to as output transformers. Also note that a low-pass filter is formed by series \( R_G \) and shunt \( C_P \) plus \( C_S \). Therefore, driving sources may limit high-frequency response if their source impedance \( R_G \) is too high. In normal 1:1 bi-filar output transformer designs, \( C_W \) actually works to capacitively couple very high frequencies between windings. Depending on the application, this can be either a defect or a feature.

### 11.1.3.3 Insertion Loss

The power output from a transformer will always be slightly less than power input to it. As current flows in its windings, their dc resistance causes additional voltage drops and power loss as heat. Broadly defined, **insertion loss** or **gain** is that caused by inserting a device into the signal path. But, because even an ideal lossless transformer can increase or decrease signal level by virtue of its turns ratio, the term **insertion loss** is usually defined as the difference in output signal level between the real transformer and an ideal one with the same turns ratio.

The circuit models, Thevenin equivalent circuits, and equations for both ideal and real transformers are shown in Fig. 11-24. For example, consider an ideal 1:1 turns ratio transformer and \( R_G = R_L = 600 \, \Omega \). Since \( N_p/N_s \) is 1, the equivalent circuit becomes simply \( E_i \) in series with \( R_G \) or 600 \, \Omega \). When \( R_L \) is connected, a simple voltage divider is formed, making \( E_O = 0.5 \, E_i \) or a 6.02 dB loss. For a real transformer having \( R_p = R_S = 50 \, \Omega \), the equivalent circuit becomes \( E_i \) in series with \( R_G + R_P + R_S \) or 700 \, \Omega \). Now, the output \( E_O = 0.462 \, E_i \) or a 6.72 dB loss. Therefore, the insertion loss of the transformer is 0.70 dB.

Calculations are similar for transformers with turns ratios other than 1:1, except that voltage is multiplied by the turns ratio and reflected impedances are multiplied by the turns ratio squared as shown in the equations. For example, consider a 2:1 turns ratio transformer, \( R_G = 600 \, \Omega \), and \( R_L = 150 \, \Omega \). The ideal transformer
output appears as 0.5 \( E_i \) in series with \( R_G/4 \) or 150 \( \Omega \). When \( R_L \) is connected, a simple voltage divider is formed making \( E_O = 0.25 \ E_i \) or a 12.04 dB loss. For a real transformer having \( R_P = 50 \, \Omega \) and \( R_S = 25 \, \Omega \), the equivalent circuit becomes 0.5 \( E_i \) in series with \( (R_G + R_P)/4 + R_S \) or 187.5 \( \Omega \). Now, the output \( E_O = 0.222 \ E_i \) or a 13.07 dB loss. Therefore, the insertion loss of this transformer is 1.03 dB.

**11.1.3.4 Sources with Zero Impedance**

One effect of using negative feedback around a high gain amplifier is to reduce its output impedance. Output impedance is reduced by the feedback factor, which is open-loop gain in dB minus closed-loop gain in dB. A typical op-amp with an open-loop gain of 80 dB, set for closed-loop gain of 20 dB, the feedback factor is 80 dB – 20 dB = 60 dB or 1000, will have its open-loop output impedance of 50 \( \Omega \) reduced by the feedback factor (1000) to about 0.05 \( \Omega \). Within the limits of linear operation—i.e., no current limiting or voltage clipping—the feedback around the amplifier effectively forces the output to remain constant regardless of loading. For all practical purposes the op-amp output can be considered a true voltage source.

As seen in Fig. 11-19, the distortion performance of any transformer is significantly improved when the driving source impedance is less than the dc resistance of the primary. However, little is gained for source impedances below about 10% of the winding dc resistance. For example, consider a typical line output transformer with a primary dc resistance of 40 \( \Omega \). A driving source impedance well under 4 \( \Omega \) will result in lowest distortion. The line drivers shown in Fig. 11-28 and Fig. 11-29 use a paralleled inductor and resistor to isolate or decouple the amplifier from the destabilizing effects of load (cable) capacitance at very high frequencies. Because the isolator’s impedance is well under an ohm at all audio frequencies, it is much preferred to the relatively large series, or build-out, resistor often used for the purpose. It is even possible for an amplifier to generate negative output resistance to cancel the winding resistance of the output transformer. Audio Precision uses such a patented circuit in their System 1 audio generator to reduce transformer-related distortion to extremely low levels.

**11.1.3.5 Bi-Directional Reflection of Impedances**

The impedances associated with audio transformers may seem confusing. Much of the confusion probably stems from the fact that transformers can simultaneously reflect two different impedances—one in each direction. One is the impedance of the driving source, as seen from the secondary, and the other is the impedance of the load, as seen from the primary. Transformers simply reflect impedances, modified by the square of their turns ratio, from one winding to another. However, because of their internal parasitic elements discussed previously, transformers tend to produce optimum results when used within a specified range of external impedances.
There is essentially no intrinsic impedance associated with the transformer itself. With no load on its secondary, the primary of a transformer is just an inductor and its impedance will vary linearly with frequency. For example, a 5 H primary winding would have an input impedance of about 3 kΩ at 100 Hz, 30 kΩ at 1 kHz, and 300 kΩ at 10 kHz. In a proper transformer design, this self-impedance, as well as those of other internal parasitics, should have negligible effects on normal circuit operation. The following applications will illustrate the point.

A 1:1 output transformer application is shown in Fig. 11-25. It has a winding inductance of about 25 H and negligible leakage inductance. The open circuit impedance, at 1 kHz, of either winding is about 150 kΩ. Since the dc resistance is about 40 Ω per winding, if the primary is short circuited, the secondary impedance will drop to 80 Ω. If we place the transformer between a zero-impedance amplifier (more on that later) and a load, the amplifier will see the load through the transformer and the load will see the amplifier through the transformer. In our example, the amplifier would look like 80 Ω to the output line/load and the 600 Ω line/load would look like 680 Ω to the amplifier. If the load were 20 kΩ, it would look like slightly less than 20 kΩ because the open circuit transformer impedance, 150 kΩ at 1 kHz, is effectively in parallel with it. For most applications, these effects are trivial.

A 4:1 input transformer example is shown in Fig. 11-26. It has a primary inductance of about 300 H and negligible winding capacitance. The open circuit impedance, at 1 kHz, of the primary is about 2 MΩ. Because this transformer has a 4:1 turns ratio and, therefore a 16:1 impedance ratio, the secondary open circuit impedance is about 125 kΩ. The dc resistances are about 2.5 kΩ for the primary and 92 Ω for the secondary. Since this is an input transformer, it must be used with the specified secondary load resistance of 2.43 kΩ for proper damping (flat frequency response). This load on the secondary will be transformed by the turns ratio to look like about 42 kΩ at the primary. To minimize the noise contribution of the amplifier stage, we need to know what the transformer secondary looks like, impedancewise, to the amplifier. If we assume that the primary is driven from the line in our previous output transformer example with its 80 Ω source impedance, we can calculate that the secondary will look like about 225 Ω to the amplifier input. Actually, any source impedance less than 1 kΩ would have little effect on the impedance seen at the secondary.

Transformers are not intelligent—they can’t magically couple signals in one direction only. Magnetic coupling is truly bi-directional. For example, Fig. 11-27 shows a three-winding 1:1:1 transformer connected to drive two 600 Ω loads. The driver sees the loads in parallel or, neglecting winding resistances, 300 Ω. Likewise, a short on either output will be reflected to the driver as a short. Of course, turns ratios and winding resistances must be taken into account to calculate actual driver loading. For the same reason, stereo L and R outputs that drive two windings on the same transformer are effectively driving each other, possibly causing distortion or damage.

11.1.3.6 Transformer Noise Figure

Although the step-up turns ratio of a transformer may provide noise-free voltage gain, some 20 dB for a 1:10 turns ratio, it’s important to understand that improve-
ments in signal-to-noise ratio are not solely due to this gain. Because most amplifying devices generate current noise as well as voltage noise at their inputs, their noise performance will suffer when turns ratio is not the optimum for that particular amplifier (see 21.1.2.3 Microphone Preamp Noise). Noise figure measures, in dB, how much the output signal-to-noise ratio of a system is degraded by a given system component. All resistances, including the winding resistances of transformers, generate thermal noise. Therefore, the noise figure of a transformer indicates the increase in thermal noise or hiss when it replaces an ideal noiseless transformer having the same turns ratio—i.e., voltage gain. The noise figure of a transformer is calculated as shown in Fig. 11-28.

11.1.3.7 Basic Classification by Application

Many aspects of transformer performance, such as level handling, distortion, and bandwidth, depend critically on the impedance of the driving source and, in most cases, the resistance and capacitance of the load. These impedances play such an important role that they essentially classify audio transformers into two basic types. Most simply stated, output transformers are used when load impedances are low, as in line drivers, while input transformers are used when load impedances are high, as in line receivers. The load for a line driver is not just the high-impedance equipment input it drives—it also includes the cable capacitance, whose impedance can become quite low at 20 kHz. The conflicting technical requirements for output and input types make their

The transformer noise figure is calculated by comparing a real transformer with its winding resistances to an ideal transformer with no winding resistances. First, transform all impedances to the secondary as shown to the left.

There are two components to the calculation.

1. The additional noise due to the increased output impedance.

\[
\text{REAL } Z_{\text{out}} = \frac{150 \times (15 + 1970 + 2465)}{150 + 15 + 1970 + 2465} = 17.205 \, \Omega \\
\text{IDEAL } Z_{\text{out}} = \frac{1150 + 15}{50 \times 15} = 13.636 \, \Omega \\
NF = 20 \log \left( \frac{17,206 \, (\text{REAL})}{13,636 \, (\text{IDEAL})} \right) = 1.01 \, \text{dB}
\]

2. The decrease in signal level at the output due to the increased series losses.

\[
\text{IDEAL } E_{\text{out}} = \frac{150}{150 + 15} = 0.909 \\
\text{REAL } E_{\text{out}} = \frac{150}{150 + 15 + 1970 + 2465} = 0.885 \\
NF = 20 \log \left( \frac{0.909 \, (\text{IDEAL})}{0.885 \, (\text{REAL})} \right) = 0.232 \, \text{dB}
\]

3. Total NF = 1.01 dB + 0.232 dB = 1.23 dB

Figure 11-28. Finding the noise figure of a transformer.
design and physical construction very different. Of course, some audio transformer applications need features of both input and output transformers and are not so easily classified.

Output transformers must have very low leakage inductance in order to maintain high-frequency bandwidth with capacitive loads. Because of this, they rarely use Faraday shields and are most often multi-filar wound. For low insertion loss, they use relatively few turns of large wire to decrease winding resistances. Since they use fewer turns and operate at relatively high signal levels, output transformers seldom use magnetic shielding. On the other hand, input transformers directly drive the usually high-resistance, low-capacitance input of amplifier circuitry. Many input transformers operate at relatively low signal levels, frequently have a Faraday shield, and are usually enclosed in at least one magnetic shield.

11.2 Audio Transformers for Specific Applications

Broadly speaking, audio transformers are used because they have two very useful properties. First, they can benefit circuit performance by transforming circuit impedances, to optimize amplifier noise performance, for example. Second, because there is no direct electrical connection between its primary and secondary windings, a transformer provides electrical or galvanic isolation between two circuits. As discussed in Chapter 37, isolation in signal circuits is a powerful technique to prevent or cure noise problems caused by normal ground voltage differences in audio systems. To be truly useful, a transformer should take full advantage of one or both of these properties but not compromise audio performance in terms of bandwidth, distortion, or noise.

11.2.1 Equipment-Level Applications

11.2.1.1 Microphone Input

A microphone input transformer is driven by the nominal 150 Ω, or 200 Ω in Europe, source impedance of professional microphones. One of its most important functions is to transform this impedance to a generally higher one more suited to optimum noise performance. As discussed in Chapter 21, this optimum impedance may range from 500 Ω to over 15 kΩ, depending on the amplifier. For this reason, microphone input transformers are made with turns ratios ranging from 1:2 to 1:10 or higher. The circuit of Fig. 11-29 uses a 1:5 turns ratio transformer, causing the microphone to appear as a 3.7 kΩ source to the IC amplifier, which optimizes its noise. The input impedance of the transformer is about 1.5 kΩ. It is important that this impedance remain reasonably flat with frequency to avoid altering the microphone response at frequency extremes, see Fig. 21-6.

In all balanced signal connections, common-mode noise can exist due to ground voltage differences or magnetic or electrostatic fields acting on the interconnecting cable. It is called common mode noise because it appears equally on the two signal lines, at least in theory. Perhaps the most important function of a balanced input is to reject (not respond to) this common-mode noise. A figure comparing the ratio of its differential or normal signal response to its common-mode response is called common mode rejection ratio or CMRR. An input transformer must have two attributes to achieve high CMRR. First, the capacitances of its two inputs to ground must be very well matched and as low as possible. Second, it must have minimal capacitance between its primary and secondary windings. This is usually accomplished by precision winding of

![Figure 11-29. Microphone preamplifier with 40 dB overall gain.](image-url)
the primary to evenly distribute capacitances and the incorporation of a Faraday shield between primary and secondary. Because the common-mode input impedances of a transformer consist only of capacitances of about 50 pF, transformer CMRR is maintained in real-world systems where the source impedances of devices driving the balanced line and the capacitances of the cable itself are not matched with great precision.3

Because tolerable common-mode voltage is limited only by winding insulation, transformers are well suited for phantom power applications. The standard arrangement using precision resistors is shown in Fig. 11-29. Resistors of lesser precision may degrade CMRR. Feeding phantom power through a center tap on the primary requires that both the number of turns and the dc resistance on either side of the tap be precisely matched to avoid small dc offset voltages across the primary. In most practical transformer designs, normal tolerances on winding radius and wire resistance make this a less precise method than the resistor pair. Virtually all microphone input transformers will require loading on the secondary to control high-frequency response. For the circuit in the figure, network $R_1$, $R_2$, and $C_1$ shape the high-frequency response to a Bessel roll-off curve. Because they operate at very low signal levels, most microphone input transformers also include magnetic shielding.

### 11.2.1.2 Line Input

A line input transformer is driven by a balanced line and, most often, drives a ground-referenced (unbalanced) amplifier stage. As discussed in Chapter 37, modern voltage-matched interconnections require that line inputs have impedances of 10 kΩ or more, traditionally called bridging inputs. In the circuit of Fig. 11-30, a 4:1 step-down transformer is used which has an input impedance of about 40 kΩ.

High CMRR is achieved in line input transformers using the same techniques as those for microphones. Again, because its common-mode input impedances consist of small capacitances, a good input transformer will exhibit high CMRR even when signal sources are real-world equipment with less-than-perfect output impedance balance. The dirty little secret of most electronically balanced input stages, especially simple differential amplifiers, is that they are very susceptible to tiny impedance imbalances in driving sources. However, they usually have impressive CMRR figures when the driving source is a laboratory generator. The pitfalls of measurement techniques will be discussed in section 11.3.1.

As with any transformer having a Faraday shield, line input transformers have significant leakage inductance and their secondary load effectively controls their high-frequency response characteristics. The load resistance or network recommended by the manufacturer should be used to achieve specified bandwidth and transient response. Input transformers are intended to immediately precede an amplifier stage with minimal input capacitance. Additional capacitive loading of the secondary should be avoided because of its adverse effect on frequency and phase response. For example, capacitive loads in excess of about 100 pF—about 3 ft of standard shielded cable—can degrade performance of a standard 1:1 input transformer.

### 11.2.1.3 Moving-Coil Phono Input

Moving-coil phonograph pickups are very low-impedance, very low-output devices. Some of them have source impedances as low as 3 Ω, making it nearly impossible to achieve optimum noise performance in an amplifier. The transformer shown in Fig. 11-31 has a

![Figure 11-30. Low-noise unity-gain balanced line input stage.](image-url)
three-section primary that can be series-connected as a 1:4 step-up for 25 \( \Omega \) to 40 \( \Omega \) devices and parallel-connected as a 1:12 step-up for 3 \( \Omega \) to 5 \( \Omega \) devices. In either case, the amplifier sees a 600 \( \Omega \) source impedance that optimizes low-noise operation. The transformer is packaged in double magnetic shield cans and has a Faraday shield. The loading network \( R_1, R_2, \) and \( C_1 \) tailor the high-frequency response to a Bessel curve.

**11.2.1.4 Line Output**

A line-level output transformer is driven by an amplifier and typically loaded by several thousand pF of cable capacitance plus the 20 k\( \Omega \) input impedance of a balanced bridging line receiver. At high frequencies, most driver output current is actually used driving the cable capacitance. Sometimes, terminated 150 \( \Omega \) or 600 \( \Omega \) lines must be driven, requiring even more driver output current. Therefore, a line output transformer must have a low output impedance that stays low at high frequencies. This requires both low resistance windings and very low leakage inductance, since they are effectively in series between amplifier and load. To maintain impedance balance of the output line, both driving impedances and inter-winding capacitances must be well matched at each end of the windings. A typical bi-filar-wound design has winding resistances of 40 \( \Omega \) each, leakage inductance of a few micro-henries, and a total inter-winding capacitance of about 20 nF matched to within 2% across the windings.

The high-performance circuit of Fig. 11-32 uses op-amp \( A_1 \) and current booster \( A_2 \) in a feedback loop setting overall gain at 12 dB. \( A_1 \) provides the high gain for a dc servo feedback loop used to keep dc offset at the output of \( A_2 \) under 100 \( \mu \)V. This prevents any significant dc flow in the primary of transformer \( T_1 \). \( X_1 \) provides capacitive load isolation for the amplifier and \( X_2 \) serves as a tracking impedance to maintain high-frequency impedance balance of the output. High-conductance diodes \( D_1 \) and \( D_2 \) clamp inductive kick to protect \( A_2 \) in case an unloaded output is driven into hard clipping.

The circuit of Fig. 11-33 is well suited to the lower signal levels generally used in consumer systems. Because its output floats, it can drive either balanced or unbalanced outputs, but not at the same time. Floating the unbalanced output avoids ground loop problems that are inherent to unbalanced interconnections.

In both previous circuits, because the primary drive of \( T_1 \) is single-ended, the voltages at the secondary will not be symmetrical, especially at high frequencies. **THIS IS NOT A PROBLEM.** Contrary to widespread myth and as explained in Chapter 37, signal symmetry has absolutely nothing to do with noise rejection in a balanced interface! Signal symmetry in this, or any other floating output, will depend on the magnitude and matching of cable and load impedances to ground. If there is a requirement for signal symmetry, the transformer should be driven by dual, polarity-inverted drivers.

The circuit of Fig. 11-34 uses a cathode follower circuit which replaces the usual resistor load in the cathode with an active current sink. The circuit operates at quiescent plate currents of about 10 mA and presents a driving source impedance of about 60 \( \Omega \) to the transformer, which is less than 10\% of its primary dc resistance. \( C_2 \) is used to prevent dc flow in the primary. Since the transformer has a 4:1 turns ratio, or 16:1 impedance ratio, a 600 \( \Omega \) output load is reflected back to the driver circuit as about 10 k\( \Omega \). Since the signal swings on the primary are four times as large as those on the secondary, high-frequency capacitive coupling is prevented by a Faraday shield. The secondary windings may be parallel connected to drive a 150 \( \Omega \) load. Because of the Faraday shield, output winding capacitances are low and the output signal...
Impedance, windings are sometimes section-wound to reduce capacitances. Resistive loading of the secondary is usually necessary both to provide damping and to present a uniform load impedance to the driving stage. Although uncommon, inter-stage transformers for solid-state circuitry are most often bi-filar wound units similar to line output designs.

The classic push-pull power output stage, with many variations over the years, has been used in hi-fi gear, PA systems, and guitar amplifiers. The turns ratio of the output transformer is generally chosen for a reflected load at the tubes of several thousand ohms plate-to-plate. A typical 30:1 turns ratio may require

11.2.1.5 Inter-Stage and Power Output

Inter-stage coupling transformers are seldom seen in contemporary equipment but were once quite popular in vacuum-tube amplifier designs. They typically use turns ratios in the 1:1 to 1:3 range and, as shown in Fig. 11-35, may use a center-tapped secondary producing phase-inverted signals to drive a push-pull output stage. Because both plate and grid circuits are relatively high symmetry will be determined largely by the balance of line and load impedances.

\[ X_1 \text{ and } X_2 \text{ are JT-OLI-3 or equivalent} \]

Figure 11-32. Typical line output application circuit.

Figure 11-33. Universal isolated output application.
many interleaved sections to achieve bandwidth extending well beyond 20 kHz.

If the quiescent plate currents and the number of turns in each half of the primary winding are matched, magnetic flux in the core will cancel at dc. Since any current-balancing in vacuum-tubes is temporary at best, these transformers nearly always use steel cores to better tolerate this unbalanced dc in their windings. The relatively high driving impedance of the tube plates results in considerable transformer related distortion. To reduce distortion, feedback around the transformer is often employed. To achieve stability (freedom from oscillation), very wide bandwidth (actually low phase shift) is required of the transformer when a feedback loop is closed around it. As a result, some of these output transformer designs are very sophisticated. Some legendary wisdom suggests as a rough guide that a good-fidelity output transformer should have a core weight and volume of at least 0.34 pounds and 1.4 cubic inches respectively per watt of rated power.4

A single-ended power amplifier is created by removing the lower tube and the lower half of the transformer primary from the circuit of Fig. 11-35. Now plate current will create a strong dc field in the core. As discussed in section 11.1.2.1, the core will likely require an air gap to avoid magnetic saturation. The air gap reduces inductance, limiting low-frequency response, and increases even-order distortion products. Such a single-ended pentode power amplifier was ubiquitous in classic AM 5-tube table radios of the fifties and sixties.

11.2.1.6 Microphone Output

There are two basic types of output transformers used in microphones, step-up and step-down. In a ribbon microphone, the ribbon element may have an impedance of well under 1 Ω, requiring a step-up transformer with a turns ratio of 1:12 or more to raise its output level and make its nominal output impedance around 150 Ω. Typ-
ical dynamic elements have impedances from 10 \( \Omega \) to 30 \( \Omega \), which require step-up turns ratios from 1:2 to 1:4. These step-up designs are similar to line output transformers in that they have no Faraday or magnetic shields, but are smaller because they operate at lower signal levels.

A condenser microphone has integral circuitry to buffer and/or amplify the signal from its extremely high-impedance transducer. Since this low-power circuitry operates from the phantom supply, it may be unable to directly drive the 1.5 k\( \Omega \) input impedance of a typical microphone preamp. The output transformer shown in Fig. 11-36, which has an 8:1 step-down ratio, will increase the impedance seen by \( Q_1 \) to about 100 k\( \Omega \). Because of its high turns ratio, a Faraday shield is used to prevent capacitive coupling of the primary signal to the output.

**Figure 11-36.** Condenser microphone output transformer.

### 11.2.2 System-Level Applications

#### 11.2.2.1 Microphone Isolation or Splitter

The primary of a transformer with a 1:1 turns ratio can bridge the output of a 150 \( \Omega \) to 200 \( \Omega \) microphone feeding one pre-amp and the secondary of the transformer can feed a duplicate of the microphone signal to another pre-amp. Of course, a simple Y cable could do this but there are potential problems. There are often large and noisy voltages between the grounds of two pre-amplifiers. The isolation provided by the transformer prevents the noise from coupling to the balanced signal line. To reduce capacitive noise coupling, Faraday shields are included in better designs and double Faraday shields in the best. As discussed in Section 11.1.3.5, the input impedances of all the pre-amps, as well as all the cable capacitances, will be seen in parallel by the microphone. This places a practical upper limit on how many ways the signal can be split. Transformers are commercially available in 2, 3, and 4-winding versions. A 3-way splitter box schematic is shown in Fig. 11-37. Since the microphone is directly connected only to the direct output, it is the only one that can pass phantom power to the microphone. To each preamp, each isolated output looks like a normal floating (ungrounded) microphone. The ground lift switches are normally left open to prevent possible high ground current flow in the cable shields.

**11.2.2.2 Microphone Impedance Conversion**

Some legacy dynamic microphones are high-impedance, about 50 k\( \Omega \), and have two-conductor cable and connector (unbalanced). When such a microphone must be connected to a standard balanced low-impedance microphone pre-amp, a transformer with a turns ratio of about 15:1 is necessary. Similar transformers can be used to adapt a low-impedance microphone to the unbalanced high-impedance input of a legacy pre-amplifier. Commercial products are available which enclose such a transformer in the XLR adapter barrel.

**Figure 11-37.** A 3-way microphone splitter box.
11.2.2.3 Line to Microphone Input or Direct Box

Because its high-impedance, unbalanced input accepts line-level signals and its output drives the low-level, low-impedance balanced microphone input of a mixing console, the device shown in Fig. 11-38 is called a direct box. It is most often driven by an electric guitar, synthesizer, or other stage instrument. Because it uses a transformer, it provides ground isolation as well. In this typical circuit, since the transformer has a 12:1 turns ratio, the impedance ratio is 144:1. When the microphone input has a typical 1.5 kΩ input impedance, the input impedance of the direct box is about 200 kΩ. The transformer shown has a separate Faraday shield for each winding to minimize capacitively coupled ground noise.

Figure 11-38. A transformer-isolated direct box.

11.2.2.4 Line Isolation or Hum Eliminators

There are a remarkable number of black boxes on the market intended to solve ground loop problems. This includes quite a number of transformer-based boxes. With rare exception, those boxes contain output transformers. Tests were performed to compare noise rejection of the original interface to one with an added output transformer and to one with an added input transformer. The tests accurately simulated typical real-world equipment, see the definitions at the end of this section.

Fig. 11-39 shows results of CMRR tests on a balanced interface using the IEC 60268-3 test procedure discussed in Section 11.3.1.2. This test recognizes that the impedances of real-world balanced outputs are not matched with the precision of laboratory equipment. While the output transformer reduces 60 Hz hum by over 20 dB, it has little effect on buzz artifacts over about 1 kHz. The input transformer increases rejection to over 120 dB at 60 Hz and to almost 90 dB at 3 kHz, where the human ear is most sensitive to faint sounds.

Fig. 11-40 shows results of ground noise rejection tests on an unbalanced interface. By definition, there is 0 dB of inherent rejection in an unbalanced interface, see Chapter 37. While the output transformer reduces 60 Hz hum by about 70 dB, it reduces buzz artifacts around 3 kHz by only 35 dB. The input transformer increases rejection to over 100 dB at 60 Hz and to over 65 dB at 3 kHz.

Fig. 11-41 shows results of CMRR tests when an unbalanced output drives a balanced input. A two-wire connection of this interface will result in zero rejection, see Chapter 37. Assuming a three-wire connection, the –30 dB plot shows how CMRR of typical electronically-balanced input stages is degraded by the 600 Ω source imbalance. Again, the output transformer improves 60 Hz hum by over 20 dB, it has little effect on buzz artifacts over about 1 kHz. The input transformer increases rejection to almost 100 dB at 60 Hz and to about 65 dB at 3 kHz.
Fig. 11-42 shows results of ground noise rejection tests when a balanced output drives an unbalanced input. Because our balanced output does not float, the direct connection becomes an unbalanced interface having, by definition, 0 dB of rejection. While the output transformer reduces 60 Hz hum by about 50 dB, it reduces buzz artifacts around 3 kHz by less than 20 dB. The input transformer increases rejection to almost 100 dB at 60 Hz and to about 65 dB at 3 kHz. In this application it is usually desirable to attenuate the signal by about 12 dB—from +4 dBu or 1.228 V to −10 dBV or 0.316 V—as well as provide ground isolation. This can be conveniently done by using a 4:1 step-down input transformer such as the one in Fig. 11-29, which will produce rejection comparable to that shown here.

One might fairly ask “Why not use a 1:4 step-up transformer when an unbalanced output drives a balanced input to get 12 dB of signal gain?” Because of the circuit impedances involved, the answer is because it doesn’t work very well. Recall that a 1:4 turns ratio has an impedance ratio of 1:16. This means that the input impedance of the pro balanced input we drive will be reflected back to the consumer output at one-sixteenth that. Since the source impedance—usually unspecified, but not the same as load impedance—of a consumer outputs is commonly 1 kΩ or more, the reflected loading losses are high. A 1:4 step-up transformer would have its own insertion losses, which we will rather optimistically assume at 1 dB. The table below shows actual gain using this transformer with some typical equipment output and input impedances (Z is impedance).

<table>
<thead>
<tr>
<th>Consumer Output Z</th>
<th>Pro Balanced Input Z</th>
</tr>
</thead>
<tbody>
<tr>
<td>10 kΩ (625 Ω)</td>
<td>20 kΩ (1.25 kΩ)</td>
</tr>
<tr>
<td>200 Ω</td>
<td>8.6 dB</td>
</tr>
<tr>
<td>500 Ω</td>
<td>5.9 dB</td>
</tr>
<tr>
<td>1 kΩ</td>
<td>2.7 dB</td>
</tr>
</tbody>
</table>

Not only will gain usually be much less than 12 dB, the load reflected to the consumer output, shown in parentheses, is excessive and will likely cause high distortion, loss of headroom, and poor low-frequency response. Often the only specification of a consumer output is 10 kΩ minimum load. It is futile to increase the turns ratio of the transformer in an attempt to overcome the gain problem—it only makes the reflected loading problems worse. In most situations, a 1:1 transformer can be used because the pro equipment can easily provide the required gain. Of course, a 1:1 input transformer will provide far superior noise immunity from ground loops as well.

The point here is that the noise rejection provided by an input transformer with a Faraday-shield is far superior to that provided by an output type. But the input transformer must be used at the receiver or destination end of an interface cable. In general, input transformers should drive no more than three feet of typical shielded cable—the capacitance of longer cables will erode their high-frequency bandwidth. Although output type transformers without a Faraday shield are not as good at reducing noise, their advantage is that they can be placed anywhere along an interface cable, at the driver end, at a patch-bay, or at the destination end, and work equally well (or poorly, compared to an input trans-
former). In all the test cases discussed in this section, results of using both an output and an input transformer produced results identical to those using only an input transformer. For example, an unbalanced output does not need to be balanced by a transformer before transmission through a cable (this is a corollary of the balance versus symmetry myth), it needs only an input transformer at the receiver. There is rarely a need to ever use both types on the same line.

**Definitions (in context of comparison tests only):**

**Balanced Output.** A normal, non-floating source having a differential output impedance of 600 Ω and common-mode output impedances of 300 Ω, matched to within ±0.1%.

**Balanced Input.** A typical electronically-balanced stage—an instrumentation circuit using 3 op-amps—having a differential input impedance of 40 kΩ and common-mode input impedances of 20 kΩ, trimmed for a CMRR over 90 dB when directly driven by the above Balanced Output.

**Unbalanced Output.** A ground-referenced output having an output impedance of 600 Ω. This is representative of typical consumer equipment.

**Unbalanced Input.** A ground-referenced input having an input impedance of 50 kΩ. This is representative of typical consumer equipment.

**No Transformer.** A direct wired connection.

**Output Transformer.** A Jensen JT-11-EMCF—a popular 1:1 line output transformer.

**Input Transformer.** A Jensen JT-11P-1—the most popular 1:1 line input transformer.

### 11.2.2.5 Loudspeaker Distribution or Constant Voltage

When a number of low-impedance loudspeakers are located far from a power amplifier, there are no good methods to interconnect them in a way that properly loads the amplifier. The problem is compounded by the fact that power losses due to the resistance of the inter-connecting wiring can be substantial. The wire gauge required is largely determined by the current it must carry and its length. Borrowing a technique from power utility companies, boosting the distribution voltage reduces the current for a given amount of power and allows smaller wire to be used in the distribution system. *Step-down* matching transformers, most often having taps to select power level and/or loudspeaker impedance, are used at each location. This scheme not only reduces the cost of wiring but allows system designers the freedom to choose how power is allocated among the speakers. These so-called constant-voltage loudspeaker distribution systems are widely used in public address, paging, and background music systems. Although the most popular is 70 V, others include 25 V, 100 V, and 140 V. Because the higher voltage systems offer the lowest distribution losses for a given wire size, they are more common in very large systems. It should also be noted that only the 25 V system is considered low-voltage by most regulatory agencies and the wiring in higher voltage systems may need to conform to power wiring practices.

It is important to understand that these nominal voltages exist on the distribution line only when the driving amplifier is operating at full rated power. Many specialty power amplifiers have outputs rated to drive these lines directly but ordinary power amplifiers rated to drive speakers can also drive such lines, according to Table 11-2.

| Table 11-2. Amplifier Power Required at Various Impedances Versus Output Voltage |
|---------------------------------|-----------------|-----------------|
| Amplifier Rated Output, Watts at 8 Ω | at 4 Ω | at 2 Ω |
| 1250 | 2500 | 5000 | 100 |
| 625 | 1250 | 2500 | 70.7 |
| 312 | 625 | 1250 | 50 |
| 156 | 312 | 625 | 35.3 |
| 78 | 156 | 312 | 25 |

For example, an amplifier rated to deliver 1,250 W of continuous average power into an 8 Ω load will drive a 70 V distribution line directly as long as the sum of the power delivered to all the loudspeakers doesn’t exceed 1,250 W. Although widely used, the term *rms watts* is technically ambiguous. In many cases, the benefits of constant-voltage distribution are desired, but the total power required is much less. In that case a *step-up* transformer can be used to increase the output voltage of an amplifier with less output. This is often called matching it to the line because such a transformer is actually transforming the equivalent line impedance down to the rated load impedance for the amplifier. Most of these step-up transformers will have a low turns ratio. For example, a 1:1.4 turns ratio would increase the 50 V output to 70 V for an amplifier rated at 300 W into 8 Ω. In such low-ratio applications, the *auto-transformer* discussed in Section 11.1.2.2 has cost and size advantages. Fig. 11-43 is a schematic of an auto-trans-
former with taps for turns ratios of 1:1.4 or 1:2 which could be used to drive a 70 V line from amplifiers rated for either 300 or 150 W respectively at 8 Ω. Several power amplifier manufacturers offer such transformers as options or accessories.

A line to voice-coil transformer is usually necessary to step-down the line voltage and produce the desired loudspeaker power, Table 11-3.

These step-down transformers can be designed several ways. Fig. 11-44 shows a design where the line voltage is selected at the primary side and the power level is selected at the secondary while Fig. 11-45 shows a design where power level is selected on the primary side and loudspeaker impedance is selected at the secondary.

As may be seen from the repeating patterns in the table above, there are many combinations of line voltage, loudspeaker impedance, and power level that result in the same required turns ratio in the matching transformer.

Since the constant-voltage line has a very low source impedance, and the transformer is loaded by a low-impedance loudspeaker, transformer high-frequency response is usually not a design issue. As in any transformer, low-frequency response is determined by primary inductance and total source impedance, which is dominated by the primary winding resistance since the driving source impedance is very low. Winding resistances of both primary and secondary contribute to insertion loss. In efforts to reduce size and cost, the fewest turns of the smallest wire possible are often used, which raises insertion loss and degrades low-frequency response. Generally, an insertion loss of 1 dB or less is considered good and 2 dB is marginally acceptable for these applications.

### Table 11-3. Transformer Step-Down Turns Ratio Required to Produce the Desired Loudspeaker Power

</tbody>
</table>

The table above lists the transformer step-down turns ratio required to produce the desired loudspeaker power for different speaker powers and line voltages.
It is very important to understand that, while the low-level frequency response of a transformer may be rated as −1 dB at 40 Hz, its rated power does NOT apply at that frequency. Rated power, or maximum signal level is discussed in Section 11.1.3.1. In general, level handling is increased by more primary turns and more core material and it takes more of both to handle more power at lower frequencies. This ultimately results in physically larger, heavier, and more expensive transformers. When any transformer is driven at its rated level at a lower frequency than its design will support, magnetic core saturation is the result. The sudden drop in permeability of the core effectively reduces primary inductance to zero. The transformer primary now appears to have only the dc resistance of its winding, which may be only a fraction of an ohms. In the best scenario, some ugly-sounding distortion will occur and the line amplifier will simply current limit. In the worst scenario, the amplifier will not survive the inductive energy fed back as the transformer comes out of saturation. This can be especially dangerous if large numbers of transformers saturate simultaneously.

In 1953, the power ratings of loudspeaker matching transformers were based on 2% distortion at 100 Hz.\(^6\) Traditionally, the normal application of these transformers has been speech systems and this power rating standard assumes very little energy will exist under 100 Hz. The same reference recommends that transformers used in systems with emphasized bass should have ratings higher than this 100 Hz nominal power rating and those used to handle organ music should have ratings of at least four times nominal. Since the power ratings for these transformers is rarely qualified by an honest specification stating the applicable frequency, it seems prudent to assume that the historical 100 Hz power rating applies to most commercial transformers.

If a background music system, for example, requires good bass response, it is wise to use over-rated transformers. Reducing the voltage on the primary side of the transformer will extend its low-frequency power handling. Its possible, using the table above, to use different taps to achieve the same ratio while driving less than nominal voltage into the transformer primary. For example, a 70 V line could be connected to the 100 V input of the transformer in Fig. 11-33 and, for example, the 10 W secondary tap used to actually deliver 5 W. In any constant-voltage system, saturation problems can be reduced by appropriate high-pass filtering. Simply attenuate low-frequency signals before they can reach the transformers. In voice-only systems, problems that arise from breath pops, dropped microphones, or signal switching transients can be effectively eliminated by a 100 Hz high-pass filter ahead of the power amplifier. In music systems, attenuating frequencies too low for the speakers to reproduce can be similarly helpful.

11.2.2.6 Telephone Isolation or Repeat Coil

In telephone systems it was sometimes necessary to isolate a circuit which was grounded at both ends. This metallic circuit problem was corrected with a repeat coil to improve longitudinal balance. Translating from telephone lingo, this balanced line had poor common-mode noise rejection which was corrected with a 1:1 audio isolation transformer. The Western Electric 111C repeat coil was widely used by radio networks and others for high-quality audio transmission over 600 Ω phone lines. It has split primary and secondary windings and a Faraday shield. Its frequency response was 30 Hz to 15 kHz and it had less than 0.5 dB insertion loss. Split windings allow them to be parallel connected for 150 Ω use.

Fig. 11-46 shows a modern version of this transformer as a general purpose isolator for low-impedance circuits, such as in a recording studio patch-bay. Optional components can be useful in some applications. For example, network \(R_1\) and \(C_1\) will flatten the input impedance over frequency, \(R_2\) will trim the input impedance to exactly 600 Ω, and \(R_3\) can be used to properly load the transformer when the external load is high-impedance or bridging.

11.2.2.7 Telephone Directional Coupling or Hybrid

Telephone hybrid circuits use bridge-nulling principles to separate signals which may be transmitted and received simultaneously or full-duplex on a 2-wire line. This nulling depends critically on well-controlled impedances in all branches of the circuits. This nulling is what suppresses the transmit signal (your own voice) in the receiver of your phone while allowing you to hear the receive signal (the other party).

A two-transformer hybrid network is shown in Fig. 11-47. The arrows and dashed lines show the current flow for a signal from the transmitter TX. Remember that the dots on the transformers show points having the same instantaneous polarity. The transformer turns ratios are assumed to be 1:1:1. When balancing network \(Z_N\) has an impedance that matches the line impedance \(Z_L\) at all significant frequencies, the currents in the \(Z_L\) loop (upper) and \(Z_N\) loop (lower) will be equal. Since they flow in opposite directions in the RX transformer (right), there is cancellation and the TX signal does not appear at RX. A signal originating from the line rather
than TX is not suppressed and is heard in RX. A common problem with hybrids of any kind is adjusting network $Z_N$ to match the telephone line, which may vary considerably in impedance even over relatively short time spans.

If the transmitter and receiver are electrically connected, the single transformer method, shown in Fig. 11-48, can be used. Any well-designed transformers with accurate turns ratio can be used in hybrid applications.

11.2.2.8 Moving-Coil Phono Step-Up

Outboard boxes are sometimes used to adapt the output of low-output, low-impedance moving-coil phono pickups to pre-amplifier inputs intended for conventional high-impedance moving-magnet pickups. These pre-amplifiers have a standard input impedance of 47 kΩ. Fig. 11-49 shows a 1:37 step-up transformer used for this purpose. It has a voltage gain of 31 dB and reflects its 47 kΩ pre-amplifier load to the pickup as about 35 Ω. This keeps loading loss on a 3 Ω pickup to about 1 dB. The series RC network on the secondary provides proper damping for smooth frequency response. Double magnetic shield cans are used because of the very low signal levels involved and the low-frequency gain inherent in the RIAA playback equalization. In these applications, it is extremely important to keep all leads to the pickup tightly twisted to avoid hum from ambient magnetic fields.
11.3 Measurements and Data Sheets

11.3.1 Testing and Measurements

11.3.1.1 Transmission Characteristics

The test circuits below are the basic setups to determine the signal transmission characteristics of output and input type transformers, respectively, shown in the diagrams as DUT for device under test. In each case, the driving source impedance must be specified and is split into two equal parts for transformers specified for use in balanced systems. For example, if a 600 Ω balanced source is specified, the resistors $R_s/2$ become 300 Ω each. The generator indicated in both diagrams is understood to have symmetrical voltage outputs. The buffer amplifiers shown are used to provide a zero source impedance, which is not available from most commercial signal sources. The generator could be used in an unbalanced mode by simply connecting the lower end of the DUT primary to ground. The specified load impedance must also be placed on the secondary. For output transformers, the load and meter are often floating as shown in Fig. 11-50. For input transformers, a specified end of the secondary is generally grounded as shown in Fig. 11-51.

These test circuits can be used to determine voltage gain or loss, turns ratio when $R_L$ is infinite, frequency response, and phase response. If the meter is replaced with a distortion analyzer, distortion and maximum operating level may be characterized. Multi-purpose equipment such as the Audio Precision System 1 or System 2 can make such tests fast and convenient. Testing of high-power transformers usually requires an external power amplifier to boost the generator output as well as some hefty power resistors to serve as loads.

11.3.1.2 Balance Characteristics

Tests for common-mode rejection are intended to apply a common-mode voltage through some specified resistances to the transformer under test. Any differential voltage developed then represents undesired conversion of common-mode voltage to differential mode by the transformer. In general terms, CMRR or common-mode rejection ratio, is the ratio of the response of a circuit to a voltage applied normally (differentially) to that of the same voltage applied in common-mode through specified impedances. This conversion is generally the result of mismatched internal capacitances in the balanced winding. For output transformers, the most common test arrangement is shown in Fig. 11-52. Common values are 300 Ω for RG and values from zero to 300 Ω for $R_s/2$. Resistor pairs must be very well matched.

![Figure 11-52. Common-mode test for output types.](image)

Traditionally, CMRR tests of balanced input stages involved applying the common-mode voltage through a pair of very tightly-matched resistors. As a result, such traditional tests were not accurate predictors of real-world noise rejection for the overwhelming majority of electronically-balanced inputs. The IEC recognized this in 1998 and solicited suggestions to revise the test. The problem arises from the fact that the common-mode output impedances of balanced sources in typical commercial equipment are not matched with laboratory precision. Imbalances of 10 Ω are quite common. This author, through an educational process about balanced interfaces in general, suggested a more realistic test which was eventually adopted by the IEC in their standards document 60268-3 “Testing of Amplifiers” in August, 2000. The “Informative Annex” of this document is a concise summary explaining the nature of a balanced interface. The method of the new test, as shown in Fig. 11-53, is simply to introduce a 10 Ω imbalance, first in one line and then in the other. The CMRR is then computed based on the highest differential reading observed.
11.3.1.3 Resistances, Capacitances, and Other Data

Other data which can be very helpful to an equipment or system designer includes resistances of each winding and capacitances from winding to winding or winding to Faraday shield or transformer frame. Do not use an ohmmeter to check winding resistances unless you are able to later demagnetize the part. Ordinary ohmmeters, especially on low-ohm ranges, can weakly magnetize the core. If an ohmmeter simply must be used, use the highest range where the current is least.

Capacitances are usually measured on impedance bridges and, to minimize the effects of winding inductions, with all windings shorted. Total capacitances can be measured this way, but balance of capacitances across a winding must be measured indirectly. CMRR tests are effectively measuring capacitance imbalances.

As shown in Fig. 11-54, sometimes the input impedance of a winding is measured with specified load on other windings. This test includes the effects of primary resistance, secondary resistance, and the parallel loss resistance RC shown in Fig. 11-8 and Fig. 11-13. If specified over a wide frequency range, it also includes the effects of primary inductance and winding capacitances.

Breakdown voltages are sometimes listed as measures of insulation integrity. This is normally done with special equipment, sometimes called a hi-pot tester, which applies a non-destructive high voltage while limiting current to a very low value.

11.3.2 Data Sheets

11.3.2.1 Data to Impress or to Inform?

Data sheets and specifications exist to allow easy comparison of one product with others. But, in a world where marketing seems to supersede all else, honest data sheets and guaranteed specifications are becoming increasingly rare. As with many other audio products, most so-called data sheets and specifications are designed to impress rather than inform. Specifications offered with unstated measurement conditions are essentially meaningless, so a degree of skepticism is always appropriate before comparisons are made. A few examples:

- Hum Eliminator and Line Level Shifter products with no noise rejection or CMRR specs at all!
- Line Level Shifter products with no gain spec at all! Section 11.2.2.4 explains why they won’t tell you!
- Maximum Power or Maximum Level listed with no frequency and no source impedance specified!

Other specifications, while technically true, are likely to mislead those not wise in the ways of transformers. For example, Maximum Level and Distortion are commonly specified at 50 Hz, 40 Hz, or 30 Hz instead of the more rigorous 20 Hz. Be careful, specs at these higher frequencies will always be much more impressive than those at 20 Hz! There is an approximate 6 dB per octave relationship at work here. A transformer specified for level or distortion at 40 Hz, for example, will handle about 6 dB less level at 20 Hz and have at least twice the distortion!

Seen in transformer-based hum eliminator advertising copy: “Frequency response 10 Hz to 40 kHz ±1 dB into 10 kΩ load” and “Distortion less than 0.002% at 1 kHz.” What about the source impedance? Response at 10 Hz and distortion are always much better when a transformer is driven from a 0 Ω source! What happens when a real-world source drives the box? For a full-range audio transformer, measuring distortion at 1 kHz is nearly meaningless. Section 11.1.3.1 explains.

11.3.2.2 Comprehensive Data Sheet Example

For reference, the following is offered as a sample of a data sheet that has been called truly useful and brutally honest. Note that minimum or maximum limits are guaranteed for the most critical specifications!

11.4 Installation and Maintenance

11.4.1 A Few Installation Tips

- Remember that there are very tiny wires inside an audio transformer. Its wire leads should never be used like a handle to pick it up. The internal bonds are strong, but pulling too hard might result in an open winding.
- Be careful with sharp tools. A gouge through the outer wrapper of an output transformer can nick or cut an internal winding.
- When mounting transformers that are in shielded cans, use either the supplied screws or ones no longer than recommended. If the screws are too long, they’ll bore right into the windings—big problem!
- Be careful about using magnetized tools. If a screwdriver will pick up a paper clip, it shouldn’t be used to install an audio transformer.
- Don’t drop a transformer. It can distort the fit of the laminations in output transformers and affect their low-frequency response. Mechanical stress, as in denting of the magnetic shield can of an input transformer will reduce its effectiveness as a shield. For the same reason, don’t over-tighten the clamps on transformers mounted with them.
- Twisting helps avoid hum pickup from ambient ac magnetic fields. This is especially true for microphone level lines in splitters, for example. Separately twist the leads from each winding—twisting the leads from all windings together can reduce noise rejection or CMRR.

11.4.2 De-Magnetization

Some subtle problems are created when transformer cores and/or their shield cans become magnetized. Generally, cores become magnetized by having dc flow in a winding, even for a fraction of a second. It can leave the core weakly magnetized. Steel cores, because of their wider hysteresis loops, are generally the most prone to such magnetization. The only way to know if the core has some permanent magnetization is to perform distortion measurements. A transformer with an un-magnetized core will exhibit nearly pure third harmonic distortion, with virtually no even order harmonic distortion while magnetized ones will show significant even order distortion, possibly with 2nd harmonic even exceeding 3rd. A test signal at a level about 30 or 40 dB below rated maximum operating level at 20 or 30 Hz is typically the most revealing because it maximizes the contribution of hysteresis distortion.

Microphone input transformers used with phantom power are exposed to this possibility whenever a microphone is connected or disconnected from a powered input. However, distortion tests before and after exposure to the worst-case 7 mA current pulses have shown that the effects are indeed subtle. Third harmonic distortion, which normally dominates transformer distortions, is unaffected. Second harmonic, which normally is near the measurement threshold, is typically increased by about 20 dB but is still some 15 dB lower than the third harmonic. Is it audible? Some say yes. But even this distortion disappears into the noise floor above a few hundred Hz. In any case, it can be prevented by connecting and disconnecting microphones only when phantom power is off. And such magnetized transformers can be de-magnetized.

Demagnetizing of low level transformers can generally be done with any audio generator having a continuously variable output. It may take a booster of some sort to get enough level for output transformers (be sure there’s no dc offset at its output!). The idea is to drive the transformer deeply into saturation, 5% THD or more, and then slowly bring the level down to zero. Saturation will, of course, be easiest at a very low frequency. How much level it takes will depend on the transformer. If you’re lucky, the level required may not be hazardous to the surrounding electronics and the de-magnetizing can be accomplished without disconnecting the transformer. Start with the generator set to 20 Hz and its minimum output level, connect it to the transformer, then slowly—over a period of a few seconds—increase the level into saturation—maintain it for a few seconds—then slowly bring it back down to minimum. For the vast majority of transformers, this process will leave them in a demagnetized state.

Shield cans are usually magnetized by having a brief encounter with a strongly magnetized tool. Sometimes, transformers are unknowingly mounted on a magnetized chassis. When the shield can of an input transformer becomes magnetized, the result is microphonic behavior of the transformer. Even though quality input transformers are potted with a semi-rigid epoxy compound to prevent breakage of very fine wires, vibration between core and can activate what is essentially a variable reluctance microphone. In this case, a good strong tape head de-magnetizer can be used to de-magnetize the can. At the end of the Jensen production line, most transformers are routinely demagnetized with a very strong de-magnetizer just prior to shipment. Although I haven’t tried it, I would expect that something like a degausser for 2 inch video tape (remember that!) would also de-magnetize even a large steel-core output transformer.

12.1 Tubes

In 1883, Edison discovered that electrons flowed in an evacuated lamp bulb from a heated filament to a separate electrode (the Edison effect). Fleming, making use of this principle, invented the Fleming valve in 1905, but when DeForest, in 1907, inserted the grid, he opened the door to electronic amplification with the audion. The millions of vacuum tubes are an outgrowth of the principles set forth by these men.¹

It was thought that, with the invention of the transistor and integrated circuits, the tube would disappear from audio circuits. This has hardly been the case. Recently tubes have had a revival because some “golden ears” like the smoothness and nature of the tube sound. The 1946 vintage 12AX7 is not dead and is still used today as are miniature tubes in condenser microphones and 6L6s in power amplifiers. It is interesting that many feel that a 50 W tube amplifier sounds better than a 250 W solid-state amplifier. For this reason, like the phonograph, tubes are still discussed in this handbook.

12.1.1 Tube Elements

Vacuum tubes consist of various elements or electrodes, Table 12-1. The symbols for these elements are shown in Fig. 12-1.

<table>
<thead>
<tr>
<th>Element</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Filament</td>
<td>The cathode in a directly heated tube that heats and emits electrons. A filament can also be a separate coiled element used to heat the cathode in an indirectly heated tube.</td>
</tr>
<tr>
<td>Cathode</td>
<td>The sleeve surrounding the heater that emits electrons. The surface of the cathode is coated with barium oxide or thoriated tungsten to increase the emission of electrons.</td>
</tr>
<tr>
<td>Plate</td>
<td>The positive element in a tube and the element from which the output signal is usually taken. It is also called an anode.</td>
</tr>
<tr>
<td>Control grid</td>
<td>The spiral wire element placed between the plate and cathode to which the input signal is generally applied. This element controls the flow of electrons or current between the cathode and the plate.</td>
</tr>
<tr>
<td>Screen grid</td>
<td>The element in a tetrode (four element) or pentode (five element) vacuum tube that is situated between the control grid and the plate. The screen grid is maintained at a positive potential to reduce the capacitance existing between the plate and the control grid. It acts as an electrostatic shield and prevents self-oscillation and feedback within the tube.</td>
</tr>
<tr>
<td>Suppressor grid</td>
<td>The gridlike element situated between the plate and screen in a tube to prevent secondary electrons emitted by the plate from striking the screen grid. The suppressor is generally connected to the ground or to the cathode circuit.</td>
</tr>
</tbody>
</table>

12.1.2 Tube Types

There are many types of tubes, each used for a particular purpose. All tubes require a type of heater to permit the electrons to flow. Table 12-2 defines the various types of tubes.

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Diode</td>
<td>A two-element tube consisting of a plate and a cathode. Diodes are used for rectifying or controlling the polarity of a signal as current can flow in one direction only.</td>
</tr>
<tr>
<td>Triode</td>
<td>A three-element tube consisting of a cathode, a control grid, and a plate. This is the simplest type of tube used to amplify a signal.</td>
</tr>
<tr>
<td>Tetrode</td>
<td>A four-element tube containing a cathode, a control grid, a screen grid, and a plate. It is frequently referred to as a screen-grid tube.</td>
</tr>
<tr>
<td>Pentode</td>
<td>A five-element tube containing a cathode, a control grid, a screen grid, a suppressor grid, and a plate.</td>
</tr>
<tr>
<td>Hexode</td>
<td>A six-element tube consisting of a cathode, a control grid, a suppressor grid, a screen grid, an injector grid, and a plate.</td>
</tr>
<tr>
<td>Heptode</td>
<td>A seven-element tube consisting of a cathode, a control grid, four other grids, and a plate.</td>
</tr>
<tr>
<td>Pentagrid</td>
<td>A seven-element tube consisting of a cathode, five grids, and a plate.</td>
</tr>
<tr>
<td>Beam-power tube</td>
<td>A power-output tube having the advantage of both the tetrode and pentode tubes. Beam-power tubes are capable of handling relatively high levels of output power for application in the output stage of an audio amplifier. The power-handling capabilities stem from the concentration of the plate-current electrons into beams of moving electrons. In the conventional tube the electrons flow from the cathode to the plate, but they are not confined to a beam. In a beam-power tube the internal elements consist of a cathode, a control grid, a screen grid, and two beam-forming elements that are tied internally to the cathode element. The cathode is indirectly heated as in the conventional tube.</td>
</tr>
</tbody>
</table>

12.1.3 Symbols and Base Diagrams

Table 12-3 gives the basic symbols used for tube circuits. The basing diagrams for various types of vacuum tubes are shown in Fig. 12-2.
12.1.4 Transconductance

Transconductance ($g_m$) is the change in the value of plate current expressed in microamperes (μA) divided by the signal voltage at the control grid of a tube, and is expressed by conductance. Conductance is the opposite of resistance, and the name mho (ohm spelled backward) was adopted for this unit of measurement. Siemens (S) have been adopted as the SI standard for conductance and are currently replacing mhos in measurement.

The basic mho or siemen is too large for practical usage; therefore, the terms microhmo (μmho) and microsiemens (μS) are used. One microhmo is equal to one-millionth of a mho.

The transconductance ($g_m$) of a tube in μmhos may be found with the equation

$$g_m = \frac{\Delta I_p}{\Delta E_{sig}}$$  \hspace{1cm} (12-1)

where,

- $\Delta I_p$ is the change of plate current,
- $\Delta E_{sig}$ is the change of control-grid signal voltage,
- $E_{bb}$ is the plate supply voltage and is held constant.

For example, a change of 1 mA of plate current for a change of 1 V at the control grid is equal to a transconductance of 1000 μmho. A tube having a change of 2 mA plate current for a change of 1 V at the control grid would have a transconductance of 2000 μmho.

$$g_m = I_{pac} \times 1000$$  \hspace{1cm} (12-2)

where,

- $g_m$ is the transconductance in microhmo or microsiemens,
- $I_{pac}$ is the ac plate current.

12.1.5 Amplification Factor

Amplification factor ($\mu$) or voltage gain ($V_g$) is the ratio of the incremental plate voltage change to the control-electrode voltage change at a fixed plate current and constant voltage on all other electrodes. This normally is the amount the signal at the control grid is increased in amplitude after passing through the tube.

Tube voltage gain may be computed using the equation

$$V_g = \frac{\Delta E_p}{\Delta E_g}$$  \hspace{1cm} (12-3)

where,

- $V_g$ is the voltage gain,
$\Delta E_p$ is the change in signal plate voltage, $\Delta E_g$ is the change in the signal grid voltage.

If the amplifier consists of several stages, the amount of amplification is multiplied by each stage. The gain of an amplifier stage varies with the type of tube and the interstage coupling used. The general equation for voltage gain is

$$V_{gt} = V_{g1} V_{g2} \cdots V_{gn} \quad (12-4)$$

where,

- $V_{gt}$ is the total gain of the amplifier,
- $V_{g1}$, $V_{g2}$, and $V_{gn}$ are the voltage gain of the individual stages.

Triode tubes are classified by their amplification factor. A low-$\mu$ tube has an amplification factor less than 10. Medium-$\mu$ tubes have an amplification factor from 10–50, with a plate resistance of 5 $\Omega$–15,000 $\Omega$. High-$\mu$ tubes have an amplification factor of 50–100 with a plate resistance of 50 k$\Omega$–100 k$\Omega$.

**12.1.6 Polarity**

Polarity reversals take place in a tube. The polarity reversal in electrical degrees between the elements of a self-biased pentode for a given signal at the control grid is shown in Fig. 12-3A. The reversals are the same for a triode. Note that, for an instantaneous positive voltage at the control grid, the voltage polarity between the grid and plate is 180° and will remain so for all normal operating conditions. The control grid and cathode are in polarity. The plate and screen-grid elements are in polarity with each other. The cathode is 180° out of polarity with the plate and screen-grid elements.

The polarity reversal of the instantaneous voltage and current for each element is shown in Fig. 12-3B. For an instantaneous positive sine wave at the control grid, the voltages at the plate and screen grid are negative, and the currents are positive. The voltage and current are both positive in the cathode resistor and are in polarity with the voltage at the control grid. The reversals are the same in a triode for a given element.

**12.1.7 Internal Capacitance**

The *internal capacitance* of a vacuum tube is created by the close proximity of the internal elements, Fig. 12-4. Unless otherwise stated by the manufacturer, the internal capacitance of a glass tube is measured using a close-fitting metal tube shield around the glass envelope connected to the cathode terminal. Generally, the capacitance is measured with the heater or filament cold and with no voltage applied to any of the other elements.
Output capacitance is measured from the plate to all other elements, except the control grid, which is connected to ground.

Grid-to-plate capacitance is measured from the control grid to the plate with all other elements connected to ground.

### 12.1.8 Plate Resistance

The plate resistance ($r_p$) of a vacuum tube is a constant and denotes the internal resistance of the tube or the opposition offered to the passage of electrons from the cathode to the plate. Plate resistance may be expressed in two ways: the dc resistance and the ac resistance. Dc resistance is the internal opposition to the current flow when steady values of voltage are applied to the tube elements and may be determined simply by using Ohm’s Law

$$r_{p_{dc}} = \frac{E_p}{I_p}$$  \hspace{1cm} (12-5)

where,

- $E_p$ is the dc plate voltage,
- $I_p$ is the steady value of plate current.

The ac resistance requires a family of plate-current curves from which the information may be extracted. As a rule, this information is included with the tube characteristics and is used when calculating or selecting components for an amplifier. The equation for calculating ac plate resistance is

$$r_{p_{ac}} = \frac{\Delta E_p}{\Delta I_p}$$  \hspace{1cm} (12-6)

where,

- $\Delta E_p$ is the change in voltage at the plate,
- $\Delta I_p$ is the change in plate current,
- $E_{sig}$ is the control grid signal voltage and is held constant.

The values of $E_p$ and $I_p$ are taken from the family of curves supplied by the manufacturer for the particular tube under consideration.

### 12.1.9 Grid Bias

Increasing the plate voltage or decreasing the grid-bias voltage decreases the plate resistance. The six methods most commonly used to bias a tube are illustrated in Fig. 12-5. In Fig. 12-5A bias cell (battery) is connected in series with the control grid. In Fig. 12-5B the tube is self-biased by the use of a resistor connected in the cathode circuit. In Fig. 12-5C the circuit is also a form of self-bias; however, the bias voltage is obtained by the use of a grid capacitor and grid-leak resistor connected between the control grid and ground. In Fig. 12-5D the bias voltage is developed by a grid-leak resistor and capacitor in parallel, connected in series with the control grid. The method illustrated in Fig. 12-5E is called combination bias and consists of self-bias and battery bias. The resultant bias voltage is the negative voltage of the battery, and the bias created by the self-bias resistor in the cathode circuit. Another combination bias circuit is shown in Fig. 12-5F. The bias battery is connected in series with the grid-leak resistor. The bias voltage at the control grid is that developed by the battery and the self-bias created by the combination of the grid resistor and capacitor.

**Figure 12-5.** Various methods of obtaining grid bias.

If the control grid becomes positive with respect to the cathode, it results in a flow of current between the
control grid and the cathode through the external circuits. This condition is unavoidable because the wires of the control grid, having a positive charge, attract electrons passing from the cathode to the plate. It is important that the control-grid voltage is kept negative, reducing grid current and distortion.

Grid-current flow in a vacuum tube is generally thought of as being caused by driving the control grid into the positive region and causing the flow of grid current.

The grid voltage, plate-current characteristics are found through a series of curves supplied by the tube manufacturer, as shown in Fig. 12-6.

The curves indicate that for a given plate voltage the plate current and grid bias may be determined. For example, the manufacturer states that for a plate voltage of 250 V and a negative grid bias of −8 V, the plate current will be 9 mA, which is indicated at point A on the 250 V curve. If it is desired to operate this tube with a plate voltage of 150 V and still maintain a plate current of 9 mA, the grid bias will have to be changed to a −3 V.

![Figure 12-6. Grid voltage, plate-current curves for a triode tube.](image)

12.1.10 Plate Efficiency

The plate efficiency ($E_p$) is calculated by the equation:

$$ E_{ff} = \frac{\text{watts}}{E_{pa} I_{pa}} \times 100 \quad (12-7) $$

where, watts is the power output, $E_{pa}$ is the average plate voltage, $I_{pa}$ is the average plate current.

The measurement is made with a load resistance in the plate circuit equal in value to the plate resistance stated by the manufacturer.

12.1.11 Power Sensitivity

Power sensitivity is the ratio of the power output to the square of the input voltage, expressed in mhos or siemens and is determined by the equation

$$ \text{Power sensitivity} = \frac{P_o}{E_{in}^2} \quad (12-8) $$

where, $P_o$ is the power output of the tube in watts, $E_{sig}$ is the rms signal voltage at the input.

12.1.12 Screen Grid

The screen grid series-dropping resistance is calculated by referring to the data sheet of the manufacturer and finding the maximum voltage that may be applied and the maximum power that may be dissipated by the screen grid. These limitations are generally shown graphically as in Fig. 12-7. The value of the resistor may be calculated using the equation

$$ R_{sg} = \frac{E_{sg} \times (E_{bb} - E_{sg})}{P_{sg}} \quad (12-9) $$

where, $R_{sg}$ is the minimum value for the screen-grid voltage-dropping resistor in ohms, $E_{sg}$ is the selected value of screen-grid voltage, $E_{bb}$ is the screen-grid supply voltage, $P_{sg}$ is the screen-grid input in watts corresponding to the selected value of $E_{sg}$.

12.1.13 Plate Dissipation

Plate dissipation is the maximum power that can be dissipated by the plate element before damage and is found with the equation

$$ \text{Watts dissipation} = E_p I_p \quad (12-10) $$
where,
$E_p$ is the voltage at the plate,
$I_p$ is the plate current.

### 12.1.14 Changing Parameters

If a tube is to operate at a different plate voltage than published, the new values of bias, screen voltage, and plate resistance can be calculated by the use of conversion factors $F_1$, $F_2$, $F_3$, $F_4$, and $F_5$. Assume the following conditions are specified for a single beam-power tube:
- Plate voltage: 250.0 V
- Screen voltage: 250.0 V
- Grid voltage: -12.5 V
- Plate current: 45.0 mA
- Screen current: 4.5 mA
- Plate resistance: 52,000.0 Ω
- Plate load: 5000.0 Ω
- Transconductance: 4100.0 μS
- Power output: 4.5 W

$F_1$ is used to find the new plate voltage

$$F_1 = \frac{E_{p_{\text{new}}}}{E_{p_{\text{old}}}}$$ (12-11)

For example, the new plate voltage is to be 180 V. The conversion factor $F_1$ for this voltage is obtained by dividing the new plate voltage by the published plate voltage Eq. 12-11:

$$F_1 = \frac{180}{250} = 0.72$$

The screen and grid voltage will be proportional to the plate voltage:

$$E_g = F_1 \times \text{old grid voltage} \quad (12-12)$$

$$E_{sg} = F_1 \times \text{old screen voltage} \quad (12-13)$$

In the example,

$$E_g = 0.72 \times (-12.5) = -9 \text{ V}$$

$$E_{sg} = 0.72 \times 250 = 180 \text{ V}.$$ $F_2$ is used to calculate the plate and screen currents

$$F_2 = F_1 \sqrt{F_1} \quad (12-14)$$

$$I_p = F_2 \times \text{old plate current} \quad (12-15)$$

$$I_s = F_2 \times \text{old screen current} \quad (12-16)$$

In the example,

$$F_2 = 0.72 \times 0.848 = 0.61$$

$$I_p = 0.61 \times 45 \text{ mA} = 27.4 \text{ mA}$$

$$I_{sg} = 0.61 \times 4.5 \text{ mA} = 2.74 \text{ mA}$$

The plate load and plate resistance may be calculated by use of factor $F_3$:

$$F_3 = \frac{F_1}{F_2} \quad (12-17)$$

$$r_p = F_3 \times \text{old internal plate resistance} \quad (12-18)$$

$$R_L = F_3 \times \text{old plate load resistance} \quad (12-19)$$

In the example,
The most satisfactory region of operation will be between 0.7 and 2.0. When the factor falls outside this region, the accuracy of operation is reduced.

### 12.1.15 Tube Heater

The data sheets of tube manufacturers generally contain a warning that the heater voltage should be maintained within ±10% of the rated voltage. As a rule, this warning is taken lightly, and little attention is paid to heater voltage variations, which have a pronounced effect on the tube characteristics. Internal noise is the greatest offender. Because of heater-voltage variation, emission life is shortened, electrical leakage between elements is increased, heater-to-cathode leakage is increased, and grid current is caused to flow. Thus, the life of the tube is decreased with an increase of internal noise.

### 12.2 Discrete Solid-State Devices

#### 12.2.1 Semiconductors

Conduction in solids was first observed by Munck and Henry in 1835 and later in 1874 by Braum. In 1905, Col. Dunwoody invented the crystal detector used in the detection of electromagnetic waves. It consisted of a bar of silicon carbide or carborundum held between two contacts. However, in 1903, Pickard filed a patent application for a crystal detector in which a fine wire was placed in contact with the silicon. This was the first mention of a silicon rectifier and was the forerunner of the present-day silicon rectifier. Later, other minerals such as galena (lead sulfide) were employed as detectors. During World War II, intensive research was conducted to improve crystal detectors used for microwave radar equipment. As a result of this research, the original point-contact transistor was invented at the Bell Telephone Laboratories in 1948.

A semiconductor is an electronic device whose main functioning part is made from materials, such as germanium and silicon, whose conductivity ranges between that of a conductor and an insulator.

Germanium is a rare metal discovered by Winkler in Saxony, Germany, in 1896. Germanium is a by-product of zinc mining. Germanium crystals are grown from germanium dioxide powder. Germanium in its purest state behaves much like an insulator because it has very few electrical charge carriers. The conductivity of germanium may be increased by the addition of small amounts of an impurity.
Silicon is a nonmetallic element used in the manufacture of diode rectifiers and transistors. Its resistivity is considerably higher than that of germanium.

The relative position of pure germanium and silicon is given in Fig. 12-8. The scale indicates the resistance of conductors, semiconductors, and insulators per cubic centimeter. Pure germanium has a resistance of approximately 60 \( \Omega \) cm.Germanium has a higher conductivity or less resistance to current flow than silicon and is used in low- and medium-power diodes and transistors.

![Figure 12-8. Resistance of various materials per cubic centimeter.](image)

The base elements used to make semiconductor devices are not usable as semiconductors in their pure state. They must be subjected to a complex chemical, metallurgical, and photolithographical process wherein the base element is highly refined and then modified with the addition of specific impurities. This precisely controlled process of diffusing impurities into the base element is called doping and converts the pure base material into a semiconductor material. The semiconductor mechanism is achieved by the application of a voltage across the device with the proper polarity so as to have the device act either as an extremely low resistance (the forward biased or conducting mode) or as an extremely high resistance (reversed bias or nonconducting mode). Because the device is acting as both a good conductor of electricity and also, with the proper reversal of voltage, as a good electrical nonconductor or insulator, it is called a semiconductor.

Some semiconductor materials are called \( p \) or positive type because they are processed to have an excess of positively charged ions. Others are called \( n \) or negative type because they are processed to have an excess of negatively charged electrons. When a \( p \)-type of material is brought into contact with an \( n \)-type of material, a \( pn \) junction is formed. With the application of the proper external voltage, a low-resistance path is produced between the \( n \) and \( p \) material. By reversing the previously applied voltage, an extremely high-resistance called the depletion layer between the \( p \) and \( n \) types results. A diode is an example because its conduction depends upon the polarity of the externally applied voltage. Combining several of these \( pn \) junctions together in a single device produces semiconductors with extremely useful electrical properties.

The theory of operation of a semiconductor device is approached from its atomic structure. The outer orbit of a germanium atom contains four electrons. The atomic structure for a pure germanium crystal is shown in Fig. 12-9A. Each atom containing four electrons forms covalent bonds with adjacent atoms, therefore, there are no “free” electrons. Germanium in its pure state is a poor conductor of electricity. If a piece of “pure” germanium (the size used in a transistor) has a voltage applied to it, only a few microamperes of current caused by electrons that have been broken away from their bonds by thermal agitation will flow in the circuit. This current will increase at an exponential rate with an increase of temperature.

When an atom with five electrons, such as antimony or arsenic, is introduced into the germanium crystal, the atomic structure is changed to that of Fig. 12-9B. The extra electrons (called free electrons) will move toward the positive terminal of the external voltage source. When an electron flows from the germanium crystal to the positive terminal of the external voltage source, another electron enters the crystal from the negative terminal of the voltage source. Thus, a continuous stream of electrons will flow as long as the external potential is maintained.

The atom containing the five electrons is the doping agent or donor. Such germanium crystals are classified as \( n \)-type germanium.

Using a doping agent of indium, gallium, or aluminum, each of which contains only three electrons in its outer orbit, causes the germanium crystal to take the atomic structure of Fig. 12-9C. In this structure, there is a hole or acceptor. The term hole is used to
denote a mobile particle that has a positive charge and that simulates the properties of an electron having a positive charge.

When a germanium crystal containing holes is subjected to an electrical field, electrons jump into the holes, and the holes appear to move toward the negative terminal of the external voltage source.

When a hole arrives at the negative terminal, an electron is emitted by the terminal, and the hole is canceled. Simultaneously, an electron from one of the covalent bonds flows into the positive terminal of the voltage source. This new hole moves toward the negative terminal causing a continuous flow of holes in the crystal.

Germanium crystals having a deficiency of electrons are classified *p-type germanium*. Insofar as the external electrical circuits are concerned, there is no difference between electron and hole current flow. However, the method of connection to the two types of transistors differs.

When a germanium crystal is doped so that it abruptly changes from an *n*-type to a *p*-type, and a positive potential is applied to the *p*-region, and a negative potential is applied to the *n*-region, the holes move through the junction to the right and the electrons move to the left, resulting in the voltage-current characteristic shown in Fig. 12-10A. If the potential is reversed, both electrons and holes move away from the junction until the electrical field produced by their displacement counteracts the applied electrical field. Under these conditions, zero current flows in the external circuit. Any minute amount of current that might flow is caused by thermal-generated hole pairs. Fig. 12-10B is a plot of the voltage versus current for the reversed condition. The leakage current is essentially independent of the applied potential up to the point where the junction breaks down.

**Figure 12-9.** Atomic structure of germanium.

**Figure 12-10.** Voltage-versus-current characteristics.
12.2.2 Diodes

The diode is a device that exhibits a low resistance to current flow in one direction and a high resistance in the other. Ideally, when reverse biasing the diode (connecting the negative of the supply to the diode anode), no current should flow regardless of the value of voltage impressed across the diode. A forward-biased diode presents a very low resistance to current flow.

Fig. 12-11 shows the actual diode characteristics. Starting with the diode reverse biased, a small reverse current does flow. The size of this reverse-leakage current has been exaggerated for clarity and typically is in the order of nanoamperes. The forward resistance is not constant, and therefore it does not yield a straight-line forward-conduction curve. Instead, it begins high and drops rapidly at relatively low applied voltage. Above a 0.5–1 V drop it approaches a steep straight line slope (i.e., low resistance).

In the reverse-biased region of Fig. 12-11, when the applied voltage (–V) becomes large enough, the leakage current suddenly begins to increase very rapidly, and the slope of the characteristic curves becomes very steep. Past the knee in the characteristic, even a small increase in reverse voltage causes a large increase in the reverse current. This steep region is called the breakdown or avalanche region of the diode characteristic.

The application of high reverse voltage causes the diode to break down and stop behaving like a diode. Peak-reverse-voltage rating, or prv is one of the two most important diode parameters. This is also referred to as the peak-inverse-voltage rating, or piv. This rating indicates how high the reverse voltage can be without approaching the knee and risking breakdown. Additional diode parameters are:

- Maximum average current
- Peak repetitive current
- Surge current

The maximum average current is limited by power dissipation in the junction. This power dissipation is represented by the product of forward voltage drop (Vf) and the forward current (If):

\[ P = V_f I_f \]  \hspace{1cm} (12-24)

**Selenium Rectifiers and Diodes.** A selenium rectifier cell consists of a nickel-plated aluminum baseplate coated with selenium, over which a low-temperature alloy is sprayed. The aluminum base serves as a negative electrode and the alloy as the positive. Current flows from the base plate to the alloy but encounters high resistance in the opposite direction. The efficiency of conversion depends to some extent on the ratio of the resistance in the conducting direction to that of the blocking direction. Conventional rectifiers generally have ratios from 100:1 to 1000:1.

Selenium rectifiers may be operated over temperatures of –55°C to +150°C (–67°F to +302°F). Rectification efficiency is on the order of 90% for three-phase bridge circuits and 70% for single-phase bridge circuits. As a selenium cell ages, the forward and reverse resistance increases for approximately one year and then stabilizes, decreasing the output voltage by approximately 15%. The internal impedance of a selenium rectifier is low and exhibits a nonlinear characteristic with respect to the applied voltage, maintaining a good voltage regulation. They are often used for battery charging.

Selenium rectifiers, because of their construction, have considerable internal capacitance which limits their operating range to audio frequencies. Approximate capacitance ranges are 0.10–0.15 μF/in² of rectifying surface.

The minimum voltage required for conduction in the forward direction is termed the threshold voltage and is about 1 V, therefore, selenium rectifiers cannot be used successfully below that voltage.

**Silicon Rectifiers and Diodes.** The high forward-to-reverse current characteristic of the silicon diode produces an efficiency of about 99%. When properly used, silicon diodes have long life and are not affected by aging, moisture, or temperature when used with the proper heat sink.

As an example, four individual diodes of 400 Vpiv may be connected in series to withstand a piv of 1600 V.
In a series arrangement, the most important consideration is that the applied voltage be equally distributed between the several units. The voltage drops across each individual unit must be very nearly identical. If the instantaneous voltage is not equally divided, one of the units may be subjected to a voltage exceeding its rated value, causing it to fail. This causes the other rectifiers to absorb the piv, often creating destruction of all the rectifiers.

Uniform voltage distribution can be obtained by the connection of capacitors or resistors in parallel with the individual rectifier unit, Fig. 12-12. Shunt resistors are used for steady-state applications, and shunt capacitors are used in applications where transient voltages are expected. If the circuit is exposed to both dc and ac, both shunt capacitors and resistors should be employed.

When the maximum current of a single diode is exceeded, two or more units may be connected in parallel. To avoid differences in voltage drop across the individual units, a resistor or small inductor is connected in series with each diode, Fig. 12-13. Of the two methods, the inductance is favored because of the lower voltage drop and consumption of power.

Zener and Avalanche Diodes. When the reverse voltage is increased beyond the breakdown knee of the diode characteristics as shown in Fig. 12-11, the diode impedance suddenly drops sharply to a very low value. If the current is limited by an external circuit resistance, operating in the “zener region” is normal for certain diodes specifically designed for the purpose. In zener diodes, sometimes simply called zeners, the breakdown characteristic is deliberately made as vertical as possible in the zener region so that the voltage across the diode is essentially constant over a wide reverse-current range, acting as a voltage regulator. Since its zener region voltage can be made highly repeatable and very stable with respect to time and temperature, the zener diode can also function as a voltage reference. Zener diodes come in a wide variety of voltages, currents, and powers, ranging from 3.2 V to hundreds of volts, from a few milliamperes to 10 A or more, and from about 250 mW to over 50 W.

Avalanche diodes are diodes in which the shape of the breakdown knee has been controlled, and the leakage current before breakdown has been reduced so that the diode is especially well suited to two applications: high-voltage stacking and clamping. In other words, they prevent a circuit from exceeding a certain value of voltage by causing breakdown of the diode at or just below that voltage.

Small-Signal Diodes. Small-signal diodes or general-purpose diodes are low-level devices with the same general characteristics as power diodes. They are smaller, dissipate much less power, and are not designed for high-voltage, high-power operation. Typical rating ranges are:

- $I_F$ (forward current) 1–500 mA
- $V_F$ (forward voltage drop at $I_F$) 0.2–1.1 V
- piv or prv 6–1000 V
- $I_R$ (leakage current at 80% prv) 0.1–1.0 μA

Switching Diodes. Switching diodes are small-signal diodes used primarily in digital-logic and control applications in which the voltages may change very rapidly so that speed, particularly reverse-recovery time, is of
 paramount importance. Other parameters of particular importance are low shunt capacitance, low and uniform $V_F$ (forward voltage drop), low $I_R$ (reverse leakage current), and in control circuits, prv.

**Noise Diodes.** *Noise diodes* are silicon diodes used in the avalanche mode (reverse biased beyond the breakdown knee) to generate broadband noise signals. All diodes generate some noise; these, however, have special internal geometry and are specially processed so as to generate uniform noise power over very broad bands. They are low-power devices (typically, 0.05–0.25 W) and are available in several different bandwidth classes from as low as 0 kHz–100 kHz to as high as 1000–18,000 MHz.

**Varactor Diodes.** *Varactor diodes* are made of silicon or gallium arsenide and are used as adjustable capacitors. Certain diodes, when operated in the reverse-biased mode at voltages below the breakdown value, exhibit a shunt capacitance that is inversely proportional to the applied voltage. By varying the applied reverse voltage, the capacitance of the varactor varies. This effect can be used to tune circuits, modulate oscillators, generate harmonics, and mix signals. Varactors are sometimes referred to as *voltage-tunable trimmer capacitors*.

**Tunnel Diodes.** The *tunnel diode* takes its name from the tunnel effect, a process where a particle can disappear from one side of a barrier and instantaneously reappear on the other side as though it had tunneled through the barrier element.

Tunnel diodes are made by heavily doping both the p and n materials with impurities, giving them a completely different voltage-current characteristic from regular diodes. This characteristic makes them uniquely useful in many high-frequency amplifiers as well as pulse generators and radiofrequency oscillators, Fig. 12-14.

What makes the tunnel diode work as an active element is the negative-resistance region over the voltage range $V_d$ (a small fraction of a volt). In this region, increasing the voltage decreases the current, the opposite of what happens with a normal resistor. Tunnel diodes conduct heavily in the reverse direction; in fact, there is no breakdown knee or leakage region.

### 12.2.3 Thyristors

Stack four properly doped semiconductor layers in series, pnpn (or npnp), and the result is a four-layer, or Shockley breakover diode. Adding a terminal (gate) to the second layer creates a gate-controlled, reverse-blocking *thyristor*, or *silicon-controlled rectifier* (SCR), as shown in Fig. 12-15A.
The four-layer diode connects (fires) above a specific threshold voltage. In the SCR, the gate controls this firing threshold voltage, called the forward blocking voltage.

To understand how four-layer devices work, separate the material of the layers into two three-layer transistor devices. Fig. 12-15B is an equivalent two-transistor representation in a positive-feedback connection. Assuming $a_1$ and $a_2$ are the current gains of the two transistor sections with each gain value less than unity, the total base current $I_b$ into the $n_1p_2n_2$ transistor is

$$I_b = a_1a_2I_b + I_o + I_g$$  \hspace{1cm} (12-25)

where,

- $a_1$ and $a_2$ are the transistor current gains,
- $I_b$ is the total base current,
- $I_o$ is the leakage current into the base of the $n_1p_2n_2$ transistor,
- $I_g$ is the current into the gate terminal.

The circuit turns on and becomes self-latching after a certain turn-on time needed to stabilize the feedback action, when the equality of Eq. 12-18 is achieved. This result becomes easier to understand by solving for $I_b$, which gives

$$I_b = \frac{I_o + I_g}{1 - a_1a_2}$$  \hspace{1cm} (12-26)

When the product $a_1a_2$ is close to unity, the denominator approaches zero and $I_b$ approaches a large value. For a given leakage current $I_o$, the gate current to fire the device can be extremely small. Moreover, as $I_b$ becomes large, $I_g$ can be removed, and the feedback will sustain the on condition since $a_1$ and $a_2$ then approach even closer to unity.

As applied anode voltage increases in the breakover diode, where $I_g$ is absent, $I_o$ also increases. When the quality of Eq. 12-18 is established, the diode fires. The thyristor fires when the gate current $I_g$ rises to establish equality in the equation with the anode voltage fixed. For a fixed $I_g$, the anode voltage can be raised until the thyristor fires, with $I_g$ determining the firing voltage, Fig. 12-16.

Once fired, a thyristor stays on until the anode current falls below a specified minimum holding current for a certain turnoff time. In addition, the gate loses all control once a thyristor fires. Removal or even reverse biasing of the gate signal will not turn off the device although reverse biasing can help speed turnoff. When the device is used with an ac voltage on the anode, the unit automatically turns off on the negative half of the voltage cycle. In dc switching circuits, however, complex means must often be used to remove, reduce, or reverse the anode voltage for turnoff.

Figure 12-17 shows a bilaterally conductive arrangement that behaves very much like two four-layer diodes (diacs), or two SCRs (triacs), parallel and oppositely conductive. When terminal A is positive and above the breakover voltage, a path through $p_1n_1p_2n_2$ can conduct; when terminal B is positive, path $p_2n_1p_1n_3$ can conduct. When terminal A is positive and a third element, terminal G, is sufficiently positive, the $p_1n_1p_2n_2$ path will fire at a much lower voltage than when G is zero. This action is almost identical with that of the SCR. When terminal G is made negative and terminal B is made positive, the firing point is lowered in the reverse, or $p_2n_1p_1n_3$, direction.

Because of low impedances in the on condition, four-layer devices must be operated with a series resistance in the anode and gate that is large enough to limit the anode-to-cathode or gate current to a safe value.

To understand the low-impedance, high-current capability of the thyristor, the device must be examined as a whole rather than by the two-transistor model. In Fig. 12-17B the $p_1n_1p_2$ transistor has holes injected to fire the unit, and the $n_1p_2n_2$ transistor has electrons injected. Considered separately as two transistors, the space-charge distributions would produce two typical transistor saturation-voltage forward drops, which are quite high when compared with the actual voltage drop of a thyristor.

However, when the thyristor shown in Fig. 12-17A is considered, the charges of both polarities exist simulta-
neously in the same $n_1$ and $p_2$ regions. Therefore, at the high injection levels that exist in thyristors, the mobile-carrier concentration of minority carriers far exceeds that from the background-doping density. Accordingly, the space charge is practically neutralized so that the forward drop becomes almost independent of the current density to high current levels. The major resistance to current comes from the ohmic contacts of the unit and load resistance.

The price paid for this low-impedance capability in a standard thyristor is a long turnoff time relative to turn-on time necessary to allow the high level of minority current carriers to dissipate. This long turnoff time limits the speed of a thyristor. Fortunately, this long turnoff time does not add significantly to switching power losses the way that a slow turnon time would.

**Turnoff time** is the minimum time between the forward anode current ceasing and the device being able to block reapplied forward voltage without turning on again.

**Reverse-recovery time** is the minimum time after forward conduction ceases that is needed to block reverse-voltage with ac applied to the anode-cathode circuit.

A third specification, **turnon time**, is the time a thyristor takes from the instant of triggering to when conduction is fully on.

These timing specifications limit the operating frequency of a thyristor. Two additional important specifications, the derivative of voltage with respect to time $(dv/dt)$ and the derivative of current with respect to time $(di/dt)$ limit the rates of change of voltage and current application to thyristor terminals.

A rapidly varying anode voltage can cause a thyristor to turn on even though the voltage level never exceeds the forward breakdown voltage. Because of capacitance between the layers, a current large enough to cause firing can be generated in the gated layer. Current through a capacitor is directly proportional to the rate of change of the applied voltage; therefore, the $dv/dt$ of the anode voltage is an important thyristor specification.

Turnon by the $dv/dt$ can be accomplished with as little as a few volts per microsecond in some units, especially in older designs. Newer designs are often rated in tens to hundreds of volts per microsecond.

The other important rate effect is the anode-current $di/dt$ rating. This rating is particularly important in circuits that have low inductance in the anode-cathode path. Adequate inductance would limit the rate of current rise when the device fires.

When a thyristor fires, the region near the gate conducts first; then the current spreads to the rest of the semiconductor material of the gate-controlled layer over a period of time. If the current flow through the device increases too rapidly during this period because the input-current $di/dt$ is too high, the high concentration of current near the gate could damage the device due to localized overheating. Specially designed gate structures can speed up the turnon time of a thyristor, and thus its operational frequency, as well as alleviate this hot-spot problem.

**Silicon-Controlled Rectifiers.** The SCR thyristor can be considered a solid-state latching relay if dc is used as the supply voltage for the load. The gate current turns on the SCR, which is equivalent to closing the contacts in the load circuit.

If ac is used as the supply voltage, the SCR load current will reduce to zero as the positive ac wave shape crosses through zero and reverses its polarity to a negative voltage. This will shut off the SCR. If the positive gate voltage is also removed it will not turn on during the next positive half cycle of applied ac voltage unless positive gate voltage is applied.

The SCR is suitable for controlling large amounts of rectifier power by means of small gate currents. The ratio of the load current to the control current can be several thousand to one. For example, a 10 A load current might be triggered on by a 5 mA control current.

The major time-related specification associated with SCRs is the $dv/dt$ rating. This characteristic reveals how fast a transient spike on the power line can be before it
false-triggers the SCR and starts its conducting without gate control current. Apart from this time-related parameter and its gate characteristics, SCR ratings are similar to those for power diodes.

SCRs can be used to control dc by using commuting circuits to shut them off. These are not needed on ac since the anode supply voltage reverses every half cycle. SCRs can be used in pairs or sets of pairs to generate ac from dc in inverters. They are also used as protective devices to protect against excessive voltage by acting as a short-circuit switch. These are commonly used in power supply crowbar overvoltage protection circuits. SCRs are also used to provide switched power-amplification, as in solid-state relays.

**Triacs.** The triac in Fig. 12-18 is a three-terminal semiconductor that behaves like two SCRs connected back to front in parallel so that they conduct power in both directions under control of a single gate-control circuit. Triacs are widely used to control ac power by phase shifting or delaying the gate-control signal for some fraction of the half cycle during which the power diode could be conducting. Light dimmers found in homes and offices and variable-speed drills are good examples of triac applications.

**Light-Activated Silicon-Controlled Rectifiers.** When sufficient light falls on the exposed gate junction, the SCR is turned on just as if the gate-control current were flowing. The gate terminal is also provided for optional use in some circuits. These devices are used in projector controls, positioning controls, photo relays, slave flashes, and security protection systems.

**Diacs.** The diac is shown in Fig. 12-19. It acts as two zener (or avalanche) diodes connected in series, back to back. When the voltage across the diac in either direction gets large enough, one of the zeners breaks down. The action drops the voltage to a lower level, causing a current increase in the associated circuit. This device is

**Opto-Coupled Silicon-Controlled Rectifiers.** An opto-coupled SCR is a combination of a light-emitting diode (LED) and a photo silicon-controlled rectifier (photo-SCR). When sufficient current is forced through the LED, it emits infrared radiation that triggers the gate of the photo-SCR. A small control current can regulate a large load current, and the device provides insulation and isolation between the control circuit (the LED) and the load circuit (the SCR). Opto-coupled transistors and Darlington transistors that operate on the same principle will be discussed later.

**12.2.4 Transistors**

There are many different types of transistors, and they are named by the way they are grown, or made. Fig. 12-20A shows the construction of a grown-junction transistor. An alloy-junction transistor is shown in Fig. 12-20B. During the manufacture of the material for a grown junction, the impurity content of the semiconductor is altered to provide npn or pnp regions. The grown material is cut into small sections, and contacts are attached to the regions. In the alloy-junction type, small dots of n- or p-type impurity elements are attached to either side of a thin wafer of p- or n-type semiconductor material to form regions for the emitter and collector junctions. The base connection is made to the original semiconductor material.

Drift-field transistors, Fig. 12-20C, employ a modified alloy junction in which the impurity concentration in the wafer is diffused or graded. The drift field speeds up the current flow and extends the frequency response of the alloy-junction transistor. A variation of the drift-field transistor is the microalloy diffused transistor, as shown in Fig. 12-20D. Very narrow base dimensions are achieved by etching techniques, resulting in a shortened current path to the collector.

Mesa transistors shown in Fig. 12-20E use the original semiconductor material as the collector, with the
base material diffused into the wafer and an emitter dot alloyed into the base region. A flat-topped peak or mesa is etched to reduce the area of the collector at the base junction. Mesa devices have large power-dissipation capabilities and can be operated at very high frequencies.

Double-diffused epitaxial mesa transistors are grown by the use of vapor deposition to build up a crystal layer on a crystal wafer and will permit the precise control of the physical and electrical dimensions independently of the nature of the original wafer. This technique is shown in Fig. 12-20F.

The field-effect transistor, or FET as it is commonly known, was developed by the Bell Telephone Laboratories in 1946, but it was not put to any practical use until about 1964. The principal difference between a conventional transistor and the FET is the transistor is a current-controlled device, while the FET is voltage controlled, similar to the vacuum tube. Conventional transistors also have a low-input impedance, which may at times complicate the circuit designer’s problems. The FET has a high-input impedance with a low-output impedance, much like a vacuum tube.

The basic principles of the FET operation can best be explained by the simple mechanism of a $pn$ junction. The control mechanism is the creation and control of a depletion layer, which is common to all reverse-biased junctions. Atoms in the $n$ region possess excess electrons that are available for conduction, and the atoms in the $p$ region have excess holes that may also allow current to flow. Reversing the voltage applied to the junction and allowing time for stabilization, very little current flows, but a rearrangement of the electrons and holes will occur. The positively charged holes will be drawn toward the negative terminals of the voltage source, and the electrons, which are negative, will be attracted to the positive terminal of the voltage source. This results in a region being formed near the center of the junction having a majority of the carriers removed and therefore called the depletion regions.

Referring to Fig. 12-21A, a simple bar composed of $n$-type semiconductor material has a nonrectifying contacts at each end. The resistance between the two end electrodes is

$$R = \frac{PL}{WT} \quad (12-27)$$

where,

- $P$ is the function of the material sensitivity,
- $L$ is the length of the bar,
- $W$ is the width,
- $T$ is the thickness.

Varying one or more of the variables of the resistance of the semiconductor changes the bar. Assume a $p$-region in the form of a sheet is formed at the top of the bar shown in Fig. 12-21B. A $pn$ junction is formed by diffusion, alloying, or epitaxial growth creating a reverse voltage between the $p$ and $n$-material producing two depletion regions. Current in the $n$-material is caused primarily by means of excess electrons. By reducing the concentration of electrons or majority carriers, the resistivity of the material is increased. Removal of the excess electrons by means of the deple-
tion region causes the material to become practically nonconductive.

Disregarding the \( p \) region and applying a voltage to the ends of the bar cause a current and create a potential gradient along the length of the bar material, with the voltage increasing toward the right, with respect to the negative end or ground. Connecting the \( p \) region to ground causes varying amounts of reverse-bias voltage across the \( pn \) junction, with the greatest amount developed toward the right end of the \( p \) region. A reverse voltage across the bar will produce the same depletion regions. If the resistivity of the \( p \)-type material is made much smaller than that of the \( n \)-type material, the depletion region will then extend much farther into the \( n \) material than into the \( p \) material. To simplify the following explanation, the depletion of \( p \) material will be ignored.

The general shape of the depletion is that of a wedge, increasing the size from left to right. Since the resistivity of the bar material within the depletion area is increased, the effective thickness of the conducting portion of the bar becomes less and less, going from the end of the \( p \) region to the right end. The overall resistance of the semiconductor material is greater because the effective thickness is being reduced. Continuing to increase the voltage across the ends of the bar, a point is reached where the depletion region is extended practically all the way through the bar, reducing the effective thickness to zero. Increasing the voltage beyond this point produces little change in current.

The \( p \) region controls the action and is termed a gate. The left end of the bar, being the source of majority carriers, is termed the source. The right end, being where the electrons are drained off, is called the drain. A cross-sectional drawing of a typical FET is shown in Fig. 12-21C, and three basic circuits are shown in Fig. 12-21F–H.

Insulated-gate transistors (IGT) are also known as field-effect transistors, metal-oxide silicon or semiconductor field-effect transistors (MOSFET), metal-oxide silicon or semiconductor transistors (MOST), and insulated-gate field-effect transistors (IGFET). All these devices are similar and are simply names applied to them by the different manufacturers.
The outstanding characteristics of the IGT are its extremely high input impedance, running to $10^{15} \, \Omega$. IGTs have three elements but four connections—the gate, the drain, the source, and an $n$-type substrate, into which two identical $p$-type silicon regions have been diffused. The source and drain terminals are taken from these two $p$ regions, which form a capacitance between the $n$ substrate and the silicon-dioxide insulator and the metallic gate terminals. A cross-sectional view of the internal construction appears in Fig. 12-21D, with a basic circuit shown in Fig. 12-21E. Because of the high input impedance, the IGT can easily be damaged by static charges. Strict adherence to the instructions of the manufacturer must be followed since the device can be damaged even before putting it into use.

IGTs are used in electrometers, logic circuits, and ultrasensitive electronic instruments. They should not be confused with the conventional FET used in audio equipment.

Transistor Equivalent Circuits, Current Flow, and Polarity. Transistors may be considered to be a T configuration active network, as shown in Fig. 12-22.

![Figure 12-22. Equivalent circuits for transistors.](image)

The current flow, phase, and impedances of the $nnp$ and $pnp$ transistors are shown in Fig. 12-23 for the three basic configurations, common emitter, common base and common collector. Note phase reversal only takes place in the common-emitter configuration.

The input resistance for the common-collector and common-base configuration increases with an increase of the load resistance $R_L$. For the common emitter, the input resistance decreases as the load resistance is increased; therefore, changes of input or output resistance are reflected from one to the other.

Fig. 12-24 shows the signal-voltage polarities of a $p$-channel field-effect transistor. Note the similarity to tube characteristics.

![Voltage, power, and current gains for a typical transistor using a common-emitter configuration are shown in Fig. 12-25. The current gain decreases as the load resistance is increased, and the voltage gain increases as the load resistance is increased. Maximum power gain occurs when the load resistance is approximately 40,000 $\Omega$, and it may exceed unity. For the common-collector connection, the current gain decreases as the load resistance is increased and the voltage gain increases as the load resistance is increased, but it never exceeds unity. Curves such as these help the designer to select a set of conditions for a specific result. The power gain varies as the ratio of the input to output impedance and may be calculated with the equation](image)
Zo is the output impedance in ohms, Zin is the input impedance in ohms.

Forward-Current-Transfer Ratio. An important characteristic of a transistor is its forward-current-transfer ratio, or the ratio of the current in the output to the current in the input element. Because of the many different configurations for connecting transistors, the forward transfer ratio is specified for a particular circuit configuration. The forward-current-transfer ratio for the common-base configuration is often referred to as alpha (α) and the common-emitter forward-current-transfer ratio as beta (β). In common-base circuitry, the emitter is the input element, and the collector is the output element. Therefore, αdc is the ratio of the dc collector current Ic to the dc emitter current Ib. For the common emitter, the βdc is then the ratio of the dc collector current Ic to the base current Ib. The ratios are also given in terms of the ratio of signal current, relative to the input and output, or in terms of ratio of change in the output current to the input current, which causes the change.

The terms α and β are also used to denote the frequency cutoff of a transistor and is defined as the frequency at which the value of α for a common-base configuration, or β for a common-emitter circuit, falls to 0.707 times its value at a frequency of 1000 Hz.

Gain-bandwidth product is the frequency at which the common-emitter forward-current-transfer ratio E is equal to unity. It indicates the useful frequency range of the device and assists in the determination of the most suitable configuration for a given application.

Bias Circuits. Several different methods of applying bias voltage to transistors are shown in Fig. 12-26, with a master circuit for aiding in the selection of the proper circuit shown in Fig. 12-27. Comparing the circuits shown in Fig. 12-26, their equivalents may be found by making the resistors in Fig. 12-27 equal to zero or infinity for analysis and study. As an example, the circuit of Fig. 12-26D may be duplicated in Fig. 12-27 by shorting out resistors R4 and R5 in Fig. 12-27.

The circuit Fig. 12-26G employs a split voltage divider for R2. A capacitor connected at the junction of the two resistors shunts any ac feedback current to ground. The stability of circuits A, D, and G in Fig. 12-26 may be poor unless the voltage drop across the load resistor is at least one-third the value of the power supply voltage Vcc. The final determining factors will be gain and stability.

Stability may be enhanced by the use of a thermistor to compensate for increases in collector current with increasing temperature. The resistance of the thermistor decreases as the temperature increases, decreasing the bias voltage so the collector voltage tends to remain constant. Diode biasing may also be used for both temperature and voltage variations. The diode is used to establish the bias voltage, which sets the transistor idling current or the current flow in the quiescent state.

When a transistor is biased to a nonconducting state, small reverse dc currents flow, consisting of leakage currents that are related to the surface characteristics of the semiconductor material and saturation currents. Saturation current increases with temperature and is related to the impurity concentration in the material. Collector-cutoff current is a dc current caused when the collector-to-base circuit is reverse biased and the...
emitter-to-base circuit is open. Emitter-cutoff current flows when the emitter to base is reverse biased and the collector-to-base circuit is open.

Small- and Large-Signal Characteristics. The transistor, like the vacuum tube, is nonlinear and can be classified as a nonlinear active device. Although the transistor is only slightly nonlinear, these nonlinearities become quite pronounced at very low and very high current and voltage levels. If an ac signal is applied to the base of a transistor without a bias voltage, conduction will take place on only one-half cycle of the applied signal voltage, resulting in a highly distorted output signal. To avoid high distortion, a dc-biased voltage is applied to the transistor, and the operating point is shifted to the linear portion of the characteristic curve. This improves the linearity and reduces the distortion to a value suitable for small-signal operation. Even though the transistor is biased to the most linear part of the characteristic curve, it can still add considerable distortion to the signal if driven into the nonlinear portion of the characteristic.

Small-signal swings generally run from less than 1 μV to about 10 mV so it is important that the dc-biased voltage be large enough that the applied ac
signal is small compared to the dc bias current and voltage. Transistors are normally biased at current values between 0.1 mA and 10 mA. For large-signal operation, the design procedures become quite involved mathematically and require a considerable amount of approximation and the use of nonlinear circuit analysis.

It is important to provide an impedance match between cascaded stages because of the wide difference of impedance between the input and output circuits of transistors. If the impedances are not matched, an appreciable loss of power will take place.

The maximum power amplification is obtained with a transistor when the source impedance matches the internal input resistance, and the load impedance matches the internal output resistance. The transistor is then said to be image matched.

If the source impedance is changed, it affects the internal output resistance of the transistor, requiring a change in the value of the load impedance. When transistor stages are connected in tandem, except for the grounded-emitter connection, the input impedance is considerably lower than the preceding stage output impedance. Therefore, an interstage transformer should be used to supply an impedance match in both directions.

When working between a grounded base and a grounded-emitter circuit, a step-down transformer is used. Working into a grounded-collector stage, a step-up transformer is used. Grounded-collector stages can also be used as an impedance-matching device between other transistor stages.

When adjusting the supply voltages for a transistor amplifier employing transformers, the battery voltage must be increased to compensate for the dc voltage drop across the transformer windings. The data sheets of the manufacturer should be consulted before selecting a transformer to determine the source and load impedances.

Transistor Noise Figure ($nf$). In a low-level amplifier, such as a preamplifier, noise is the most important single factor and is stated as the SNR or $nf$. Most amplifiers employ resistors in the input circuit which contribute a certain amount of measurable noise because of thermal activity. This power is generally about $-160$ dB, re: $1$ W, for a bandwidth of $10,000$ Hz. When the input signal is amplified, the noise is also amplified. If the ratio of the signal power to noise power is the same, the amplifier is noiseless and has a noise figure of unity or more. In a practical amplifier some noise is present, and the degree of impairment is the noise figure ($nf$) of the amplifier, expressed as the ratio of signal power to noise power at the output:

$$nf = \frac{S_1 \times N_o}{S_o \times N_1} \quad (12-29)$$

where,

- $S_1$ is the signal power,
- $N_1$ is the noise power,
- $S_o$ is the signal power at the output,
- $N_o$ is the noise at the output.

$$nf_{dB} = 10 \log (nf \text{ of the power ratio}) \quad (12-30)$$

For an amplifier with various $nf$, the SNR would be:

<table>
<thead>
<tr>
<th>$nf$</th>
<th>SNR</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 dB</td>
<td>1.26</td>
</tr>
<tr>
<td>3 dB</td>
<td>2</td>
</tr>
<tr>
<td>10 dB</td>
<td>10</td>
</tr>
<tr>
<td>20 dB</td>
<td>100</td>
</tr>
</tbody>
</table>

An amplifier with an $nf$ below 6 dB is considered excellent.

Low $nf$ can be obtained by the use of an emitter current of less than 1 mA, a collector voltage of less than 2 V, and a signal-source resistance below 2000 $\Omega$.

Internal Capacitance. The paths of internal capacitance in a typical transistor are shown in Fig. 12-28. The width of the $pn$ junction in the transistor varies in accordance with voltage and current, and the internal capacitance also varies. Variation of collector-base capacitance $C$ with collector voltage and emitter current is shown in Figs. 12-28B and C. The increase in the width of the $pn$ junction between the base and collector, as the reverse bias voltage ($V_{CB}$) is increased, is reflected in lower capacitance values. This phenomenon is equivalent to increasing the spacing between the plates of a capacitor. An increase in the emitter current, most of which flows through the base-collector junction, increases the collector-base capacitance ($C_{CB}$). The increased current through the $pn$ junction may be considered as effectively reducing the width of the $pn$ junction. This is equivalent to decreasing the spacing between the plates of a capacitor, therefore increasing the capacitance.

The average value of collector-base capacitance ($C_{CB}$) varies from 2–50 pF, depending on the type transistor and the manufacturing techniques. The collector-emitter capacitance is caused by the $pn$ junction. It normally is five to ten times greater than that of the collector-base capacitance and will vary with the emitter current and collector voltage.
The effect is the base disappears as the collector-base space-charge layer contacts the emitter, creating relatively low resistance between the emitter and the collector. This causes a sharp rise in the current. The transistor action then ceases. Because there is no voltage breakdown in the transistor, it will start functioning again if the voltage is lowered to a value below where punch-through occurs.

When a transistor is operated in the punch-through region, its functioning is not normal, and heat is generated internally that can cause permanent damage to the transistor.

Breakdown Voltage. Breakdown voltage is that voltage value between two given elements in a transistor at which the crystal structure changes and current begins to increase rapidly. Breakdown voltage may be measured with the third electrode open, shorted, or biased in either the forward or reverse direction. A group of collector characteristics for different values of base bias are shown in Fig. 12-30. The collector-to-emitter breakdown voltage increases as the base-to-emitter bias is decreased from the normal forward values through zero to reverse. As the resistance in the base-to-emitter circuit decreases, the collector characteristics develop two breakdown points. After the initial breakdown, the collector-to-emitter voltage decreases with an increasing collector current, until another breakdown occurs at the lower voltage.

Breakdown can be very destructive in power transistors. A breakdown mechanism, termed second breakdown, is an electrical and thermal process in which
current is concentrated in a very small area. The high current, together with the voltage across the transistor, causes intense heating, melting a hole from the collector to the emitter. This causes a short circuit and internal breakdown of the transistor.

The fundamental limitation to the use of transistors is the breakdown voltage \((B V_{CEO})\). The breakdown voltage is not sharp so it is necessary to specify the value of collector current at which breakdown will occur. This data is obtained from the data sheet of the manufacturer.

**Transistor Load Lines.** Transistor load lines are used to design circuits. An example of circuit design uses a transistor with the following characteristics:

- Maximum collector current: 10 mA
- Maximum collector voltage: –22 V
- Base current: 0 to 300 μA
- Maximum power dissipation: 300 mW

The base current curves are shown in Fig. 12-31A. The amplifier circuit is to be Class A, using a common-emitter circuit, as shown in Fig. 12-31B. By proper choice of the operating point, with respect to the transistor characteristics and supply voltage, low-distortion Class A performance is easily obtained within the transistor power ratings.

The first requirement is a set of collector-current, collector-voltage curves for the transistor to be employed. Such curves can generally be obtained from the data sheets of the manufacturer. Assuming that such data is at hand and referring to Fig. 12-31A, a curved line is plotted on the data sheet, representing the maximum power dissipation by the use of the equation

\[
I_c = \frac{P_c}{V_c}
\]

or

\[
V_c = \frac{P_c}{I_c}
\]

where,

\(I_c\) is the collector current,

\(P_c\) is the maximum power dissipation of the transistor,

\(V_c\) is the collector voltage.

At any point on this line at the intersection of \(V_c I_c\), the product equals 0.033 W or 33 mW. In determining the points for the dissipation curve, voltages are selected along the horizontal axis and the corresponding current is equated using:

\[
I_c = \frac{P_c}{V_{CE}}
\]

The current is determined for each of the major collector-voltage points, starting at 16 V and working backward until the upper end of the power curve intersects the 300 μA base current line. After entering the value on the graph for the power dissipation curve, the area to the left of the curve encompasses all points within the maximum dissipation rating of the transistor. The area to the right of the curve is the overload region and is to be avoided.

The operating point is next determined. A point that results in less than a 33 mW dissipation is selected somewhere near the center of the power curve. For this example, a 5 mA collector current at 6 V, or a dissipation of 30 mW, will be used. The selected point is indi-
cated on the graph and circled for reference. A line is drawn through the dot to the maximum collector current, 10 mA, and downward to intersect the $V_{CE}$ line at the bottom of the graph, which, for this example, is 12 V. This line is termed the *load line*. The load resistance $R_L$ may be computed with

$$R_L = \frac{dV_{CE}}{dI_C}$$  \hspace{1cm} (12-34)

where,

- $R_L$ is the load resistance,
- $dV_{CE}$ is the range of collector-to-emitter voltage,
- $dI_C$ is the range of collector current.

In the example,

$$R_L = \frac{0 - 12}{0 - 0.01} = \frac{12}{0.01} = 1200\Omega$$

Under these conditions, the entire load line dissipates less than the maximum value of 33 mW, with 90 μA of base current and 5 mA of collector current. The required base current of 90 μA may be obtained by means of one of the biasing arrangements shown in Fig. 12-26.

To derive the maximum power output from the transistor, the load line may be moved to the right and the operating point placed in the maximum dissipation curve, as shown in Fig. 12-31C. Under these conditions, an increase in distortion may be expected. As the operating point is now at 6.5 V and 5 mA, the dissipation is 33 mW. Drawing a line through the new operating point and 10 mA (the maximum current), the voltage at the lower end of the load line is 13.0 V; therefore, the load impedance is now 1300 Ω.

### 12.3 Integrated Circuits

An *integrated circuit* (IC) is a device consisting of hundreds and even thousands of components in one small enclosure, and came into being when manufacturers learned how to grow and package semiconductors and resistors.

The first ICs were small scale and usually too noisy for audio circuits; however, as time passed, the noise was reduced, stability increased, and the operational amplifier (op-amp) IC became an important part of the audio circuit. With the introduction of medium-scale integration (MSI) and large-scale integration (LSI) circuits, power amplifiers were made on a single chip with only capacitors, gain, and frequency compensation components externally connected.

Typical circuit components might use up a space 4 mils × 6 mils (1 mil = 0.001 inch) for a transistor, 3 mils × 4 mils for a diode, and 2 mils × 12 mils for a resistor. These components are packed on the surface of the semiconductor wafer and interconnected by a metal pattern that is evaporated into the top surface. Leads are attached to the wafer that is then sealed and packaged in several configurations, depending on their complexity.

ICs can be categorized by their method of fabrication or use. The most common are monolithic or hybrid and linear or digital. Operational amplifiers and most analog circuits are linear while flip-flops and on-off switch circuits are digital.

An IC is considered *monolithic* if it is produced on one single chip and *hybrid* if it consists of more than one monolithic chip tied together and/or includes discrete components such as transistors, resistors, and capacitors.

With only a few external components, ICs can perform math functions, such as trigonometry, squaring, square roots, logarithms and antilogarithms, integration, and differentiation. ICs are well suited to act as voltage comparators, zero-crossing detectors, ac and dc amplifiers, audio and video amplifiers, null detectors, and sine-, square-, or triangular-wave generators, and all at a fraction of the cost of discrete-device circuits.

#### 12.3.1 Monolithic Integrated Circuits

All circuit elements, both active and passive, are formed at the same time on a single wafer. The same circuit can be repeated many times on a single wafer and then cut to form individual 50 mil² ICs.

Bipolar transistors are often used in ICs and are fabricated much like the discrete transistor by the planar process. The differences are the contact-to-the-collector region is through the top surface rather than the substrate, requiring electrical isolation between the substrate and the collector. The integrated transistor is isolated from other components by a pn junction that creates capacitance, reducing high-frequency response and increasing leakage current, which in low-power circuits can be significant.

Integrated diodes are produced the same way as transistors and can be regarded as transistors whose terminals have been connected to give the desired characteristics.
Resistors are made at the same time as transistors. The resistance is characterized in terms of its sheet resistance, which is usually 100–200 Ω/square material for diffused resistors and 50–150 Ω/square material for deposited resistors. To increase the value of a resistor, square materials are simply connected in series.

It is very difficult to produce resistors with much closer tolerance than 10%; however, it is very easy to produce two adjacent resistors to be almost identical. When making comparator-type circuits, the circuits are balanced and are made to perform on ratios rather than absolute values. Another advantage is uniformity in temperature. As the temperature of one component varies, so does the temperature of the other components, allowing good tracking between components and circuits so ICs are usually more stable than discrete circuits.

Capacitors are made as thin-film integrated capacitors or junction capacitors. The thin-film integrated capacitor has a deposited metal layer and an $n^+$ layer isolated with a carrier-free region of silicon dioxide. In junction capacitors, both layers are diffused low-resistance semiconductor materials. Each layer has a dopant of opposite polarity; therefore, the carrier-free region is formed by the charge-depleted area at the $pn$ junction.

The MOSFET transistor has many advantages over the bipolar transistor for use in ICs as it occupies only $\frac{1}{25}$ the area of the bipolar equivalent due to lack of isolation pads. The MOSFET acts like a variable resistor and can be used as a high-value resistor. For instance, a 100 kΩ resistor might occupy only 1 mil$^2$ as opposed to 250 mil$^2$ for a diffused resistor.

The chip must finally be connected to terminals or have some means of connecting to other circuits, and it must also be packaged to protect it from the environment. Early methods included using fine gold wire to connect the chip to contacts. This was later replaced with aluminum wire ultrasonically bonded.

Flip-chip and beam-lead methods eliminate the problems of individually bonding wires. Relatively thick metal is deposited on the contact pads before the ICs are separated from the wafer. The deposited metal is then used to contact a matching metal pattern on the substrate. In the flip-chip method, globules of solder deposited on each contact pad ultrasonically bond the chip to the substrate.

In the beam-lead method, thin metal tabs lead away from the chip at each contact pad. The bonding of the leads to the substrate reduces heat transfer into the chip and eliminates pressure on the chip.

The chip is finally packaged in either hermetically sealed metal headers or is encapsulated in plastic, which is an inexpensive method of producing ICs.

### 12.3.2 Hybrid Integrated Circuits

Hybrid circuits combine monolithic and thick- and thin-film discrete components for obtaining the best solution to the design.

Active components are usually formed as monolithics; however, sometimes discrete transistors are soldered into the hybrid circuit.

Passive components such as resistors and capacitors are made with thin- and thick-film techniques. Thin films are 0.001–0.1 mil thick, while thick films are normally 60 mils thick. Resistors can be made with a value from ohms to megohms with a tolerance of 0.05% or better.

High-value capacitors are generally discrete, miniature components that are welded or soldered into the circuit, and low-value capacitors can be made as film capacitors and fabricated directly on the substrate.

Along with being certain that the components will fit into the hybrid package, the temperature must also be taken into account. The temperature rise $T_R$ of the package can be calculated with the following equation:

$$T_R = T_C - T_A = P_T \theta_{CA}$$

where,

- $T_C$ is the case temperature,
- $T_A$ is the ambient temperature,
- $P_T$ is the total power dissipation,
- $\theta_{CA}$ is the case-to-ambient thermal resistance.

The $\theta_{CA}$ for a package in free air can be approximated at 35°C/W/in$^2$ or a device will have a 35°C rise in temperature above ambient if 1 W is dissipated over an area of 1 in$^2$.

### 12.3.3 Operational Voltage Amplifiers (Op-Amp)

One of the most useful ICs for audio is the op-amp. Op-amps can be made with discrete components, but they would be very large and normally unstable to temperature and external noise.

An op-amp normally has one or more of the following features:

- Very high input impedance (>10$^6$–10$^{12}$ Ω).
- Very high open-loop (no feedback) gain.
• Low output impedance (<200 Ω).
• Wide frequency response (>100 MHz).
• Low input noise.
• High symmetrical slew rate and/or high input dynamic range.
• Low inherent distortion.

By adding external feedback paths, gain, frequency response, and stability can be controlled.

Op-amps are normally two-input differential devices; one input inverting the signal and the second input not inverting the signal, and hence called noninverting. Several typical op-amp circuits are shown in Fig. 12-32.

Because there are two inputs of opposite polarity, the output voltage is the difference between the inputs where

\[ E_{O(+)} = A_I E_2 \]  \hspace{1cm} (12-36)
\[ E_{O(-)} = A_I E_1 \]  \hspace{1cm} (12-37)

\( E_O \) is calculated with the equation

\[ E_O = A_I \times (E_1 - E_2) \]  \hspace{1cm} (12-38)

Often one of the inputs is grounded, either through a direct short or a capacitor. Therefore, the gain is either

\[ E_O = A_I E_1 \]  \hspace{1cm} (12-39)

or

\[ E_O = A_I E_2 \]  \hspace{1cm} (12-40)

To provide both a positive and negative output with respect to ground, a positive and negative power supply is required, as shown in Fig. 12-33. The supply should be regulated and filtered. Often a + and – power supply is not available, such as in an automobile, so the op-amp must operate on a single supply, as shown in Fig. 12-34. In this supply, the output dc voltage is set by adjusting \( R_1 \) and \( R_2 \) so the voltage at the noninverting input is about one-third the power supply voltage.

![Typical op-amp circuits.](image-url)
The diodes and zener diodes in Fig. 12-35 are used to protect the op-amp from damage caused by transients, reverse voltage, and overdriving. $D_6$ and $D_7$ clip the inputs before overdriving, $D_1$ and $D_2$ protect against reverse polarity, $D_4$ and $D_5$ regulate the supply, and $D_3$ limits the total voltage across the op-amp.

![Figure 12-33. Positive- and negative-type power supply.](image1)

![Figure 12-34. Simple circuit for operating on a single-ended power supply.](image2)

![Figure 12-35. Diode protection circuits for op-amps.](image3)

The dc error factors result in an output offset voltage $E_{Oo}$, which exists between the output and ground when it should be zero. The dc offset error is most easily corrected by supplying a voltage differential between the inverting and noninverting inputs, which can be accomplished by one of several methods, Fig. 12-36. Connecting the feedback resistor $R_f$ usually causes an offset and can be found with the equation

$$E_{Oo} = I_{bias}R_f$$  \hspace{1cm} (12-41)

To obtain minimum offset, make the compensating resistor shown in Fig. 12-36A equal to

$$R_{comp} = \frac{R_f}{R_f + R_{in}}$$  \hspace{1cm} (12-42)

If this method is not satisfactory, the methods of Figs. 12-36B or C might be required.

Many op-amps are internally compensated. Often it is advantageous to compensate a device externally to optimize bandwidth and slew rate, lowering distortion. Internally compensated op-amp ICs come in standard
packages—the 8 pin TO-99 metal can, the 8 pin dual-in-line package (MINI DIP), and the 14 pin DIP.

**Inverting Amplifiers.** In the *inverting amplifier* the + input is grounded and the signal is applied to the minus (−) input, Fig. 12-37. The output of the circuit is determined by the input resistor \( R_1 \) and the feedback resistor \( R_f \).

\[
E_O = E_{in} \left( \frac{-R_f}{R_1} \right) \quad (12-43)
\]

where,
\( E_{in} \) is the signal input voltage in volts,
\( R_f \) is the feedback resistor in ohms,
\( R_1 \) is the input resistor in ohms.

The low frequency rolloff is

\[
f_C = \frac{1}{2\pi R_1 C_1} \quad (12-44)
\]

![Figure 12-37. A simple inverting amplifier.](image)

**Noninverting Amplifier.** In the *noninverting amplifier*, Fig. 12-38, the signal is applied to the plus input, while the minus input is part of the feedback loop. The output is

\[
E_O = I_{in} \left( \frac{1 + R_f}{R_1} \right) \quad (12-45)
\]

The low-frequency rolloff is in two steps.

\[
f_{C_1} = \frac{1}{2\pi R_1 C_1}
\]

\[
f_{C_2} = \frac{1}{2\pi R_3 C_2}
\]

To keep low-frequency noise gain at a minimum, keep \( f_{C_1} > f_{C_2} \).

**Power Supply Compensation.** The power supply for wideband op-amp circuits should be bypassed with capacitors, Fig. 12-39A, between the plus and minus pin and common. The leads should be as short as possible and as close to the IC as possible. If this is not possible, bypass capacitors should be on each printed circuit board.

**Input Capacitance Compensation.** Stray input capacitance can lead to oscillation in feedback op-amps because it represents a potential phase shift at the frequency of

\[
f = \frac{1}{2\pi R_f C_s} \quad (12-48)
\]

where,
\( R_f \) is the feedback resistor,
\( C_s \) is the stray capacitance.

One way to reduce this problem is to keep the value of \( R_f \) low. The most useful way, however, is to add a compensation capacitor, \( C_p \) across \( R_f \) as shown in Fig. 12-39B. This makes \( C_p/R_f \) and \( C_s/R_{in} \) a frequency compensated divider.

**Output Capacitance Compensation.** Output capacitance greater than 100 pF can cause problems, requiring a series resistor \( R_o \) being installed between the output of the IC and the load and stray capacitance as shown in Fig. 12-39C. The feedback resistor \( R_f \) is connected after \( R_o \) to compensate for the loss in signal caused by \( R_o \). A compensating capacitor \( (C_f) \) bypasses \( R_f \) to reduce gain at high frequencies.

**Gain and Bandwidth.** A perfect op-amp would have infinite gain and infinite bandwidth. In real life however, the dc open loop voltage gain is around 100,000 or 100 dB and the bandwidth where gain is 0 is 1 MHz, Fig. 12-40.

To determine the gain possible in an op-amp, for a particular bandwidth, determine the bandwidth, follow vertically up to the open loop gain response curve and horizontally to the voltage gain. This, of course, is with no feedback at the upper frequency. For example, for a
frequency bandwidth of 0–10 kHz, the maximum gain of the op-amp in Fig. 12-40 is 100. To have lower distortion, it would be better to have feedback at the required upper frequency limit. To increase this gain beyond 100 would require a better op-amp or two op-amps with lower gain connected in series.

**Differential Amplifiers.** Two differential amplifier circuits are shown in Fig. 12-41. The ability of the differential amplifier to block identical signals is useful to reduce hum and noise that is picked up on input lines such as in low-level microphone circuits. This rejection is called common-mode rejection and sometimes eliminates the need for an input transformer.
In Fig. 12-41A, capacitors \( C_1 \) and \( C_2 \) block dc from the previous circuit and provide a 6 dB/octave rolloff below

\[
f_{C_1} = \frac{1}{2\pi R_1 C_1} \quad (12-49)
\]

\[
f_{C_2} = \frac{1}{2\pi (R_3 + R_4) C_2} \quad (12-50)
\]

The output voltage is

\[
E_O = (E_{in_2} - E_{in_1}) \frac{R_2}{R_1} \quad (12-51)
\]

To reduce the common mode rejection ratio (CMRR),

\[
\frac{R_2}{R_1} \equiv \frac{R_4}{R_3} \quad (12-52)
\]

and

\[
f_{C_1} = f_{C_2} \quad (12-53)
\]

**Summing Inverter Amplifiers.** In the summing inverter, Fig. 12-32G, the virtual ground characteristic of the amplifier’s summing point is used to produce a scaling adder. In this circuit, \( I_{in} \) is the algebraic sum of the number of inputs.

\[
I_{in_1} = \frac{E_{in_1}}{R_{in_1}}
\]

\[
I_{in_2} = \frac{E_{in_2}}{R_{in_2}} \quad (12-54)
\]

\[
I_{in_n} = \frac{E_{in_n}}{R_{in_n}}
\]

and the total input current is

\[
I_{in} = I_{in_1} + I_{in_2} + \ldots I_{in_n} = I_f \quad (12-55)
\]

and

\[
I_f = \frac{-E_O}{R_f} \quad (12-56)
\]

Therefore

\[
I_{in_1} + I_{in_2} + \ldots I_{in_n} = \frac{-E_O}{R_f} \quad (12-57)
\]

The output voltage is found with the equation

\[
E_O = \left[ R_{in_1} \left( \frac{R_f}{R_{in_1}} \right) + R_{in_2} \left( \frac{R_f}{R_{in_2}} \right) + \ldots R_{in_n} \left( \frac{R_f}{R_{in_n}} \right) \right] \quad (12-58)
\]

It is interesting that even though the inputs mix at one point, all signals are isolated from each other and one signal does not effect the others and one impedance does not effect the rest.

**Operational Transconductance Amplifiers.** The operational transconductance amplifier (OTA) provides transconductance gain and current output rather than voltage gain and output as in an operational amplifier. The output is the product of the input voltage and amplifier transconductance, and it can be considered an infinite impedance current generator.

Varying the bias current on the OTA can completely control the open-loop gain of the device and can also control the total power input.

OTAs are useful as multipliers, automatic gain control (AGC) amplifiers, sample and hold circuits, multiplexers, and multivibrators to name a few.

### 12.3.4 Dedicated Analog Integrated Circuits for Audio Applications

**By Les Tyler and Wayne Kirkwood, THAT Corp.**

The first ICs used in audio applications were general-purpose op-amps like the famous Fairchild µA741. Early op-amps like the classic 741 generally had drawbacks that limited their use in professional audio, from limited slew rate to poor clipping behavior.

Early on, IC manufacturers recognized that the relatively high-volume consumer audio market would make good use of dedicated ICs tailored to specific applications such as phono preamplifiers and companders. The National LM381 preamplifier and Signetics NE570 compander addressed the needs of consumer equipment makers producing high-volume products such as phono preamplifiers and cordless telephones. Operational Transconductance Amplifiers, such as the RCA CA3080, were introduced around 1970 to primarily serve the industrial market. It was not long before professional audio equipment manufacturers adapted OTAs for professional audio use as early voltage-
controlled amplifiers (VCAs). However, through the 1970s all these integrated circuits were intended more for use in consumer and industrial applications than professional audio.

In the mid-1970s, semiconductor manufacturers began to recognize that professional audio had significantly different requirements from the needs of consumer audio or industrial products. The Philips TDA1034 was the first op-amp to combine low noise, 600 Ω drive capability and high slew rate—all important characteristics to pro audio designers. Shortly after its introduction, Philips transferred production of the TDA1034 to the newly purchased Signetics division which re-branded it the NE5534. At about the same time, Texas Instruments and National Semiconductor developed general-purpose op-amps using a combination of bipolar and FET technology (the TI TLO70- and TLO80- series, and the National LF351-series, sometimes called “BIFET”). These parts offered high slew rates, low distortion, and modest noise (though not the 600 Ω drive capability of the 5534). While not specifically aimed at pro audio, these characteristics made them attractive to pro audio designers. Along with the NE5534, these op-amps became pro audio industry standards much like the 12AX7 of the vacuum tube era.

Op-amps are fundamentally general-purpose devices. The desire to control gain via a voltage, and the application of such technology to tape noise reduction, in particular, created a market for ICs that were dedicated to a specific function. This paralleled the way that phono preamplifiers spawned ICs designed for preamplification. In many ways, the VCA drove the development of early pro audio ICs.

The design of audio VCAs benefitted from the early work of Barrie Gilbert, inventor of the “Gilbert Cell” multiplier, who in 1968 published “a precise four-quadrant multiplier with subnanosecond response.”1 Gilbert discovered a current mode analog multiplication cell using current mirrors that was linear with respect to both of its inputs. Although its primary appeal at the time was to communications system designers working at RF frequencies, Gilbert laid the groundwork for many audio VCA designs.

In 1972, David E. Blackmer received U.S. Patent 3,681,618 for an “RMS Circuit with Bipolar Logarithmic Converter” and in the following year patent 3,714,462 for a “Multiplier Circuit” useful as an audio voltage-controlled amplifier. Unlike Gilbert, Blackmer used the logarithmic properties of bipolar transistors to perform the analog computation necessary for gain control and rms level detection. Blackmer’s development was targeted at professional audio.2,3

Blackmer’s timing could not have been better as the number of recording tracks expanded and, due to reduced track width coupled with the effect of summing many tracks together, tape noise increased. The expanded number of recorded tracks also increased mix complexity. Automation became a desirable feature for recording consoles because there just were not enough hands available to operate the faders.

Companies such as dbx Inc. and Dolby Laboratories benefited from this trend with tape noise reduction technologies and, in the case of dbx, VCAs for console automation. Blackmer’s discrete transistor-based rms level detectors and VCAs, made by dbx, were soon used in companding multitrack tape noise reduction and console automation systems.

The early Blackmer VCAs used discrete NPN and PNP transistors that required careful selection to match each other. Blackmer’s design would benefit greatly from integration into monolithic form. For some time this proved to be very difficult. Nonetheless, Blackmer’s discrete audio VCAs and Gilbert’s transconductance cell laid the groundwork for dedicated audio ICs. VCAs became a major focus of audio IC development.

Electronic music, not professional recording, primarily drove the early integration of monolithic VCAs and dedicated audio ICs. In 1976, Ron Dow of Solid State Music (SSM) and Dave Ross of E-mu Systems developed some of the first monolithic ICs for analog synthesizers. SSM’s first product was the SSM2000 monolithic VCA.4 Solid State Music, later to become Solid State Microtechnology, developed an entire line of audio ICs including microphone preamplifiers, VCAs, voltage-controlled filters, oscillators, and level detectors. Later, Douglas Frey developed a VCA topology known as the operational voltage-controlled element (OVCE) that was first used in the SSM2014.5 Doug Curtis, of Interdesign and later founder of Curtis Electro Music (CEM), also developed a line of monolithic ICs for the synthesizer market that proved to be very popular with manufacturers such as Oberheim, Moog, and ARP.6 VCAs produced for electronic music relied on NPN transistor gain cells to simplify integration.

In the professional audio market, Paul Buff of Valley People, David Baskind and Harvey Rubens of VCA Associates, and others in addition to Blackmer also advanced discrete VCA technology. Baskind and Rubens eventually produced a VCA IC that ultimately became the Aphex/VCA Associates “1537.”7

Blackmer’s VCAs and rms detectors used the precise logarithmic characteristics of bipolar transistors to perform mathematical operations suitable for VCAs and rms detection. The SSM, CEM, and Aphex products
used variations on the linear multiplier, where a differential pair, or differential quad, is varied to perform VCA functions and analog voltage-controlled filtering. Close transistor matching and control of temperature-related errors are required for low distortion and control feed-through in all VCA topologies.

The Gilbert multiplier, the CA3080-series of OTAs, and the VCAs produced by SSM, CEM, and Aphex all relied solely on NPN transistors as the gain cell elements. This greatly simplified the integration of the circuits. Blackmer’s log-antilog VCAs required, by contrast, precisely matched NPN and PNP transistors. This made Blackmer’s VCAs the most difficult to integrate. dbx finally introduced its 2150-series monolithic VCAs in the early 1980s, almost six years after the introduction of the SSM2000.

Many of the earlier developers of VCAs changed ownership or left the market as analog synthesis faded. Analog Devices currently produces many of the SSM products after numerous ownership changes. THAT Corporation assumed the patent portfolio of dbx Inc. Today Analog Devices, THAT Corporation, and Texas Instruments’ Burr Brown division are the primary manufacturers making analog ICs specifically for the professional audio market.

12.3.4.1 Voltage-Controlled Amplifiers

Modern IC VCAs take advantage of the inherent and precise matching of monolithic transistors that, when combined with on-chip trimming, lowers distortion to very low levels. Two types of IC audio VCAs are commonly used and manufactured today: those based on Douglas Frey’s Operational Voltage Controlled Element (OVCE) and those based on David Blackmer’s bipolar log-antilog topology.

The Analog Devices SSM2018. The Frey OVCE gain cell was first introduced in the SSM2014 manufactured by Solid State Microtechnology (SSM). SSM was acquired by Precision Monolithics, Inc, which was itself acquired by Analog Devices, who currently offers a Frey OVCE gain cell branded the SSM2018T. Frey’s original patents, U.S. 4,471,320 and U.S. 4,560,947, built upon the work of David Baskind and Harvey Rubens (see U.S. Patent 4,155,047) by adding corrective feedback around the gain cell core. Fig. 12-42 shows a block diagram of the SSM2018T VCA.

The OVCE is unique in that it has two outputs: $V_G$ and $V_{1-G}$. As the $V_G$ output increases gain with respect to control voltage, the $V_{1-G}$ output attenuates. The result is that the audio signal pans from one output to the other as the control voltage is changed.

The following expressions show how this circuit works mathematically:

\[
V_{out1} = V_G = 2K \times V_{in} \tag{12-59}
\]

and

![Figure 12-42. A block diagram of the SSM2018T VCA. Courtesy Analog Devices, Inc.](image-url)
$V_{out2} = V_1 - G$

$$= 2(1 - K) \times V_{in}$$ (12-60)

where,

$K$ varies between 0 and 1 as the control voltage is changed from full attenuation to full gain.

When the control voltage is 0 V, $K = 0.5$ and both output voltages equal the input voltage. The value $K$ is exponentially proportional to the applied control voltage; in the SSM2018T, the gain control constant in the basic VCA configuration is -30 mV/dB, so the decibel gain is directly proportional to the applied control voltage. This makes the part especially applicable to audio applications.

The SSM2018 has many applications as a VCA, but its use as a voltage-controlled panner (VCP) is perhaps one of the most unique, Fig. 12-43.

\[ I_{out} = \text{antilog}[(\log I_{in}) + 0] \]
\[ = I_{in} \times [\text{antilog}0] \]
\[ = I_{in} \times 1 \]
\[ I_{out} = I_{in} \]

Blackmer VCAs exploit the logarithmic properties of a bipolar junction transistor (BJT). In the basic Blackmer circuit, the input signal $I_{in}$ (the Blackmer VCA works in the current, not the voltage domain) is first converted to its log-domain equivalent. A control voltage, $E_C$, is added to the log of the input signal. Finally, the antilog is taken of the sum to provide an output signal $I_{out}$. This multiplies $I_{in}$ by a control constant, $E_C$. When needed, the input signal voltage is converted to a current via an input resistor, and the output signal current is converted back to a voltage via an op-amp and feedback resistor.

Like the Frey OVCE, the Blackmer VCA’s control voltage ($E_C$) is exponentiated in the process. This makes the control law exponential, or linear in dB. Many of the early embodiments of VCAs for electronic music were based on linear multiplication and required exponential converters, either external or internal to the VCA, to obtain this desirable characteristic. Fig. 12-44 shows the relationship between gain and $E_C$ for a Blackmer VCA.

Audio signals are of both polarities; that is, the sign of $I_{in}$ in the above equations will be either positive or negative at different times. Mathematically, the log of a negative number is undefined, so the circuit must be designed to handle both polarities. The essence of David Blackmer’s invention was to handle each phase—positive and negative—of the signal waveform...
with different “genders” of transistors—NPN and PNP—and to provide a class A-B bias scheme to deal with the crossover region between the two. This made it possible to generate a sort of bipolar log and antilog. A block diagram of a Blackmer VCA is shown in Fig. 12-45.

![Figure 12-45. THAT 2180 equivalent schematic. Courtesy THAT Corporation.](image)

Briefly, the circuit functions as follows. An ac input signal current $I_{IN}$ flows in pin 1, the input pin. An internal operational transconductance amplifier (OTA) maintains pin 1 at virtual ground potential by driving the emitters of $Q_1$ and (through the Voltage Bias Generator) $Q_3$. $Q_3/D_3$ and $Q_1/D_1$ act to log the input current, producing a voltage ($V_3$) that represents the bipolar logarithm of the input current. (The voltage at the junction of $D_1$ and $D_2$ is the same as $V_3$, but shifted by four forward $V_{BE}$ drops.)

Pin 8, the output, is usually connected to a virtual ground. As a result, $Q_2/D_2$ and $Q_4/D_4$ take the bipolar antilog of $V_3$, creating an output current flowing to the virtual ground, which is a precise replica of the input current. If pin 2 ($E_{C+}$) and pin 3 ($E_{C-}$) are held at ground, the output current will equal the input current. For pin 2 positive or pin 3 negative, the output current will be scaled larger than the input current. For pin 2 negative or pin 3 positive, the output current is scaled smaller than the input.

The log portion of the VCA, $D_1/Q_1$ and $D_3/Q_3$, and the antilog stages, $D_2/Q_2$ and $D_4/Q_4$ in Fig. 12-45, require both the NPN and the PNP transistors to be closely matched to maintain low distortion. As well, all the devices (including the bias network) must be at the same temperature. Integration solves the matching and temperature problems, but conventional “junction-isolated” integration is notorious for offering poor-performing PNP devices. Frey and others avoided this problem by basing their designs exclusively on NPN devices for the critical multiplier stage. Blackmer’s design required “good” PNPs as well as NPNs.

One way to obtain precisely matched PNP transistors that provide discrete transistor performance is to use an IC fabrication technology known as dielectric isolation. THAT Corporation uses dielectric isolation to fabricate integrated PNP transistors that equal or exceed the performance of NPNs. With dielectric isolation, the bottom layers of the devices are available early in the process, so both N- and P-type collectors are possible. Furthermore, each transistor is electrically insulated from the substrate and all other devices by an oxide layer, which enables discrete transistor performance with the matching and temperature characteristics only available in monolithic form.

In Fig. 12-45, it can also be seen that the Blackmer VCA has two $E_C$ inputs having opposite control response—$E_{C+}$ and $E_{C-}$. This unique characteristic allows both control inputs to be used simultaneously. Individually, gain is exponentially proportional to the voltage at pin 2, and exponentially proportional to the negative of the voltage at pin 3. When both are used simultaneously, gain is exponentially proportional to the difference in voltage between pins 2 and 3. Overall, because of the exponential characteristic, the control voltage sets gain linearly in decibels at 6 mV/DB.

Fig. 12-46 shows a typical VCA application based on a THAT2180 IC. The audio input to the VCA is a current; an input resistor converts the input voltage to a current. The VCA output is also a current. An op-amp and its feedback resistor serve to convert the VCA’s current output back to a voltage.

As with the basic topologies from Gilbert, Dow, Curtis, and other transconductance cells, the current input/output Blackmer VCA can be used as a variable conductance to tune oscillators, filters, and the like. An example of a VCA being used to control a first-order state-variable filter is shown in Fig. 12-47 with the response plot in Fig. 12-48.

When combined with audio level detectors, VCAs can be used to form a wide range of dynamics processors, including compressors, limiters, gates, duckers,
12.3.4.2 Peak, Average, and RMS Level Detection

It is often desirable to measure audio level for display, dynamics control, noise reduction, instrumentation, etc. Level detectors take different forms: among the most common are those that represent peak level, some form of average level over time, and root-mean-square (more simply known as rms level).

Peak signal level is usually interpreted to mean the highest instantaneous level within the audio bandwidth. Measuring peak level involves a detector with very fast charge (attack) response and much slower decay. Peak levels are often used for headroom and overload indication and in audio limiters to prevent even brief overload of transmission or storage media. However, peak measurements do not correlate well with perceived loudness, since the ear responds not only to the amplitude, but also to the duration of a sound.

Average-responding level detection is performed by rectification followed by a smoothing resistor/capacitor (R-C) filter whose time constants are chosen for the application. If the input is averaged over a sufficiently long period, the signal envelope is detected. Again, general-purpose op-amps serve quite well as rectifiers with R-C networks or integrators serving as averaging filters.

Rms level detection is unique in that it provides an ac measurement suitable for the calculation of signal power. Rms measurements of voltage, current, or both indicate effective power. Effective power is the heating power of a dc signal equivalent to that offered by an ac signal. True rms measurements are not affected by the signal waveform complexity, while peak and average readings vary greatly depending on the nature of the waveform. For example, a resistor heated by a 12 Vac rms signal produces the same number of watts—and heat—as a resistor connected to 12 Vac. This is true regardless of whether the ac waveform is a pure sinusoid, a square wave, a triangle wave or music. In instrumentation, rms is often referred to as true rms to distinguish it from average-responding instruments that are calibrated to read rms only for sinusoidal inputs. Importantly, in audio signal-processing applications, rms response is thought to closely approximate the human perception of loudness.

12.3.4.3 Peak and Average Detection with Integrated Circuits

The fast response of a peak detector is often desirable for overload indication or dynamics control when a signal needs to be limited to fit the strict level confines of a transmission or storage medium. A number of op-amp-based circuits detect peak levels using full or half-wave rectification. General-purpose op-amps are quite useful for constructing peak detectors and are discussed in Section 12.3.3. The recently discontinued Analog Devices PKD01 was perhaps the only peak detector IC suited for audio applications.

Average-responding level detection is performed by rectification followed by a smoothing resistor/capacitor (R-C) filter whose time constants are chosen for the application. If the input is averaged over a sufficiently long period, the signal envelope is detected. Again, general-purpose op-amps serve quite well as rectifiers with R-C networks or integrators serving as averaging filters.

Rms level detection has many applications in acoustic and industrial instrumentation. As mentioned previously, rms level detectors are thought to respond similarly to...
the human perception of loudness. This makes them particularly useful for audio dynamics control.

Rms is mathematically defined as the square root of the mean of the square of a waveform. Electronically, the mean is equal to the average, which can be approximated by an R-C network or an op-amp-based integrator. However, calculating the square and square root of waveforms is more difficult.

Designers have come up with a number of clever techniques to avoid the complexity of numerical rms calculation. For example, the heat generated by a resistive element may be used to measure power. Power is directly proportional to the square of the voltage across, or current through, a resistor, so the heat given off is proportional to the square of the applied signal level. To measure large amounts of power having very complex waveforms, such as the RF output of a television transmitter, a resistor dummy load is used to heat water. The temperature rise is proportional to the transmitter power. Such caloric instruments are naturally slow to respond, and impractical for the measurement of sound. Nonetheless, solid-state versions of this concept have been integrated, as, for example U.S. Patent 4,346,291, invented by Roy Chapel and Macit Gurol. This patent, assigned to instrumentation manufacturer Fluke, describes the use of a differential amplifier to match the power dissipated in a resistive element, thus measuring the true rms component of current or voltage applied to the element. While very useful in instrumentation, this technique has not made it into audio products due to the relatively slow time constants of the heating element.

To provide faster time constants to measure small rms voltages or currents with complex waveforms such as sound, various analog computational methods have been employed. Computing the square of a signal generally requires extreme dynamic range, which limits the usefulness of direct analog methods in computing rms value. As well, the square and square-root operations require complex analog multipliers, which have traditionally been expensive to fabricate.

As with VCAs, the analog computation required for rms level detection is simplified by taking advantage of the logarithmic properties of bipolar junction transistors. The seminal work on computing rms values for audio applications was developed by David E. Blackmer, who received U.S. Patent 3,681,618 for an “RMS Circuit with Bipolar Logarithmic Converter.” Blackmer’s circuit, discussed later, took advantage of two important log-domain properties to compute the square and square root. In the log domain, a number is squared by multiplying it by 2; the square root is obtained by dividing it by 2.

For example, to square the signal $V_{in}$ use

---

**Figure 12-47.** VCA state-variable filter. Courtesy THAT Corporation.

**Figure 12-48.** State-variable filter response. Courtesy THAT Corporation.
\[ V_{in}^2 = \text{antilog}[(\log V_{in}) \times 2] \]  
(12-62)

To take the square root of \( V \log \),
\[ \sqrt{V \log} = \text{antilog}\left[\frac{\log(V \log)}{2}\right] \]  
(12-63)

12.3.4.5 RMS Level Detection ICs

Because RMS level detectors are more complex than either peak- or average-responding circuits, they benefit greatly from integration. Fortunately, a few ICs are suitable for the professional audio applications. Two ICs currently in production are the Analog Devices AD636 and the THAT Corporation THAT2252.

**Analog Devices AD636.** The AD636 has enjoyed wide application in audio and instrumentation. Its predecessor, the AD536, was used in the channel dynamics processor of the SSL 4000 series console in conjunction with a dbx VCA. Thousands of these channels are in daily use worldwide.

The AD636 shown in Fig. 12-49 provides both a linear-domain RMS output and a dB-scaled logarithmic output. The linear output at pin 8 is ideal for applications where the RMS input voltage must be read with a dc meter. Suitably scaled, 1 Vrms input can produce 1 Vdc at the buffer output, pin 6.

In audio applications such as signal processors, it is often most useful to express the signal level in dB. The AD636 also provides a dB-scaled current output at pin 5. The linear dB output is particularly useful with exponentially controlled VCAs such as the SSM2018 or THAT 2180 series.

Averaging required to calculate the mean of the sum of the squares is performed by a capacitor, \( C_{AV} \), connected to pin 4. Fig. 12-50 shows an AD636 used as an audio dB meter for measurement applications.

**THAT Corporation THAT2252.** The 2252 IC uses the technique taught by David Blackmer to provide wide dynamic range, logarithmic linear dB output, and relatively fast time constants. Blackmer’s detector delivers a fast attack with a slow linear dB decay characteristic in the log domain.17 Because it was specifically developed for audio applications, it has become a standard for use in companding noise reduction systems and VCA-based compressor/limiters.

A simplified schematic of Blackmer’s RMS detector, used in the THAT2252, is shown in Fig. 12-51.

The audio input is first converted to a current \( I_{in} \) by an external resistor (not shown in Fig. 12-51). \( I_{in} \) is full-wave rectified by a current mirror rectifier formed by OA1 and \( Q_1-Q_3 \), such that IC4 is a full-wave rectified version of \( I_{in} \). Positive input currents are forced to flow through \( Q_1 \), and mirrored to \( Q_2 \) as IC2; negative input currents flow through \( Q_3 \) as IC3; both IC2 and IC3 thus flow through \( Q_4 \). (Note that pin 4 is normally connected to ground through an external 20 \( \Omega \) resistor.)

Performing the absolute value before logarithmic conversion avoids the problem that, mathematically, the log of a negative number is undefined. This eliminates the requirement for bipolar logarithmic conversion and the PNP transistors required for log-domain VCAs.

OA2, together with \( Q_4 \) and \( Q_5 \), forms a log amplifier. Due to the two diode-connected transistors in the feedback loop of OA2, the voltage at its output is proportional to twice the log of IC4. This voltage, \( V_{log} \), is therefore proportional to the log of \( I_{in}^2 \) (plus the bias voltage \( V_2 \)).

To average \( V_{log} \), pin 6 is usually connected to a capacitor \( C_T \) and a negative current source \( R_T \). See Fig. 12-52. The current source establishes a quiescent dc bias current, \( I_T \) through diode-connected \( Q_6 \). Over time, \( C_T \) charges to 1 Vbe below \( V_{log} \).

\( Q_6 \)’s emitter current is proportional to the antilog of its \( V_{be} \). The potential at the base (and collector) of \( Q_6 \) represents the log of \( I_{in}^2 \) while the emitter of \( Q_6 \) is held at ac ground via the capacitor. Thus, the current in \( Q_6 \) is proportional to the square of the instantaneous change in input current. This dynamic antilogging causes the capacitor voltage to represent the log of the mean of the square of the input current. Another way to characterize the operation of \( Q_6 \), \( C_T \), and \( R_T \) is that of a “log domain” filter.20
In the THAT2252, the square root portion of the rms calculation is not computed explicitly but is implied by the constant of proportionality for the output. Since, in the log domain, taking the square root is equivalent to dividing by two, the voltage at the output (pin 7) is proportional to the mean of the square at approximately 3 mV/dB and proportional to the square root of the mean of the square at approximately 6 mV/dB.

The attack and release times of rms detectors are locked in a relationship to each other and separate controls for each are not possible while still maintaining rms response. Varying the value of $CT$ and $RT$ in the THAT2252, and $CAV$ in the AD636 allow the time constant to be varied to suit the application. More complex approaches, such as a nonlinear capacitor, are possible with additional circuitry.21

Fig. 12-52 shows a typical application for the THAT2252. The input voltage is converted to a current by $R_{in}$. $C_{in}$ blocks input dc and internal op-amp bias currents. The network around pin 4 sets the waveform symmetry for positive versus negative input currents. Internal bias for the THAT2252 is set by $R_b$ and bypassed by a 1 μF capacitor. $R_T$ and $C_T$ set the timing of the log-domain filter. The output signal (pin 7) is 0 V when the input signal current equals a reference current determined by $I_{bias}$ and $I_T$. It varies in dc level above and below this value to represent the dB input level at the rate of ~6 mV/dB.

Fig. 12-53 shows the tone burst response of a THAT2252, while Fig. 12-54 is a plot of THAT2252 output level versus input level. The THAT2252 has linear dB response over an almost 100 dB range.

The Analog Devices AD636 and THAT Corporation THAT2252 provide precise, low-cost rms detection due to their integration into monolithic form. On their own, rms detectors are very useful at monitoring signal level, controlling instrumentation, and other applications. When combined with VCAs for gain control, many different signal processing functions can be realized including noise reduction, compression, and limiting.
12.3.5 Integrated Circuit Preamplifiers

The primary applications of preamplifiers for professional audio in the post-tape era are for use with microphones. Before the development of monolithic ICs dedicated to the purpose, vacuum tubes, discrete bipolar or field-effect transistors, or general-purpose audio op-amps were used as preamplifiers. Dynamic microphones generally produce very small signal levels and have low output impedance. Ribbon microphones are notorious for low output levels. For many audio applications, significant gain (40–60 dB) is required to bring these mic level signals up to pro audio levels. Condenser microphones, powered by phantom power, external power supplies, or batteries, often produce higher signal levels requiring less gain.

To avoid adding significant noise to the microphone’s output, professional audio preamplifiers must have very low input noise. Transformer-coupled preamps ease the requirement for very low noise amplification, since they take advantage of the voltage step-up possible within the input transformer. Early transformerless, or active, designs required performance that eluded integration until the early 1980s. Until semiconductor process and design improvements permitted it and the market developed to generate sufficient demand, most microphone preamplifiers were based on discrete transistors or discrete transistors augmented with commercially available op-amps.

Virtually all professional microphones use two signal lines to produce a balanced output. This allows a preamplifier to distinguish the desired differential audio signal—which appears as a voltage difference between the two signal lines—from hum and noise pickup—which appears as a “common-mode” signal with the same amplitude and polarity on both signal lines. Common mode rejection quantifies the ability of the preamplifier to reject common mode interference while accepting differential signals.

Therefore, one goal of a pro-audio mic preamp is to amplify differential signals in the presence of common-mode hum. As well, the preamp should ideally add no more noise than the thermal noise of the source impedance—well below the self-noise of the microphone and ambient acoustic noise.

Phantom power is required for many microphones, especially professional condenser types. This is usually a +48 Vdc power supply applied to both polarities of the differential input through 6.8 kΩ resistors (one for each input polarity). Dc supply current from the microphone returns through the ground conductor. Phantom power appears in common mode essentially equal on both inputs. The voltage is used to provide power to the circuitry inside the microphone.

12.3.5.1 Transformer input microphone preamplifiers

Many microphone preamplifiers use transformers at their inputs. Transformers, although costly, provide voltage gain that can ease the requirements for low noise in the subsequent amplifier. The transformer’s voltage gain is determined by the turns ratio of the secondary versus the primary. This ratio also transforms impedance, making it possible to match a low-impedance microphone to a high-impedance amplifier without compromising noise performance.

A transformer’s voltage gain is related to its impedance ratio by the following equation:

$$Gain = 20 \log \frac{Z_s}{\sqrt{Z_p}}$$

(12-64)
where,

$Gain$ is the voltage gain in dB of the transformer,

$Z_p$ is the primary transformer impedance in ohms,

$Z_s$ is the secondary transformer impedance in ohms.

A properly designed transformer with a 150 Ω primary and 15 kΩ secondary produces 20 dB of free voltage gain without adding noise. Well-made transformers also provide high common-mode rejection, which helps avoid hum and noise pickup. This is especially important with the low output voltages and long cable runs common with professional microphones. In addition, transformers provide galvanic isolation by electrically insulating the primary circuit from the secondary while allowing signal to pass. While usually unnecessary in microphone applications, this provides a true ground lift, which can eliminate ground loops in certain difficult circumstances.

Transformer isolation is also useful when feeding phantom power (a +48 Vdc current-limited voltage to power internal circuitry in the microphone) down the mic cable from the preamp input terminals. Phantom power may be connected through a center tap on the primary to energize the entire primary to +48 Vdc, or supplied through resistors (usually 6.8 kΩ) to each end of the primary of the transformer. (The latter connection avoids dc currents in the coils, which can lead to premature saturation of the core magnetics.) The galvanic isolation of the transformer avoids any possibility of the 48 Vdc signal from reaching the secondary windings.

12.3.5.2 Active Microphone Preamplifiers Eliminate Input Transformers

As is common in electronic design, transformers do have drawbacks. Perhaps the most prominent one is cost: a Jensen Transformer, Inc. JT-115K-E costs approximately $75 US or $3.75 per dB of gain. From the point of view of signal, transformers add distortion due to core saturation. Transformer distortion has a unique sonic signature that is considered an asset or a liability—depending on the transformer and whom you ask. Transformers also limit frequency response at both ends of the audio spectrum. Furthermore, they are susceptible to picking up hum from stray electromagnetic fields.

Well-designed active transformerless preamplifiers can avoid these problems, lowering cost, reducing distortion, and increasing bandwidth. However, transformerless designs require far better noise performance from the active circuitry than transformer-based preamps do. Active mic preamps usually require capacitors (and other protection devices) to block potentially damaging effects of phantom power.

12.3.5.3 The Evolution of Active Microphone Preamplifier ICs

Active balanced-input microphone preamplifier ICs were not developed until the early 1980s. Early IC fabrication processes did not permit high-quality low-noise devices, and semiconductor makers were uncertain of the demand for such products.

Active transformerless microphone preamplifiers must have fully differential inputs because they interface to balanced microphones. The amplifiers described here, both discrete and IC, use a current feedback CFB topology with feedback returned to one (or both) of the differential input transistor pair’s emitters. Among its many attributes, current feedback permits differential gain to be set by a single resistor.

Current feedback amplifiers have a history rooted in instrumentation amplifiers. The challenges of amplifying low-level instrumentation signals are very similar to microphones. The current feedback instrumentation amplifier topology, known at least since Demrow’s 1968 paper, was integrated as early as 1982 as the Analog Devices AD524 developed by Scott Wurcer. A simplified diagram of the AD524 is shown in Fig. 12-55. Although the AD524 was not designed as an audio preamp, the topology it used later became a de facto standard for IC microphone preamps. Demrow and Wurcer both used a bias scheme and fully balanced topology in which they wrapped op-amps around each of the two input transistors to provide both ac and dc feedback. Gain is set by a single resistor connected between the emitters (shown as 40 Ω, 404 Ω, and 4.44 kΩ), and feedback is provided by two resistors ($R_{56}$ and $R_{57}$). The input stage is fully symmetrical and followed by a precision differential amplifier to convert the balanced output to single ended. Wurcer’s AD524 required laser-trimmed thin film resistors with matching to 0.01% for an 80 dB common mode rejection ratio at unity gain.

Audio manufacturers, using variations on current feedback and the Demrow/Wurcer instrumentation amp, produced microphone preamps based on discrete low-noise transistor front ends as early as 1978; an example is the Harrison PC1041 module. In December of 1984, Graeme Cohen also published his discrete transistor topology; it was remarkably similar to the work of Demrow, Wurcer, and the Harrison preamps.
Solid State Music, or SSM, which later became Solid State Microtechnology, developed the first active microphone preamp IC for professional audio around 1982. SSM specialized in producing niche-market semiconductors aimed at the professional audio business. The SSM2011 was almost completely self-contained, requiring only a handful of external resistors and capacitors to provide a complete preamp system. One unique feature of the SSM2011 was an on-chip LED overload and signal presence indicator.

SSM later produced the SSM2015 and the SSM2016 designed by Derek Bowers. The SSM2016, and the SSM2011 and 2015 that preceded it, did not use a fully balanced topology like Wurcer’s AD524 and the Harrison PC1041. The SSM parts used an internal op-amp to convert the differential stage output to single-ended. This allowed external feedback resistors to be used, eliminating the performance penalty of on-chip diffused resistors. The SSM2016 was highly successful but required external precision resistors and up to three external trims. SSM was later acquired by Precision Monolithics and eventually by Analog Devices (ADI). The SSM2016 was extremely successful and, after its discontinuance in the mid-1990s, became highly sought after.

Analog Devices introduced the SSM2017 self contained preamp, also designed by Bowers, as a replacement for the SSM2016. The SSM2017 used internal laser-trimmed thin-film resistors that permitted the fully balanced topology of the AD524 and discrete preamps to be realized as an IC. Analog Devices manufactured the SSM2017 until about 2000 when it was discontinued. A year or two later, ADI released the 2019 which is available today.

The Burr Brown division of Texas Instruments offered the INA163, which had similar performance to the SSM2017, but was not pin compatible with it. After the 2017 was discontinued, TI introduced its INA217 in the SSM2017 pinout. Today, TI produces a number of INA-family instrumentation amplifiers suitable for microphone preamps including the INA103, INA163, INA166, INA217, and the first digitally gain-controlled preamp: the PGA2500.

In 2005, THAT Corporation introduced a series of microphone preamplifiers in pinouts to match the familiar SSM2019/INA217 as well as the INA163. The THAT1510 and the performance-enhanced THAT1512 use dielectric isolation to provide higher bandwidth than the junction-isolated INA and SSM series products. (Dielectric isolation is explained in the section on audio VCAs.)

While all offer relatively high performance, the three different families of parts have different strengths and weaknesses. Differences exist in gain bandwidth, noise floor, distortion, gain structure, and supply consumption. The optimum part for any given application will depend on the exact requirements of the designer. A designer considering any one of these parts should compare their specs carefully before finalizing a new design.

12.3.5.4 Integrated Circuit Mic Preamplifier Application Circuits

The THAT1510 series block diagram is shown in Fig. 12-57. Its topology is similar to those of the TI and ADI parts. A typical application circuit is shown in Fig. 12-58. The balanced mic-level signal is applied to the input pins, In+ and In−. A single resistor (R_G), connected between pins R_G1 and R_G2, sets the gain in conjunction with the internal resistors R_A and R_B. The input stage consists of two independent low-noise amplifiers in a balanced differential amplifier configuration with both ac and dc feedback returned to the emitters of the differential pair. This topology is essentially identical to the AD524 current feedback amplifier as described by Wurcer et al.

The output stage is a single op-amp differential amplifier that converts the balanced output of the gain stage into single-ended form. The THAT1500 series offers a choice of gains in this stage: 0 dB for the 1510, and −6 dB for the 1512. Gain is controlled by the input-side resistor values: 5 kΩ for the 1510 and 10 kΩ for the 1512.

The gain equations for the THAT1510 are identical to that of the SSM2017/2019 and the INA217. The INA163 and THAT 1512 have unique gain equations.
For the THAT 1510, SSM 2019, and INA217 the equation is

\[ Av = 1 + \frac{10 \, k\Omega}{R_G} \]  \hspace{1cm} (12-65)

For the INA163 it is

\[ Av = 1 + \frac{6 \, k\Omega}{R_G} \]  \hspace{1cm} (12-66)

For the THAT1512 it is

\[ Av = 0.5 + \frac{5 \, k\Omega}{R_G} \]  \hspace{1cm} (12-67)

where, 
\[ Av \] is the voltage gain of the circuit.

All these parts can reach unity gain but the value of \( R_G \) required varies considerably. For the 1510, 2017, 2019, 163, and 217, gain is 0 dB (\( Av = 1 \)) when \( R_G \) is open: this is the minimum gain of all these ICs. For the 1512, gain is –6 dB (\( Av = 0.5 \)) with \( R_G \) open. To go from 60 dB to 0 dB gain, \( R_G \) must span a large range: 10 \( \Omega \) to 10 k\( \Omega \) for the 1510 and its equivalents.

\( R_G \) is typically a reverse log potentiometer (or set of switched resistors) to provide smooth rotational control of gain. In many applications, and, as shown in Fig. 12-57, a large value capacitor is placed in series with \( R_G \) to limit the dc gain of the device, thus preventing shifts in output dc-offset with gain changes. For 60 dB of gain with the THAT1512, \( R_G = 5 \, \Omega \) (6 \( \Omega \) in the case of the INA163). Because of this, \( C_G \) must be quite large, typically ranging from 1000 \( \mu \)F to 6800 \( \mu \)F to preserve low frequency response. Fortunately, \( C_G \) does not have to support large voltages: 6.3 V is acceptable.

Parts from all manufacturers exhibit excellent voltage noise performance of ~1 nV/\sqrt{Hz} at high gains. Differences in noise performance begin to show up at lower gains, with the THAT 1512 offering the best performance (~34 nV/\sqrt{Hz} at 0 dB gain) of the group. These parts are all generally optimized for the relatively low source impedances of dynamic microphones with typically a few hundred ohm output impedance.

Fig. 12-57 provides an application example for direct connection to a dynamic microphone. Capacitors \( C_1–C_3 \) filter out radio frequencies that might cause interference (forming an RFI filter). \( R_1 \) and \( R_2 \) provide a bias current path for the inputs and terminate the microphone output. \( R_G \) sets the gain as defined in the previous equation. \( C_G \) blocks dc in the input stage feedback loop, limiting the dc gain of this stage to unity and avoiding output offset change with gain. \( C_6 \) and \( C_9 \) provide power supply bypass.

Fig. 12-58 shows the THAT1512 used as a preamp capable of being used with phantom power. \( C_1–C_3 \) provide RFI protection. \( R_5 \) and \( R_6 \) feed phantom power to the microphone. \( R_9 \) terminates the microphone. \( C_4 \) and \( C_5 \) block 48 Vdc phantom potential from the THAT1512. \( R_3 \), \( R_4 \), and \( D_1–D_4 \) provide current limiting and overvoltage protection from phantom power faults. \( R_1 \) and \( R_2 \) are made larger than previously shown to reduce the loading on \( C_4 \) and \( C_5 \).

Many variations are possible on these basic circuits, including digital control of gain, dc servos to reduce or eliminate some of the ac-coupling needed, and exotic power supply arrangements that can produce response down to dc. For more information on possible configurations, see application notes published by Analog Devices, Texas Instruments, and THAT Corporation. (All available at their respective web sites: www.analog.com, www.ti.com, www.thatcorp.com.)
Modern IC microphone preamplifiers provide a simple building block with performance equaling discrete solutions without a costly input transformer.

12.3.6 Balanced Line Interfaces

In professional audio, interconnections between devices frequently use balanced lines. These are especially important when analog audio signals are sent over long distances, where the ground references for the send and receive ends are different or where noise and interference may be picked up in the interconnection cables.

Differences in signal ground potentials arise as a result of current flowing into power-line safety grounds. These currents, flowing through finite ground impedances between equipment, can produce up to several volts potential difference between the ground references within a single building. These currents, usually at the power line frequency and its harmonics, produce the all-too-familiar hum and buzz known to every sound engineer.

Two other forms of interference, electrostatic and magnetic, also create difficulty. Cable shielding reduces electrostatic interference from fields, typically using braided copper, foil wrap, or both. Magnetic interference from fields is much harder to prevent via shielding. The impact of magnetic fields in signal cables is reduced by balanced cable construction using twisted pair cable. Balanced circuits benefit from the pair’s twist by ensuring that magnetic fields cut each conductor equally. This in turn ensures that the currents produced by these fields appear in common mode, wherein the voltages produced appear equally in both inputs.

The balanced line approach comes out of telephony, in which voice communications are transmitted over many miles of unshielded twisted pair cables with reasonable fidelity and freedom from hum and interference pickup. Two principles allow balanced lines to work. First, interference—whether magnetic or electrostatic—is induced equally in both wires in the twisted paired-conductor cable, and second, the circuits formed by the source and receiver, plus the two wires connecting them form a balanced bridge, Fig. 12-59. Interfering signals appear identically (in common-mode) at the two (+ and −) inputs, while the desired audio signal appears as a difference (the differential signal) between the two inputs.
A common misconception in the design of balanced interfaces is that the audio signals must be transmitted as equal and opposite polarity on both lines. While this is desirable to maximize headroom in many situations, it is unnecessary to preserve fidelity and avoid noise pickup. It is enough if the bridge formed by the combination of the circuit’s two common-mode source impedances (not the signals) working against the two common-mode load impedances remains balanced in all circumstances.

In telephony, and in early professional audio systems, transformers were used at both the inputs and outputs of audio gear to maintain bridge balance. Well-made output transformers have closely matched common-mode source impedances and very high common-mode impedance. (Common-mode impedance is the equivalent impedance from one or both conductors to ground.) The floating connections of most transformers—whether used for inputs or outputs—naturally offer very large common-mode impedance. Both of these factors, matched source impedances for output transformers, and high common-mode impedance (to ground) for both input and output transformers, work together to maintain the balance of the source/load impedance bridge across a wide range of circumstances. In addition, transformers offer galvanic isolation, which is sometimes helpful when faced with particularly difficult grounding situations.

On the other hand, as noted previously in the section on preamplifiers, transformers have drawbacks of high cost, limited bandwidth, distortion at high signal levels, and magnetic pickup.

### 12.3.6.1 Balanced Line Inputs

Transformers were used in early balanced line input stages, particularly in the days before inexpensive op-amps made it attractive to replace them. The advent of inexpensive op-amps, especially compared to the cost of transformers, motivated the development of active transformerless inputs. As the state of the art in op-amps improved, transformer-coupled inputs were replaced by less expensive, high-performance active stages based on general-purpose parts like the Texas Instruments TL070 and TL080 series, the National Semiconductor LF351 series, and the Signetics NE5534.

As with microphone preamplifiers, common-mode rejection is an important specification for line receiver inputs. The most common configuration for active balanced line input stages used in professional audio is the simple circuit shown in Fig. 12-60. To maintain high common-mode rejection (CMR), the four resistors used must match very closely. To maintain a 90 dB CMR, for example, the resistor ratio $R_1/R_2$ must match that of $R_3/R_4$ within 0.005%. The requirement for precision-matched resistors to provide high CMR drove the development of specialized line receiver ICs.

To maintain the high CMR potential of precision balanced line receivers, the interconnections between stages must be made through low-resistance connections, and the impedances in both lines of the circuit must be very nearly identical. A few ohms of contact resistance external to the line driver and receiver (due, for example, to oxidation or poor contact) or any imbalance in the driving circuit, can significantly reduce CMR by unbalancing the bridge circuit. The imbalance can be at the source, in the middle at a cable junction, or near the input of the receiving equipment. Although many balanced line receivers provide excellent CMR under ideal conditions, few provide the performance of a transformer under less-than-ideal real world circumstances.

![Figure 12-60. 1240 basic circuit. Courtesy THAT Corporation.](image)

### 12.3.6.2 Balanced Line Outputs

Transformers were also used in early balanced output stages, for the same reasons as they are used in inputs. However, to drive 600 Ω loads, an output transformer must have more current capacity than an input transformer that supports the same voltage levels. This increased the cost of output transformers, requiring more copper and steel than input-side transformers and putting pressure on designers to find alternative outputs. Early active stages were either discrete or used discrete output transistors to boost the current available from
op-amps. The NE5534, with its capability to directly drive a 600 Ω load, made it possible to use op-amps without additional buffering as output stages.

One desirable property of transformer-coupled output stages was that the output voltage was the same regardless of whether the output was connected differentially or in single-ended fashion. While professional audio gear has traditionally used balanced input stages, sound engineers commonly must interface to consumer and semi-pro gear that use single-ended input connections referenced to ground. Transformers behave just as well when one terminal of their output winding is shorted to the ground of a subsequent single-ended input stage. On the other hand, an active-balanced output stage that provides equal and opposite drive to the positive and negative outputs will likely have trouble if one output is shorted to ground.

This led to the development of a cross-coupled topology by Thomas Hay of MCI that allowed an active balanced output stage to mimic this property of transformers. When loaded equally by reasonable impedances (e.g., 600 Ω or more) Hay’s circuit delivers substantially equal—and opposite-polarity voltage signals at either output. However, because feedback is taken differentially, when one leg is shorted to ground, the feedback loop automatically produces twice the voltage at the opposing output terminal. This mimics the behavior of a transformer in the same situation.

While very clever, this circuit has at least two drawbacks. First, its resistors must be matched very precisely. A tolerance of 0.1% (or better) is often needed to ensure stability, minimize sensitivity to output loading, and maintain close matching of the voltages at either output. (Though, as noted earlier, this last requirement is unnecessary for good performance.) The second drawback is that the power supply voltage available to the two amplifiers limits the voltage swing at each output. When loaded differentially, the output stage can provide twice the voltage swing than it can when driving a single-ended load. But this means that headroom is reduced 6 dB with single-ended loads.

One way to ensure the precise matching required by Hay’s circuit is to use laser-trimmed thin-film resistors in an integrated circuit. SSM was the first to do just that when they introduced the SSM2142, a balanced line output driver with a cross-coupled topology.

12.3.6.3 Integrated Circuits for Balanced Line Interfaces

Instrumentation amplifier inputs have similar requirements to those of an audio line receiver. The INA105, originally produced by Burr Brown and now Texas Instruments, was an early instrumentation amplifier that featured laser-trimmed resistors to provide 86 dB common-mode rejection. Although its application in professional audio was limited due to the performance of its internal op-amps, the INA105 served as the basis for the modern audio-balanced line receiver.

In 1989, the SSM Audio Products Division of Precision Monolithics introduced the SSM2141 balanced line receiver and companion SSM2142 line driver. The SSM2141 was offered in the same pinout as the INA105 but provided low noise and a slew rate of almost 10 V/μs. With a typical CMR of 90 dB, the pro-audio industry finally had a low-cost, high-performance replacement for the line input transformer. The SSM2142 line driver, with its cross-coupled outputs, became a low-cost replacement for the output transformer. Both parts have been quite successful.

Today, Analog Devices (which acquired Precision Monolithics) makes the SSM2141 line receiver and the SSM2142 line driver. The SSM2143 line receiver, designed for 6 dB attenuation, was introduced later to offer increased input headroom. It also provides overall unity gain operation when used with an SSM2142 line driver, which has 6 dB of gain.

The Burr Brown division of Texas Instruments now produces a similar family of balanced line drivers and receivers, including dual units. The INA134 audio differential line receiver is a second source to the SSM2141. The INA137 is similar to the SSM2143 and also permits gains of ±6 dB. Both devices owe their pinouts to the original INA105. Dual versions of both parts are available as the INA2134 and 2137. TI also makes cross-coupled line drivers known as the DRV134 and DRV135.

THAT Corporation also makes balanced line drivers and receivers. THAT’s 1240 series single and 1280 series dual balanced line receivers use laser-trimmed resistors to provide high common rejection in the familiar SSM2141 (single) and INA2134 (dual) pinouts. For lower cost applications, THAT offers the 1250- and 1290-series single and dual line receivers. These parts eliminate laser trimming, which sacrifices CMR to reduce cost. Notably, THAT offers both dual and single line receivers in the unique configuration of ±3 dB gain, which can optimize dynamic range for many common applications.

THAT Corporation also offers a unique line receiver, the THAT1200 series, based on technology licensed from William E. Whitlock of Jensen Transformers, Inc. (U.S. Patent 5,568,561). This design, dubbed InGe-nius (a trademark of THAT Corporation), bootstraps the common-mode input impedance to raise it into the
megohm range of transformers. This overcomes the loss of common-mode rejection when the impedances feeding the line receiver are slightly unbalanced and permits transformer-like operation. The InGenius circuit will be discussed in a following section.

THAT also offers the THAT1646 balanced line driver, which has identical pinout to the SSM2142 and DRV134/135. THAT’s 1606 balanced line driver is unique among these parts in that it provides not only a differential output, but also a differential input—enabling a more direct connection to digital-to-analog converters.

The THAT1646 and 1606 use a unique output topology unlike conventional cross-coupled outputs which THAT calls “OutSmarts” (another trademark). OutSmarts is based on U.S. Patent 4,979,218 issued to Chris Strahm, then of Audio Teknology Incorporated. Conventional cross-coupled outputs lose common-mode feedback when one output is shorted to ground to accommodate a single-ended load. This allows large signal currents to flow into ground, increasing crosstalk and distortion. Strahm’s circuit avoids this by using an additional feedback loop to provide current feedback. Application circuits for the THAT1646 will be described in the section “Balanced Line Outputs.”

12.3.6.4 Balanced Line Input Application Circuits

Conventional balanced line receivers from Analog Devices, Texas Instruments, and THAT Corporation are substantially equivalent to the THAT1240 circuit shown in Fig. 12-61. Some variations exist in the values of $R_1$–$R_4$ from one manufacturer to the other that will influence input impedance and noise. The ratio of $R_1/R_3$ to $R_2/R_4$ establishes the gain with $R_1 = R_3$ and $R_2 = R_4$. $V_{out}$ is normally connected to the sense input resistor with the reference pin grounded.

Line receivers usually operate at either unity gain (SSM2141, INA134, THAT1240, or THAT1250) or in attenuation (SSM2143, INA137, THAT1243, or THAT1246, etc.). When a perfectly balanced signal (with each input line swinging $\frac{1}{2}$ the differential voltage) is converted from differential to single-ended by a unity gain receiver, the output must swing twice the voltage of either input line for a net voltage gain of +6 dB. With only +21 dBu output voltage available from a line receiver powered by bipolar 15 V supplies, additional attenuation is often needed to provide headroom to accommodate pro audio signal levels of +24 dBu or more. The ratios $R_1/R_2$ and $R_3/R_4$ are 2:1 in the SSM2143, INA137, and THAT1246 to provide 6 dB attenuation. These parts accommodate up to +27 dBu inputs without clipping their outputs when running from bipolar 15 V supplies. The THAT1243, and THAT’s other ±3 dB parts (the 1253, 1283, and 1293) are unique with their 0.707 attenuation. This permits a line receiver that accommodates +24 dBu inputs but avoids additional attenuation that increases noise. A –3 dB line receiver is shown in Fig. 12-62.

The ±6 dB parts from all three manufacturers (and the ±3 dB parts from THAT) may be configured for gain instead of attenuation. To accomplish this, the reference and sense pins are used as inputs with the $In-$ pin connected to $V_{out}$ and the $In+$ pin connected to ground. A line receiver configured for 6 dB gain is shown in Fig. 12-63.

Balanced line receivers may also be used to provide sum-difference networks for mid-side (M/S or M-S) encoding/decoding as well as general-purpose applications requiring precise difference amplifiers. Such applications take advantage of the precise matching of resistor ratios possible via monolithic, laser-trimmed
resistors. In fact, while these parts are usually promoted as input stages, they have applications to many circuits where precise resistor ratios are required. The typical 90 dB common-mode rejection advertised by many of these manufacturers requires ratio matching to within 0.005%.

Any resistance external to the line receiver input appears in series with the highly matched internal resistors. A basic line receiver connected to an imbalanced circuit is shown in Fig. 12-64. Even a slight imbalance, one as low as 10 Ω from connector oxidation or poor contact, can degrade common-mode rejection. Fig. 12-65 compares the reduction in CMR for low common-mode impedance line receivers versus the THAT1200 series or a transformer.

The degradation of common-mode rejection from impedance imbalance comes from the relatively low-impedance load of simple line receivers interacting with external impedance imbalances. Since unwanted hum and noise appear in common-mode (as the same signal in both inputs), common-mode loading by common-mode input impedance is often a significant source of error. (The differential input impedance is the load seen by differential signals; the common-mode input impedances is the load seen by common-mode signals.) To reduce the effect of impedance imbalance, the common-mode input impedance, but not the differential impedance, must be made very high.

12.3.6.5 Balanced Line Receivers with the Common-Mode Performance of a Transformer

The transformer input stage has one major advantage over most active input stages: its common-mode input impedance is extremely high regardless of its differential input impedance. This is because transformers offer floating connections without any connection to ground. Active stages, especially those made with the simple SSM2141-type IC have common-mode input impedances of approximately the same value as their differential input impedance. (Note that for simple differential stages such as these, the common-mode and differential input impedances are not always the same.) Op-amp input bias current considerations generally make it difficult to use very high impedances for these simple stages. A bigger problem is that the noise of these stages increases with the square root of the impedances chosen, so large input impedances inevitably cause higher noise.

Noise and op-amp requirements led designers to choose relatively low impedances (10 kΩ–25 kΩ). Unfortunately, this means these stages have relatively low common-mode input impedance as well (20 kΩ–50 kΩ). This interacts with the common-mode output impedance (also relative to ground) of the driving stage, and added cable or connector resistance. If the driver, cable, or connectors provide an unequal, nonzero common-mode output impedance, the input stage loading will upset the natural balance of any
common-mode signal, converting it from common-mode to differential. No amount of precision in the input stage’s resistors will reject this common-mode-turned-to-differential signal. This can completely spoil the apparently fine performance available from the precisely matched resistors in simple input stages.

An instrumentation amplifier, Fig. 12-66, may be used to increase common-mode input impedance. Input resistors $R_{i1}$ and $R_{i2}$ must be present to supply a bias current return path for buffer amplifiers OA1 and OA2. $R_{i1}$ and $R_{i2}$ can be made large—in the MΩ range—to minimize the effect of impedance imbalance. While it is possible to use this technique to make line receivers with very high common-mode input impedances, doing so requires specialized op-amps with bias-current compensation or FET input stages. In addition, this requires two more op-amps in addition to the basic differential stage (OA3).

With additional circuitry, even higher performance can be obtained by modifying the basic instrumentation amplifier circuit. Bill Whitlock of Jensen Transformers, Inc. developed and patented (U.S. Patent 5,568,561) a method of applying bootstrapping to the instrumentation amplifier in order to further raise common-mode input impedance. THAT Corporation incorporated this technology in its InGenius series of input stage ICs.

### 12.3.6.6 InGenius High Common-Mode Rejection Line Receiver ICs

Fig. 12-67 shows the general principle behind ac bootstrapping in a single-ended connection. By feeding the ac component of the input into the junction of $R_7$ and $R_8$, the effective value of $R_a$ (at ac) can be made to appear quite large. The dc value of the input impedance (neglecting $R_s$ being in parallel) is $R_a + R_b$. Because of bootstrapping, $R_a$ and $R_b$ can be made relatively small values to provide op-amp bias current, but the ac load on $R_s$ ($Z_{in}$) can be made to appear to be extremely large relative to the actual value of $R_a$.

![Figure 12-66. Instrumentation amplifier. Courtesy THAT Corporation.](image)

![Figure 12-67. Single ended bootstrap. Courtesy THAT Corporation.](image)

A circuit diagram of an InGenius balanced line receiver using the THAT1200 is shown in Fig. 12-68. (All the op-amps and resistors are internal to the IC.) $R_5$–$R_6$ provides dc bias to internal op-amps OA1 and OA2. Op-amp OA4, along with $R_{10}$ and $R_{11}$ extract the common-mode component at the input and feed the ac common-mode component back through $C_b$ to the junction of $R_7$ and $R_8$. Because of this positive feedback, the effective values of $R_7$ and $R_8$—at ac—are multiplied into the MΩ range. In its data sheet for the 1200 series ICs, THAT cautions that $C_b$ should be at least 10 μf to maintain common-mode input impedance ($Z_{inCM}$) of at least 1 MΩ at 50 Hz. Larger capacitors can increase $Z_{inCM}$ at low power-line frequencies up to the IC’s practical limit of ~10 MΩ. This limitation is due to the precision of the gain of the internal amplifiers.

![Figure 12-68. Balanced line receiver. Courtesy THAT Corporation.](image)

The outputs of OA1 and OA2 contain replicas of the positive and negative input signals. These are converted to single-ended form by a precision differential ampli-
fier OA3 and laser-trimmed resistors $R_1$–$R_4$. Because OA1 and OA2 isolate the differential amplifier, and the positive common-mode feedback ensures very high common-mode input impedance, a 1200-series input stage provides 90 dB CMR even with high levels of imbalance.

It took Bill Whitlock and Jensen Transformers, Inc. to provide an active input as good as a transformer operating under conditions likely to be found in the real world.

A basic application circuit using the THAT1200 series parts is shown in Fig. 12-69.

12.3.6.7 Balanced Line Drivers

The Analog Devices SSM2142 and Texas Instruments DRV series balanced line drivers use a cross-coupled method to emulate a transformer’s floating connection and provide constant level with both single-ended (grounded) terminations and fully balanced loads. A block diagram of a cross-coupled line driver is shown in Fig. 12-70. The force and sense lines are normally connected to each output either directly or through small electrolytic coupling capacitors. A typical application of the SSM2142 driving an SSM2141 (or SSM2143) line receiver is provided in Fig. 12-71.

If one output of the cross-coupled line driver outputs is shorted to ground in order to provide a single-ended termination, the full short-circuit current of the device will flow into ground. Although this is not harmful to the device, and is in fact a recommended practice, large clipped signal currents will flow into ground, which can produce crosstalk within the product using the stage, as well as in the output signal line itself.

THAT Corporation licensed a patented technology developed by Chris Strahm of Audio Teknology Incorporated. U.S. Patent 4,979,218, issued in December 1990, describes a balanced line driver that emulates a floating transformer output by providing a current-feedback system where the current from each output is equal and out of phase to the opposing output. THAT trademarked this technology as OutSmarts and introduced its THAT1646 line driver having identical pinout and functionality to the SSM2142. THAT also offers a version of the 1646 with differential inputs known as the THAT1606. Fig. 12-72 is a simplified block diagram of the THAT1646.

The THAT1646 OutSmarts internal circuitry differs from other manufacturer’s offerings. Outputs $D_{out-}$ and $D_{out+}$ supply current through 25 $\Omega$ build-out resistors. Feedback from both sides of these resistors is returned into two internal common-mode feedback paths. The driven side of the build-out resistors are fed back into the common-mode $C_{in-}$ input while the load side of the build-out resistors, through the sense– and sense+ pins,
provide feedback into the $C_{in+}$ input. A current feedback bridge circuit allows the 1646 to drive one output shorted to ground to allow a single-ended load to be connected. The output short increases gain by 6 dB, similarly to conventional cross-coupled topologies. However, it does so without loss of the common-mode feedback loop. The resulting current feedback prevents large, clipped signal currents flowing into ground. This reduces the crosstalk and distortion produced by these currents.

A typical application circuit for the THAT1646 is shown in Fig. 12-73.

To reduce the amount of common-mode dc offset, the circuit in Fig. 12-74 is recommended. Capacitors $C_1$ and $C_2$, outside the primary signal path, minimize common-mode dc gain, which reduces common-mode output offset voltage and the effect of OutSmarts at low frequencies. Similar capacitors are used in the ADI and TI parts to the same effect, although OutSmarts’ current feedback does not apply.

THAT’s 1606 version of OutSmarts provides a differential input for easier connection to a digital-to-analog converter’s output. A typical application of the THAT1606 is shown in Fig. 12-75. Another advantage to the 1606 is that it requires only a single low-value capacitor (typically a film type) versus the two larger capacitors required by the THAT1646, SSM2142, or DRV134.

Active balanced line drivers and receivers offer numerous advantages over transformers providing lower cost, weight, and distortion, along with greater bandwidth and freedom from magnetic pickup. When used properly, active devices perform as well as, and in many ways better than, the transformers they replace. With careful selection of modernIC building blocks from several IC makers, excellent performance is easy to achieve.

12.3.7 Digital Integrated Circuits

Digital ICs produce an output of either 0 or 1. With digital circuits, when the input reaches a preset level, the output switches polarity. This makes digital circuitry relatively immune to noise.

Bipolar technology is characterized by very fast propagation time and high power consumption, while MOS technology has relatively slow propagation times, low power consumption, and high circuit density. Fig. 12-76 shows typical circuits and characteristics of the major bipolar logic families.

Table 12-4 gives some of the terminology common to digital circuitry and digital ICs.
Table 12-4. Digital Circuit Terminology

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adder</td>
<td>Switching circuits that generate sum and carry bits.</td>
</tr>
<tr>
<td>Address</td>
<td>A code that designates the location of information and instructions.</td>
</tr>
<tr>
<td>AND</td>
<td>A Boolean logic operation that performs multiplication. All inputs must be true for the output to be true.</td>
</tr>
<tr>
<td>Asynchronous</td>
<td>A free-running switching network that triggers successive instructions.</td>
</tr>
<tr>
<td>Bit</td>
<td>Abbreviation for binary digit; a unit of binary information.</td>
</tr>
<tr>
<td>Buffer</td>
<td>A noninverting circuit used to handle fan-out or convert input and output levels.</td>
</tr>
<tr>
<td>Byte</td>
<td>A fixed-length binary-bit pattern (word).</td>
</tr>
<tr>
<td>Clear</td>
<td>To restore a device to its standard state.</td>
</tr>
<tr>
<td>Clock</td>
<td>A pulse generator used to control timing of switching and memory circuits.</td>
</tr>
<tr>
<td>Clock rate</td>
<td>The frequency (speed) at which the clock operates. This is normally the major speed of the computer.</td>
</tr>
<tr>
<td>Counter</td>
<td>A device capable of changing states in a specified sequence or number of input signals.</td>
</tr>
<tr>
<td>Counter, binary</td>
<td>A single input flip-flop. Whenever a pulse appears at the input, the flip-flop changes state (called a T flip-flop).</td>
</tr>
<tr>
<td>Counter, ring</td>
<td>A loop or circuit of interconnected flip-flops connected so that only one is on at any given time. As input signals are received, the position of the on state moves in sequence from one flip-flop to another around the loop.</td>
</tr>
<tr>
<td>Fan-in</td>
<td>The number of inputs available on a gate.</td>
</tr>
<tr>
<td>Fan-out</td>
<td>The number of gates that a given gate can drive. The term is applicable only within a given logic family.</td>
</tr>
<tr>
<td>Flip-flop</td>
<td>A circuit having two stable states and the ability to change from one state to the other on application of a signal in a specified manner.</td>
</tr>
<tr>
<td>Flip-flop, D</td>
<td>D stands for delay. A flip-flop whose output is a function of the input that appeared one pulse earlier; that is, if a 1 appears at its input, the output will be a 1 pulse later.</td>
</tr>
<tr>
<td>Flip-flop, JK</td>
<td>A flip-flop having two inputs designated J and K. At the application of a clock pulse, a 1 on the J input will set the flip-flop to the 1 or on state; a 1 on the K input will reset it to the 0 or off state; and 1s simultaneously on both inputs will cause it to change state regardless of the state it had been in.</td>
</tr>
<tr>
<td>Flip-flop, RS</td>
<td>A flip-flop having two inputs designated R and S. At the application of a clock pulse, a 1 on the S input will set the flip-flop to the 1 or on state; and a 1 on the R input will reset it to the 0 or off state. It is assumed that 1s will never appear simultaneously at both inputs.</td>
</tr>
<tr>
<td>Flip-flop, R, S, T</td>
<td>A flip-flop having three inputs, R, S, and T. The R and S inputs produce states as described for the RS flip-flop above; the T input causes the flip-flop to change states.</td>
</tr>
<tr>
<td>Flip-flop, T</td>
<td>A flip-flop having only one input. A pulse appearing on the input will cause the flip-flop to change states.</td>
</tr>
<tr>
<td>Gate</td>
<td>A circuit having two or more inputs and one output, the output depending on the combination of logic signals at the inputs. There are four types: AND, OR, NAND, NOR. The definitions below assume positive logic is used.</td>
</tr>
<tr>
<td>Gate, AND</td>
<td>All inputs must have 1-state signals to produce a 0-state output.</td>
</tr>
<tr>
<td>Gate, NAND</td>
<td>All inputs must have 1-state signals to produce a 1-state output.</td>
</tr>
<tr>
<td>Gate, NOR</td>
<td>Any one or more inputs having a 1-state signal will yield a 0-state output.</td>
</tr>
<tr>
<td>Gate, OR</td>
<td>Any one or more inputs having a 1-state signal is sufficient to produce a 1-state output.</td>
</tr>

<tbody>
<tr>
<td>Inverter</td>
<td>The output is always in the opposite logic state as the input. Also called a NOT circuit.</td>
</tr>
<tr>
<td>Memory</td>
<td>A storage device into which information can be inserted and held for use at a later time.</td>
</tr>
<tr>
<td>NAND gate</td>
<td>The simultaneous presence of all inputs in the positive state generates an inverted output.</td>
</tr>
<tr>
<td>Negative logic</td>
<td>The more negative voltage (or current) level represents the 1-state; the less negative level represents the 0-state.</td>
</tr>
<tr>
<td>NOR gate</td>
<td>The presence of one or more positive inputs generates an inverted output.</td>
</tr>
<tr>
<td>NOT</td>
<td>A boolean logic operator indicating negation. A variable designated NOT will be the opposite of its AND or OR function. A switching function for only one variable.</td>
</tr>
<tr>
<td>OR</td>
<td>A boolean operator analogous to addition (except that two truths will only add up to one truth). Of two variables, only one need be true for the output to be true.</td>
</tr>
<tr>
<td>Parallel operator</td>
<td>Pertaining to the manipulation of information within computer circuits in which the digits of a word are transmitted simultaneously on separate lines. It is faster than serial operation but requires more equipment.</td>
</tr>
<tr>
<td>Positive logic</td>
<td>The more positive voltage (or current) level represents the 1-state; the less positive level represents the 0-state.</td>
</tr>
<tr>
<td>Propagation delay</td>
<td>A measure of the time required for a change in logic level to spread through a chain of circuit elements.</td>
</tr>
<tr>
<td>Pulse</td>
<td>A change of voltage or current of some finite duration and magnitude. The duration is called the pulse width or pulse length; the magnitude of the change is called the pulse amplitude or pulse height.</td>
</tr>
<tr>
<td>Register</td>
<td>A device used to store a certain number of digits in the computer circuits, often one word. Certain registers may also include provisions for shifting, circulating, or other operations.</td>
</tr>
<tr>
<td>Rise time</td>
<td>A measure of the time required for a circuit to change its output from a low level (zero) to a high level (one).</td>
</tr>
<tr>
<td>Serial operation</td>
<td>The handling of information within computer circuits in which the digits of a word are transmitted one at a time along a single line. Though slower than parallel operation, its circuits are much less complex.</td>
</tr>
<tr>
<td>Shift register</td>
<td>An element in the digital family that uses flip-flops to perform a displacement or movement of a set of digits one or more places to the right or left. If the digits are those of a numerical expression, a shift may be the equivalent of multiplying the number by a power of the base.</td>
</tr>
<tr>
<td>Skew</td>
<td>Time delay or offset between any two signals.</td>
</tr>
<tr>
<td>Synchronous timing</td>
<td>Operation of a switching network by a clock pulse generator. Slower and more critical than asynchronous timing but requires fewer and simpler circuits.</td>

13.1 Heatsinks

13.1.1 Thermal Management of Today’s Audio Systems

By Henry Villaume, Villaume Associates, LLC

Today’s audio systems, like all electronic systems are being powered by smaller devices, packaged in smaller systems that are generating more heat. We need to increase our level of understanding on all of the latest techniques for the management of this added heat in as effective a means as possible. Let’s first start with the understanding of the three methods of heat transfer—specifically, convection, conduction, and radiation as all three methods of heat transfer contribute to the complete thermal management provided by the heatsinks installed in an audio system.

13.1.1.1 Convection

Convection is the transfer of heat from a solid surface to the surrounding gas, which is always air in the case of a typical audio system. This method of heat transfer drives the amount of required fin surface area that is accessible to the surrounding air so that it may heat up the surrounding air, allow it to move away, and make room for the process to repeat itself. This process can be greatly accelerated with the use of a fan to provide more energy to the moving of the air than just the natural buoyant force of the heated air.

Natural convection is when there is no external fan and the heat transfer occurs with very low air flow rates, typically as low as 35 linear feet per minute (lfm) for obstructed natural convection to 75 lfm for optimum unobstructed vertical natural convection. Natural convection is never zero air flow rate because without air movement there would be no heat transfer. Think of the closed cell plastic foam insulation. It works as an insulator because the closed cell prevents the air from moving away.

Forced convection is when a system fan imparts a velocity to the air surrounding the heatsink fins. The fan may be physically attached to the convective fin surface area of the heatsink to increase the air velocity over the fin surfaces. There is impingement flow—fan blows down from on top of the fins—and through flow—fan blows from the side across the fin set.

Forced convection thermal systems are most generally significantly smaller (50% or more) than their natural convection equivalents. The penalties for the smaller size are the added power to operate the fan, an added failure mechanism, the added cost, and the noise from the fan. Fan noise is probably the most important consideration when applying them in audio systems.

13.1.1.2 Conduction

Conduction is the transfer of heat from one solid to the next adjacent solid. The amount and thermal gradient of heat transfer are dependent on the surface finishes—flatness and roughness—and the interfacial pressure generated by the attachment system. This mechanically generated force is accomplished by screws, springs, snap assemblies, etc. The thermal effectiveness of a conductive interface is measured by the resultant temperature gradient in °C. This may be calculated from the interface thermal resistance at the mounted pressure times the watts of energy moving across the joint divided by the cross-sectional area. These temperature gradients are most significant for high wattage components in small packages—divisors less than 1.0 are, in actual effect, multipliers. Good thermal solutions have attachment systems that generate pressures of 25–50 psi.

Table 13-1 compares the thermal performance of most of the common interface material groups with a dry joint—this makes amply clear why it is never acceptable to specify or default through design inaction to a dry joint.

</tbody>
</table>
The primary heat transfer driving force is the temperature difference between $T_{\text{maxcase}}$ and $T_{\text{maxambient}}$ modified by the conductive delta $T$ losses in the interface and any extraordinary hot spot offsets and spreading losses. If heatsinks are mounted over spread hot spots these last conductive losses are not sufficiently large to consider. They really only become significant when considering very unusual arrangements—high-watt density loads such as typical LEDs.

13.1.1.3 Radiation

Radiation is the third and least important method of heat transfer for audio system heatsinks. Radiation has a maximum 20–25% impact in natural convection applications with a negligible impact after 200 lfm applications. Radiation is a function of the fourth power of the absolute temperature difference between the hot side and surrounding cooler surfaces that look at each other and their respective emissivities. In the real world in which we live, these are not significant enough to suggest a lot of effort to understand and optimize.

Aluminum extruded heatsinks were typically made black in an anodizing process at a significant cost to get an emissivity of 0.95 (dimensionless). The typical aluminum surface forms an oxide film in less than a second after machining with an emissivity of about 0.30–0.40. Nominally, almost half the benefit will come free so that our advice is “Leave the radiation effects alone.” What you get beneficially you were going to largely get anyway, free from Mother Nature.

In review, heatsinks use all three methods of heat transfer to produce the desired effect of cooling the typical electronic component in the typical audio system.

13.1.1.4 Summary

Convection is usually the most significant method, and it depends on having sufficient fin surface area in direct contact with the surrounding air and design features to minimize the insulating effects of boundary films. Aerodynamic shapes and adequate open fin spacing that allows free air movement are critical design issues.

Conduction is the first step in the heat transfer chain in that conduction transfers the heat from the device into heatsink, then through the heatsink to the fin surface where convection takes over. Some heatsinks need conduction enhancements such as heat pipes to keep the conduction temperature gradients to a value that is low enough to allow the convection to complete the heat transfer without exceeding the application temperature limits.

Radiation is a secondary level effect that is always present, marginally significant in natural convection, but not economical to control.

13.1.2 New Technologies to Make Things Fit More Easily

The range of technologies, materials, and fabrication processes available to the thermal designer today is quite impressive. The primary goal when employing these advanced technologies, materials, and fabrication processes is to increase the effective density of the resultant heat transfer system. Technically, we are increasing the volumetric efficiency of the thermal solution proposed for a given application. In “man speak” the required heatsink gets much smaller in size and therefore fits more easily into the ever-shrinking product envelope. A smaller heatsink has a decreased conductive thermal spreading resistance and therefore a smaller conductive temperature gradient. In this section we are going to assume that we have a convective solution defined for a baseline heatsink. The baseline heatsink is fabricated from an extruded aluminum alloy (6063-T5). The following paragraphs will describe a technology, material or fabrication process and give a volume ratio or range of volume ratios that can be applied to the existing solution to quickly see the benefit of applying this technology, material, or fabrication process to the audio application at hand. Ratios that are less than 1.00 are indicating a reduction in heatsink volume.

Thermal solution problem solving is an iterative process balancing the application boundary specifications against the affordable technologies/materials/fabrication processes until a system compromise solution is defined. For example; marketing has directed that only a natural convection solution is acceptable but the heatsink is too big. One solution might require the $T_{\text{maxambient}}$ be reduced by 5°C and the heatsink be fabricated from copper, C110 soldered together. This could reduce the size of the heatsink by 25–35%. The penalties would be the weight would increase between to and three times and the unit cost of the heatsink increase by three to four times. There are software systems that specialize in defining these trade-offs rapidly, allowing a real-time compromise to be made, even during the design review meeting with marketing.
Table 13-2 summarizes the thermal solution benefits possible with the proper application of new technologies, materials and fabrication processes.

Extruded heatsinks have fin thicknesses that are much greater, thicker than required thermally. They are thicker to accommodate the strength requirements of the die, which is close to the melting point of aluminum during the extrusion process.

Bonded fin and folded fin heatsink designs use sheet stock for the fins so that they may be optimally sized as required to carry the thermal load without regard to the mechanical requirements of the extrusion process. These heatsinks can, therefore, without compromising the required open fin spacing, have a greater number of fins and be convectively much more volumetrically effective. These sheet metal fins are attached to the heatsink bases with either thermal epoxy adhesives or solders. Since this joint only represents ~3 % of the total thermal resistance of the heatsink, the adhesive choice is never critical.

Air flow management is the most critical parameter to control in optimizing the convective heat transfer for any thermal solution. Baffles, shrouds, and fan sizing are all very critical in making the most of the convective portion of the heat transfer thermal solution. Some months ago we were confronted with an audio amplifier that had two rows of very hot components. With two facing extrusions that formed a box shape, we mounted a fan at the end and blew the air down the chute with great success. The air flow was fully contained and no leakage occurred. And so the audio cooling tube was born.

There should always be a space—0.5–0.8 inches along the axis of the fan—between the fan outlet and the fin set that is fully shrouded to force the air to pass over the convective fin surfaces. This is called the plenum. Its function is to allow the upstream pressure generated by the fan to reach an equilibrium and thereby equalize the air flow through each fin opening.

Audio systems that require fans need to be carefully designed to have an air flow path that is well defined so that the fan may be operated at a minimal speed. This results in the fan generating a minimum of noise. High-velocity fans are noisy. Noise abatement is very expensive and seldom truly satisfactory, therefore, the best solution is to minimize the fan generated noise.

### 13.1.3 How Heatsinks Work

**by Glen Ballou**

*Heatsinks* are used to remove heat from a device, often the semiconductor junction. To remove heat, there must be a temperature differential ($\Delta T$) between the junction and the air. For this reason, heat removal is always after the fact. Unfortunately, there is also resistance to heat transfer between the junction and its case, any insulating material, the heatsink, and the air, Fig. 13-1.

13.1.3.1 Thermal Resistance

The total thermal resistance between the junction and the air is the sum of the individual thermal resistances

$$\Sigma \theta = \theta_{JC} + \theta_{CI} + \theta_{IS} + \theta_{SA}$$  \hspace{1cm} (13-1)

where,

- $I$ is the thermal resistance in degrees Celsius per watt ($^\circ$C/W),
- $JC$ is the junction to case,
- $CI$ is the case to insulator,
- $IS$ is the insulator to heatsink,
- $SA$ is the heatsink to air.

The temperature at the junction can be determined from the ambient temperature, the thermal resistance between the air and the junction, and the power dissipated at the junction.

$$T_J = T_A + \theta_{JA}P_D$$  \hspace{1cm} (13-2)

where,

- $T_A$ is the temperature of the air,
- $\theta_{JA}$ is the thermal resistance from the air to the junction,
- $P_D$ is the power dissipated.

If the junction temperature was known, then the power dissipated at the junction can be determined

$$P_D = \frac{\Delta T}{\Sigma \theta}$$  \hspace{1cm} (13-3)

where,

- $\Delta T$ is $T_J - T_A$.

13.1.3.2 Heatsink Materials and Design

Heatsinks are generally made from extruded aluminum or copper and are painted black, except for the areas in which the heat-producing device is mounted. The size of heatsinks will vary with the amount of heat to be radiated and the ambient temperature and the maximum average forward current through the element. Several different types of heatsinks are pictured in Fig. 13-2.

The rate of heat flow from an object is

$$Q = \frac{KA\Delta T}{L}$$  \hspace{1cm} (13-4)

For best conduction of heat, the material should have a high thermal conductivity and have a large cross-sectional area. The ambient or material temperature should be maintained as low as possible, and the thermal path should be short.

The heat may also be transferred by convection and radiation. When a surface is hotter than the air about it, the density of the air is reduced and rises, taking heat with it. The amount of heat (energy) radiated by a body is dependent on its surface area, temperature, and emissivity. For best results, the heatsink should:

- Have maximum surface area/volume (hence the use of vertical fins).
• Be made of a high thermal conductivity material.
• Have material of high emissivity (painted aluminum or copper).
• Have proper ventilation and location (should be below, not above, other heat radiators).
• Be placed so that the lowest power device is below the higher power devices, and all devices should be as low as possible on the heatsink.

The overall effectiveness of a heatsink is dependent to a great extent on the intimacy of the contact between the device to be cooled and the surface of the heatsink. Intimacy between these two is a function of the degree of conformity between the two surfaces and the amount of pressure that holds them together. The application of a silicone oil to the two surfaces will help to minimize air gaps between the surfaces, improving conduction. The use of a mica washer between the base of the device to be cooled and the heatsink will add as much as 0.5°C/W to the thermal resistance of the combination. Therefore, it is recommended that (whenever possible) an insulating washer be used to insulate the entire heatsink from the chassis to which it is to be mounted. This permits the solid-state device to be mounted directly to the surface of the heatsink (without the mica washer). In this way, the thermal resistance of the mica washer is avoided.

Today high thermal conductive/high electrical insulation materials are available to electrically insulate the transistor case from the heatsink. They come in the form of silicon rubber insulators, hard-coat-anodized finish aluminum wafers, and wafers with a high beryllium content.

A typical heatsink is shown in Fig. 13-3. This sink has 165 in² of radiating surface. The graph in Fig. 13-4 shows the thermal characteristics of a heatsink with a transistor mounted directly on its surface. A silicone oil is used to increase the heat transfer. This graph was made with the heatsink fins in a vertical plane, with air flowing from convection only. Fig. 13-5 shows the effect of thermal resistance with forced air blown along the length of the fin.

A transistor mounting kit is shown in Fig. 13-6. Several different types of silicon fluids are available to improve heat transfer from the device to the heatsink. The fluid is applied between the base of the transistor and the surface of the heatsink or, if the transistor is insulated from the heatsink, between the base and the mica washer and the mica washer and the heatsink. For diodes pressed into a heatsink, the silicone fluid is applied to the surface of the diode case before pressing it into the heatsink. The purpose of the silicone fluid is to provide good heat transfer by eliminating air gaps.

Thermally conductive adhesives can also be used. These adhesives offer a high heat transfer, low shrinkage, and a coefficient of thermal expansion comparable to copper and aluminum.

The thermal capacity of a cooling fin or heatsink must be large compared to the thermal capacity of the
device and have good thermal conductivity across its entire area. The specific thermal resistance $\rho$ of interface materials used for heatsinks and insulating devices is shown in Table 13-3.

The thermal resistance $\theta$ for these materials can be determined by the equation

$$ \theta = \frac{\rho t}{A} \quad (13-5) $$

where,

- $\rho$ is the specific thermal resistance in °C in/W,
- $t$ is the material thickness in inches,
- $A$ is the area in square inches.

For instance, a square copper plate 4 inches per side and 1/8 inch thick would have a $\theta$ of 0.00078°C/W, while a mica insulator 0.003 inch thick with a diameter of 1 inch would have a $\theta$ of 0.25°C/W. If the semiconductor dissipates 100 W, the temperature drop across the copper plate would be 0.07°C (0.13°F) and across the mica washer it would be 25°C (45°F). In transistor replacement in older equipment, it would be best to replace the mica insulator with a new type of insulator.

In the selection of a heatsink material, the thermal conductivity of the material must be considered. This determines the thickness required to eliminate thermal gradients and the resultant reduction in emissivity. An aluminum fin must be twice as thick as a comparable copper fin, and steel must be eight times as thick as copper.

Except for the smallest low-current solid-state devices, most devices must use a heatsink, either built in or external.

Space for heatsinks is generally limited, so the minimum surface area permissible may be approximately calculated for a flat aluminum heat plate by

$$ A = \frac{133 W}{\Delta T} \text{ in}^2 \quad (13-6) $$

where,

- $W$ is the power dissipated by the device,
- $\Delta T$ is the temperature differences between the ambient and case temperature in °C.

The approximate wattage dissipated by the device can be calculated from the load current and the voltage drop across it

$$ W = I_L V_D \quad (13-7) $$

where,

- $I_L$ is the load current,
- $V_D$ is the voltage drop across the device.
For a triac, $V_D$ is about 1.5 V; for SCRs, about 0.7 V. For transistors it could be from 0.7 V to more than 100 V.

The following is an example of how to determine the minimum surface area required for a flat aluminum heatsink to keep the case temperature of 75°C (167°F) for a triac while delivering a load current of 15 A, at 25°C (77°F) ambient and a voltage drop across the triac of 1.5 V.

$$\Delta T = T_{case} - T_{ambient}$$
$$\Delta T = 75°C - 25°C$$
$$\Delta T = 50°C$$

Using Eq. 13-7

$$W = V_D I_L$$
$$W = 1.5 \times 15$$
$$W = 22.5 \text{ W}$$

Using Eq. 13-6

$$A = \frac{133 W}{\Delta T} \text{ in}^2$$
$$A = \frac{133 \times 22.5}{50}$$
$$A = 59.85 \text{ in}^2$$

It is important that the case temperature, $T_{case}$, does not exceed the maximum allowed for a given load current, $I_L$ (see typical derating curves in Fig. 13-70).

In restricted areas, forced-convection cooling may be necessary to reduce the effective thermal resistance of the heatsink. When forced air cooling is used to cool the component, the cubic feet per minute (cfm or ft³/min) required is determined by

$$cmf = \frac{Btu/h}{60} \times 0.02 \text{ temperature rise}$$
$$cmf = \frac{1.76Q}{\Delta TK}$$

where,

1 W is 3.4 Btu,

temperature rise is in °C,

$Q$ is the heat dissipated in watts,

$\Delta T$ is the heatsink mounting temperature minus the ambient temperature,

$K$ is the coupling efficiency (0.2 for wide spaced fins, 0.6 for close spaced fins).

### 13.2 Relays

A relay is an electrically operated switch connected to or actuated by a remote circuit. The relay causes a second circuit or group of circuits to operate. The relay may control many different types of circuits connected to it. These circuits may consist of motors, bells, lights, audio circuits, power supplies, and so on, or the relay...
may be used to switch a number of other circuits at the same time or in sequence from one input.

Relays may be electromechanical or solid state. Both have advantages and disadvantages. Only a few years ago relays were big and cumbersome and required either an octal-type socket or were externally wired. Today relays are very compact and come in many layouts. A few are given below.

**Solder Connectors.** Connectors vary in size and spacing, depending on the current carrying capacity.

**Octal Sockets.** Plug into standard 8 pin and 11 pin sockets.

**Rectangular Sockets.** Plug into a 10 pin, 11 pin, 12 pin, 14 pin, 16 pin, 22 pin, or 28 pin socket.

**DIP Relays.** Designed to mount directly on a printed circuit board on a 0.1 inch spacing. Sockets can be 8 pin or 16 pin.

**SIP 4 Pin Relay.** Plug into a SIP socket or mount on a printed circuit board on a 0.2 inch in-line spacing.

### 13.2.1 Glossary of Terms

This glossary was compiled from NARM Standard RS-436, MIL STD 202, and MIL STD R5757.

**Actuate Time.** The time measured from coil energization to the stable contact closure (Form A) or stable contact opening (Form B) of the contact under test. (See also Operate Time.)

**Ampere Turns (AT).** The product of the number of turns in an electromagnetic coil winding and the current in amperes passing through the winding.

**Bandwidth.** The frequency at which the RF power insertion loss of a relay is 50%, or −3 dB.

**Bias, Magnetic.** A steady magnetic field applied to the magnetic circuit of a switch to aid or impede its operation in relation to the coil’s magnetic field.

**Bounce, Contact.** Intermittent and undesired opening of closed contacts or closing of opened contacts usually occurring during operate or release transition.

**Breakdown Voltage.** The maximum voltage that can be applied across the open switch contacts before electrical breakdown occurs. In reed relays it is primarily dependent on the gap between the reed switch contacts and the type of gas fill used. High AT switches within a given switch family have larger gaps and higher breakdown voltage. It is also affected by the shape of the contacts, since pitting or whiskering of the contact surfaces can develop regions of high electric field gradient that promote electron emission and avalanche breakdown. Since such pitting can be asymmetric, breakdown voltage tests should be performed with forward and reverse polarity. When testing bare switches, ambient light can affect the point of avalanche and should be controlled or eliminated for consistent testing. Breakdown voltage measurements can be used to detect reed switch capsule damage. See Paschen Test.

**Carry Current.** The maximum continuous current that can be carried by a closed relay without exceeding its rating.

**Coaxial Shield.** Copper alloy material that is terminated to two pins of a reed relay within the relay on each side of the switch. Used to simulate the outer conductor of a coaxial cable for high-frequency transmission.

**Coil.** An assembly consisting of one or more turns of wire around a common form. In reed relays, current applied to this winding generates a magnetic field that operates the reed switch.

**Coil AT.** The coil amperes turns (AT) is the product of the current flowing through the coil (and therefore directly related to coil power) and the number of turns. The coil AT exceeds the switch AT by an appropriate design margin to ensure reliable switch closure and adequate switch overdrive. Sometimes abbreviated as \(NI\), where \(N\) is the number of turns and \(I\) is the coil current.

**Coil Power.** The product, in watts, of the relay’s nominal voltage and current drawn at that voltage.

**Cold Switching.** A circuit design that ensures the relay contacts are fully closed before the switched load is applied. It must take into account bounce, operate and release time. If technically feasible, cold switching is the best method for maximizing contact life at higher loads.

**Contact.** The ferromagnetic blades of a switch often plated with rhodium, ruthenium, or tungsten material.

**Contact Resistance, Dynamic.** Variation in contact resistance during the period in which contacts are in motion after closing.

**Contact Resistance, Static.** The dc resistance of closed contacts as measured at their associated contact terminals. Measurement is made after stable contact closure is achieved.
Crosstalk (Crosstalk Coupling). When applied to multichannel relays, the ratio, expressed in dB, of the signal power being emitted from a relay output contact to the power being applied to an adjacent input channel at a specified frequency.

**Duty Cycle.** A ratio of energized to de-energized time.

**Electrostatic Shield.** Copper alloy material terminated to one pin within the reed relay. Used to minimize coupling and electrostatic noise between the coil and contacts.

**Form-A.** Contact configuration that has one single pole–single throw normally open (SPST n.o.) contact.

**Form-B.** Contact configuration that has one single pole–single throw normally closed (SPST n.c.) contact.

**Form-C.** Contact configuration that has one single pole–double throw (SPDT) contact. (One common point connected to one normally open and one normally closed contact.) Sometimes referred to as a transfer contact.

**Hard Failure.** Permanent failure of the contact being tested.

**Hermetic Seal.** An enclosure that is sealed by fusion to ensure a low rate of gas leakage. In a reed switch, a glass-to-metal seal is employed.

**Hot Switching.** A circuit design that applies the switched load to the switch contacts at the time of opening and closure.

**Hysteresis.** When applied to reed relays, the difference between the electrical power required to initially close the relay and the power required to just maintain it in a closed state. (Usually expressed in terms of the relay’s pull-in voltage and drop-out voltage.) Some degree of hysteresis is desirable to prevent chatter and is also an indicator of adequate switch contact force.

**Impedance (Z).** The combined dc resistance and ac reactance of a relay, at a specified frequency and if found with the equation

\[ Z = R + jX \]  \hspace{1cm} (13-9)

where,

- \( R \) is the dc resistance,
- \( X \) is \( 2\pi fL - \frac{1}{2\pi fC} \),
- \( f \) is the frequency.

Because of the small residual capacitance across the open contacts of a reed relay, the impedance decreases at higher frequencies, resulting in lower isolation at higher frequencies. Conversely, increasing inductive reactance at higher frequencies causes the impedance of a closed relay to rise, increasing the insertion loss at higher frequencies.

**Impedance Discontinuity.** A deviation from the nominal RF impedance of 50 Ω at a point inside a reed relay. Impedance discontinuities cause signal absorption and reflectance problems resulting in higher signal losses. They are minimized by designing the relay to have ideal transmission line characteristics.

**Insertion Loss.** The ratio of the power delivered from an ac source to a load via a relay with closed contacts, compared to the power delivered directly, at a specified frequency, and is found with the equation

\[ \text{Insertion Loss} = -20\log \frac{V_t}{V_i} \]  \hspace{1cm} (13-10)

where,

- \( V_t \) is the transmitted voltage,
- \( V_i \) is the incident voltage.

Insertion loss, isolation and return loss are often expressed with the sign reversed; for example, the frequency at which 50% power loss occurs may be quoted as the −3 dB point. Since relays are passive and always produce net losses, this does not normally cause confusion.

**Inrush Current.** Generally, the current waveform immediately after a load is connected to a source. Inrush current can form a surge flowing through a relay that is switching a low-impedance source load that is typically a highly reactive circuit or one with a nonlinear load characteristic such as a tungsten lamp load. Such abusive load surges are sometimes encountered when relays are inadvertently connected to test loads containing undischarged capacitors or to long transmission lines with appreciable amounts of stored capacitive energy. Excessive inrush currents can cause switch contact welding or premature contact failure.

**Insulation Resistance.** The dc resistance between two specified test points.

**Isolation.** The ratio of the power delivered from a source to a load via a relay with open contacts, compared to the power delivered directly, at a specified frequency. If \( V_i \) is the incident voltage and \( V_t \) is the transmitted voltage, then isolation can be expressed in decibel format as
where, 
\( V_t \) is the transmitted voltage,
\( V_i \) is the incident voltage.

**Latching Relay.** A bistable relay, typically with two coils, that requires a voltage pulse to change state. When pulse is removed from the coil, the relay stays in the state in which it was last set.

**Life Expectancy.** The average number of cycles that a relay will achieve under specified load conditions before the contacts fail due to sticking, missing or excessive contact resistance. Expressed as mean cycles before failure (MCBF).

**Low Thermal Emf Relay.** A relay designed specifically for switching low-voltage level signals such as thermocouples. These types of relays use a thermally compensating ceramic chip to minimize the thermal offset voltage generated by the relay.

**Magnetic Interaction.** The tendency of a relay to be influenced by the magnetic field from an adjacent energized relay. This influence can result in depression or elevation of the pull-in and dropout voltage of the affected relay, possibly causing them to fall outside their specification. Magnetic interaction can be minimized by alternating the polarity of adjacent relay coils, by magnetic shielding, or by placing two relays at right angles to each other.

**Magnetic Shield.** A ferromagnetic material used to minimize magnetic coupling between a relay and external magnetic fields.

**Mercury Wetted Contact.** A form of reed switch in which the reeds and contacts are wetted by a film of mercury obtained by a capillary action from a mercury pool encapsulated within the reed switch. The switch in this type of relay must be mounted vertically to ensure proper operation.

**Missing (Contacts).** A reed switch failure mechanism, whereby an open contact fails to close by a specified time after relay energization.

**Nominal Voltage.** The normal operating voltage of the relay.

**Operate Time.** The time value measured from the energization of the coil to the first contact closure, Form A, or the first contact open, Form B.

**Operate Voltage.** The coil voltage measured at which a contact changes state from its unenergized state.

**Overdrive.** The fraction or percentage by which the voltage applied to the coil of a relay exceeds its pull-in voltage. An overdrive of at least 25% ensures adequate closed contact force and well-controlled bounce times, which result in optimum contact life. For instance, Coto Technology’s relays are designed for a minimum of 36% overdrive so a relay with a nominal coil voltage of 5 V will pull in at no greater than 3.75 V.

When using reed relays, the overdrive applied to the relay should not drop below 25% under field conditions. Issues such as power supply droop and voltage drops across relay drivers can cause a nominally acceptable power supply voltage to drop to a level where adequate overdrive is not maintained.

**Release Time.** The time value measured from coil de-energization to the time of the contact opening, Form-A or first contact closure, Form-B.

**Release Voltage.** The coil voltage measured at which the contact returns to its de-energized state.

**Return Loss.** The ratio of the power reflected from a relay to that incident on the relay, at a specified frequency and can be found with the equation

\[
\text{Return loss} = -20 \log \frac{V_r}{V_i} \tag{13-12}
\]

where, 
\( V_r \) is the reflected voltage,
\( V_i \) is the incident voltage.

**Signal Rise Time.** The rise time of a relay is the time required for its output signal to rise from 10–90% of its final value, when the input is changed abruptly by a step function signal.

**Shield, Coaxial.** A conductive metallic sheath surrounding a reed relay’s reed switch, appropriately connected to external pins by multiple internal connections, and designed to preserve a 50 Ω impedance environment within the relay. Used in relays designed for high-frequency service to minimize impedance discontinuities.

**Shield, Electrostatic.** A conductive metallic sheath surrounding a reed relay’s reed switch, connected to at least one external relay pin, and designed to minimize capacitive coupling between the switch and other relay components, thus reducing high-frequency noise pickup. It is similar to a coaxial shield, but not designed to maintain a 50 Ω RF impedance environment.
Shield, Magnetic. An optional plate or shell constructed of magnetically permeable material such as nickel-iron or mu-metal, fitted external to the relay’s coil. Its function is to reduce the effects of magnetic interaction between adjacent relays and to improve the efficiency of the relay coil. A magnetic shell also reduces the influence of external magnetic fields, which is useful in security applications. Magnetic shields can be fitted externally or may be buried inside the relay housing.

Soft Failure. Intermittent self-recovering failure of a contact.

Sticking (Contacts). A switch failure mechanism, whereby a closed contact fails to open by a specified time after relay de-energization. Can be subclassified as hard or soft failures.

Switch AT. The ampere turns required to close a reed switch, pull-in AT, or just to maintain it closed, drop-out AT, and is specified with a specific type and design of coil. Switch AT depends on the length of the switch leads and increases when the reed switch leads are cropped. This must be taken into account when specifying a switch for a particular application.

Switching Current. The maximum current that can be hot-switched by a relay at a specified voltage without exceeding its rating.

Switching Voltage. The maximum voltage that can be hot-switched by a relay at a specified current without exceeding its rating. Generally lower than breakdown voltage, since it has to allow for any possible arcing at the time of contact breaking.

Transmission Line. In relay terms an interruptible waveguide consisting of two or more conductors, designed to have a well-controlled characteristic RF impedance and to efficiently transmit RF power from source to load with minimum losses, or to block RF energy with minimum leakage. Structures useful within RF relays include microstrips, coplanar waveguides, and coaxial transmission line elements.

VSWR (Voltage Standing Wave Ratio). The ratio of the maximum RF voltage in a relay to the minimum voltage at a specified frequency and calculated from

\[ VSWR = \frac{1 + \rho}{1 - \rho} \]

where,
\[ \rho \] is the the voltage reflected back from a closed relay terminated at its output with a standard reference impedance, normally 50 Ω.

13.2.2 Contact Characteristics

Contacts may switch either power or dry circuits. A power circuit always has current flowing, while a dry circuit has minimal or no current flowing, such as an audio circuit. A dry or low-level circuit typically is less than 100 mV or 1 mA.

The mechanical design of the contact springs is such that when the contacts are closed, they slide for a short distance over the surfaces of each other before coming to rest. This is called a wiping contact, and it ensures good electrical contact.

Contacts are made of silver, palladium, rhodium, or gold and may be smooth or bifurcated. Bifurcated contacts have better wiping and cleaning action than smooth contacts and, therefore, are used on dry circuits.

There are various combinations of contact springs making up the circuits that are operated by the action of the relay. Typical spring piles are shown in Fig. 13-9.

As contacts close, the initial resistance is relatively high, and any films, oxides, and so on further increase the contact resistance. Upon closing, current begins to flow across the rough surface of the contacts, heating and softening them until the entire contact is mating, which reduces the contact resistance to milliohms. When the current through the circuit is too low to heat and soften the contacts, gold contacts should be used since the contacts do not oxidize and, therefore, have low contact resistance. On the other hand, gold should not be used in power circuits where current is flowing.

The contact current specified is the maximum current, often the make-or-break current. For instance, the make current of a motor or capacitor may be 10–15 times as high as its steady-state operation. Silver cadmium oxide contacts are very common for this type of load. The contact voltage specified is the maximum voltage allowed during arcing during break. The break voltage of an inductor can be 50 times the steady-state voltage of the circuit.

To protect the relay contacts from high transient voltages, arc suppression should be used. For dc loads, this may be in the form of a reverse-biased diode (rectifier), variable resistor (varistor), or RC network, as shown in Fig. 13-10.

The contact current specified is the maximum current, often the make-or-break current. For instance, the make current of a motor or capacitor may be 10–15 times as high as its steady-state operation. Silver cadmium oxide contacts are very common for this type of load. The contact voltage specified is the maximum voltage allowed during arcing during break. The break voltage of an inductor can be 50 times the steady-state voltage of the circuit.

The R and C in an RC circuit are calculated with the following equations:

\[ C = \frac{I^2}{10} \mu F \]
When using a rectifier, the rectifier is an open circuit to the power source because it is reverse biased; however, when the circuit breaks, the diode conducts. This technique depends on a reverse path for the diode to conduct; otherwise, it will flow through some other part of the circuit. It is important that the rectifier have a voltage rating equal to the transient voltage.

Contact bounce occurs in all mechanical-type relays except the mercury-wetted types that, because of the thin film of mercury on the contacts, do not break during make. Bounce creates noise in the circuit, particularly when switching audio where it acts as a dropout.

13.2.3 Relay Loads

Never assume that a relay contact can switch its rated current no matter what type of load it sees. High in-rush currents or high induced back electromotive force (emf) like those of Fig. 13-11 can quickly erode or weld elec-
tromechanical relay contacts and destroy solid-state relays.

13.2.3.1 The Effects of Various Loads

**Incandescent Lamps.** The cold resistance of a tungsten-filament lamp is extremely low, resulting in in-rush currents as much as 15 times the steady-state current. This is why lamp burnout almost always occurs during turn on.

**Capacitive Loads.** The initial charging current to a capacitive circuit can be extremely high, since the capacitor acts as a short circuit, and current is limited only by the circuit resistance. Capacitive loads may be long transmission lines, filters for electromagnetic interference (emi) elimination, and power supplies.

**Motor Loads.** High in-rush current is drawn by most motors, because at standstill their input impedance is very low. This is particularly bad when aggravated by contact bounce causing several high-current makes and breaks before final closure. When the motor rotates, it develops an internal back emf that reduces the current. Depending on the mechanical load, the starting time may be very long and produce a relay-damaging in-rush current.

**Inductive Loads.** In-rush current is limited by inductance; however, when turned off, energy stored in magnetic fields must be dissipated.

**Dc Loads.** These are harder to turn off than ac loads because the voltage never passes through zero. When electromagnetic radiation (emr) contacts open, an arc is struck that may be sustained by the applied voltage, burning contacts.

### 13.2.4 Electromechanical Relays

Regardless of whether the relay operates on ac or dc, it will consist of an actuating coil, a core, an armature, and a group of contact springs that are connected to the circuit or circuits to be controlled. Associated with the armature are mechanical adjustments and springs.
mechanical arrangement of the contacts may be such that when the relay is at rest, certain circuits are either open or closed. If the contacts are open when the relay is at rest (not energized) they are called normally open contacts.

Relays are wound in many different manners, Fig. 13-12. Among them are the single wound, double wound, trifilar wound, bifilar wound, and two coil, which are nonelectromagnetic.

In the quick-operate type, the armature is attracted immediately to the pole piece of the electromagnet when the control circuit is closed.

Slow-operate relays have a time-delay characteristic; that is, the armature is not immediately attracted to the pole piece of the electromagnet when the control circuit is closed. To accomplish this a copper collar is placed around the armature end of the pole piece. They differ from the slow-release variety in that the latter type has the copper collar around the end of the pole piece opposite from the armature.

A polarized relay is designed to react to a given direction of current and magnitude. Polarized relays use a permanent magnet core. Current in a given direction increases the magnetic field, and in the opposite direction it decreases the field. Thus, the relay will operate only for a given direction of current through the coil.

A latching relay is stable in both positions. One type of latching relay contains two separate actuating coils. Actuating one coil latches the relay in one position where it remains until it is unlatched by energizing the other coil.

A second and more modern type is a bistable magnetic latching relay. This type is available in single- or dual-coil latching configurations. Both are bistable and will remain in either state indefinitely. The coils are designed for intermittent duty: 10 s maximum on-time. The relay sets or resets on a pulse of 100 ms or greater. Fig. 13-13 shows the various contact and coil forms.

13.2.4.2 Ac Relays

Alternating-current (ac) relays are similar in construction to the dc relays. Since ac has a zero value every half cycle, the magnetic field of an ac-operated relay will have corresponding zero values in the magnetic field every half cycle.

At and near the instants of zero current, the armature will leave the core, unless some provision is made to hold it in position. One method consists of using an armature of such mass that its inertia will hold it in position. Another method makes use of two windings on separate cores. These windings are connected so that their respective currents are out of phase with each other. Both coils effect a pull on the armature when current flows in both windings.

A third type employs a split pole piece of which one part is surrounded by a copper ring acting as a shorted turn. Alternating current in the actuating coil winding induces a current in the copper coil. This current is out of phase with the current in the actuating coil and does not reach the zero value at the same instant as the

**Figure 13-12.** Types of relay coil windings.

### 13.2.4.1 Dc Relays

Direct current (dc) relays are designed to operate at various voltages and currents by varying the dc resistance of the actuating coils, and may vary from a few to several thousand ohms. Dc relays may operate as marginal, quick-operate, slow-operate, or polarized.

A marginal relay operates when the current through its winding reaches a specified value, and it releases when the current falls to a given value.
current in the actuating coil. As a result, there is always enough pull on the armature to hold it in the operating position.

An ac differential relay employs two windings exactly alike, except they are wound in opposite directions. Such relays operate only when one winding is energized. When both windings are energized in opposite directions, they produce an aiding magnetic field, since the windings are in opposite directions. When the current through the actuating coils is going in the same direction, the coils produce opposite magnetic fields. If the current through the two coils is equal, the magnetic fields neutralize each other and the relay is nonoperative.

A differential polar relay employs a split magnetic circuit consisting of two windings on a permanent magnet core. A differential polar relay is a combination of a differential and a polarized relay.

13.2.5 Reed Relays

Reed relays were developed by the Bell Telephone Laboratories in 1960 for use in the Bell System central offices. The glass envelope is surrounded by an electromagnetic coil connected to a control circuit. Although originally developed for the telephone company, such devices have found many uses in the electronics industry.

The term reed relay covers dry reed relays and mercury-wetted contact relays, all of which use hermetically sealed reed switches. In both types, the reeds (thin, flat blades) serve multiple functions, as conductor, contacts, springs, and magnetic armatures. Reed relays are usually soldered directly onto a circuit board or plugged into a socket that is mounted onto a circuit board.

13.2.5.1 Contact Resistance and Dynamics

Reed relays have much better switching speed than electromechanical relays. The fastest Coto Technology switching reed relay is the 9800 series, with a typical actuate time of 100 μs. Release time is approximately 50 μs. Actuate time is defined as the period from coil energization until the contact is closed and has stopped bouncing. After the contacts have stopped bouncing, they continue to vibrate while in contact with one another for a period of about 1 ms. This vibration creates a wiping action and variable contact pressure.

Static contact resistance (SCR) is the resistance across the contact terminals of the relay after it has been closed for a sufficient period of time to allow for complete settling. For most reed relays, a few milliseconds is more than adequate, but the relay industry uses 50 ms to define the measurement.

Another contact resistance measurement that has provided great insight into the overall quality of the relay is contact resistance stability (CRS). CRS measures the repeatability of successive static contact resistance measurements.

13.2.5.2 Magnetic Interaction

Reed relays are subject to external magnetic effects including the earth’s magnetic field (equivalent to approximately 0.5 AT and generally negligible), electric motors, transformers external magnets, etc., which may change performance characteristics. Such magnetic sources include one common source of an external magnetic field acting on a relay or another relay oper-
ating in close proximity. The potential for magnetic coupling must be taken into account when installing densely packed single- or multichannel relays.

An example of magnetic interaction is shown in Fig. 13-14 where two relays, K1 and K2, with identical coil polarities are mounted adjacent to each other. When K2 is “off”, relay K1 operates at its designed voltage. When K2 is activated, the magnetic fields oppose so the effective magnetic flux within K1 is reduced, requiring an increase in coil voltage to operate the reed switch. For closely packed relays without magnetic shields, a 10–20% increase in operate voltage is typical, which can drive the relays above their specified limits. The opposite effect occurs if K1 and K2 are polarized in opposite directions making the operating voltage for K1 less.

There are several ways to reduce magnetic interaction between relays:

- Specify relays that incorporate an internal or external magnetic shield.
- Apply an external magnetic shield to the area where the relays are mounted. A sheet of mu-metal or other high-magnetic-permeability ferrous alloy 2–5 mils thick is effective.
- Provide increased on-center spacing between relays. Each doubling of this distance reduces the interaction effect by a factor of approximately four.
- Avoid simultaneous operation of adjacent relays.
- Provide alternating coil polarities for relays used in a matrix.

13.2.5.3 Environmental Temperature Effects

The resistance of the copper wire used in reed relay coils increases by 0.4% /1°C rise in temperature. Reed relays are current-sensitive devices so their operate and release levels are based on the current input to the coil. If a voltage source is used to drive the relays, an increase in coil resistance causes less current to flow through the coil, so the voltage must be increased to compensate and maintain current flow. Industry standards define that relays are typically specified at 25°C ambient. If the relay is used in higher ambient conditions or near external sources of heat, this must be carefully considered.

For example, a standard relay nominally rated at 5 Vdc has a 3.8 Vdc maximum operate value at 25°C as allowed by the specifications. If the relay is used in a 75°C environment, the 50°C temperature rise increases the operate voltage by 50 × 0.4%, or 20%. The relay now will operate at 3.8 Vdc + (3.8 Vdc × 20%), or 4.56 Vdc. If there is more than a 0.5 Vdc drop in supply voltage due to a device driver or sagging power supply, the relay may not operate. Under these conditions there will be increases in operate and release timing to approximately the same 20%.

13.2.5.4 Dry Reed Relays

Because of the tremendous increases in low-level logic switching, computer applications, and other business machine and communication applications, dry reed relays have become an important factor in the relay field. They have the great advantage of being hermetically sealed, making them impervious to atmospheric contamination. They are very fast in operation and when operated within their rated contact loads, they have a very long life. They can be manufactured automatically and therefore are relatively inexpensive. A typical dry reed switch capsule is shown in Fig. 13-15.

In this basic design, two opposing reeds are sealed into a narrow glass capsule and overlap at their free ends. At the contact area, they are plated with rhodium over gold to produce a low contact resistance when they
Heatsinks and Relays

meet. The capsule, surrounded by an electromagnetic coil, is made of glass and filled with a dry inert gas. When the coil is energized in the basic Form A contact combination, the normally open contacts are brought together; when the field is removed the reeds separate by their own spring tension.

Some may contain permanent magnets for magnetic biasing to achieve normally closed contacts (Form B). Single-pole, double-throw contact combinations (Form C) are also available. Current rating, which is dependent on the size of the reed and the type and amount of plating, may range from low level to 1 A. Effective contact protection is essential in most applications unless switching is done dry.

Relay packages using up to four Form C and six Form A dry reed switches are common, providing multiple switching arrangements. The reed relay may be built for a large variety of operational modes such as pulse relay, latch relay, crosspoint relay, and logic relay. These relays may also be supplied with electrostatic or magnetic shields. The relay in Fig. 13-16 has two Form C contacts.

**Figure 13-16.** Coto Technology 2342 multipole relay, Courtesy Coto Technology.

Reed switches have the following characteristics:

- A high degree of reliability stemming from their controlled contact environment.
- Consistency of performance resulting from a minimum number of parts.
- Long operational life.
- Ease of packaging as a relay.
- High-speed operation.
- Small size.
- Low cost.

**Number of Switches.** There appears to be no limit to the number of switches that can be actuated by a common coil. However, as the number increases, coil efficiency decreases and power input increases. This can lead to a practical limitation. On the other hand, the increase in power required to operate one more switch capsule is usually less than the total required if the assembly were split in two. The single contact relay is the most frequently used but relays with four or more switches in a single coil are quite common.

**Sensitivity.** The power input required to operate dry reed relays is determined by the sensitivity of the particular reed switch used, by the number of switches operated by the coil, by the permanent magnet biasing (if used), and by the efficiency of the coil and the effectiveness of its coupling to the reeds. The minimum input required to effect closure ranges from milliwatts for a single capsule sensitive unit to several watts for a multipole relay.

**Operate Time.** Coil time constant, overdrive, and the characteristics of the reed switch determine operate time. With maximum overdrive, reed relays will operate in approximately 200 μs or less. Drive at rated voltage usually results in a 1 ms operate time.

**Release Time.** With the relay coil unsuppressed, dry reed switch contacts release in a fraction of a millisecond. Form A contacts open in as little as 50 μs. Magnetically biased Form B contacts and normally closed contacts of Form C switches reclose from 100 μs to 1 ms, respectively.

If the relay coil is suppressed, release times are increased. Diode suppression can delay release for several milliseconds, depending on coil characteristics, drive level, and reed release characteristics.

**Bounce.** As with the other hard contact switches, dry reed contacts bounce on closure. The duration of bounce is typically quite short and is in part dependent on drive level. In some of the faster devices, the sum of operate time and bounce is relatively constant so as drive is increased, the operate time decreases and bounce increases.

While normally closed contacts of a Form C switch bounce more than normally open contacts, magnetically biased Form B contacts exhibit essentially the same bounce as Form A.

**Contact Resistance.** Because the reeds in a dry reed switch are made of a magnetic material that has a high volume resistivity, terminal-to-terminal resistance is somewhat higher than in some other types of relays. Typical specification limit for initial maximum resistance of a Form A reed relay is 0.200 Ω.
13.2.5.5 Mercury-Wetted Contact Relays

Mercury-wetted contact relays are a form of reed relays consisting of a glass-encapsulated reed with its base immersed in a pool of mercury and the other end capable of moving between one or two stationary contacts. The mercury flows up to the reed by capillary action and wets the contact surface of the moving end of the reed as well as the contact surfaces of the stationary contacts. Thus a mercury-to-mercury contact is maintained in a closed position. The mercury-wetted relay is usually actuated by a coil around the capsule.

Aside from being extremely fast in operation and having relatively good load-carrying capacity, mercury-wetted contact relays have extremely long life since the mercury films are reestablished at each contact closure and contact erosion is eliminated. Since the films are “stretchable,” there is no contact bounce. Contact interface resistance is extremely low.

Three disadvantages of this type of reed relays are:
1. The freezing point of mercury is (–38.8°C or –37.8°F).
2. They have poor resistance to shock and vibration.
3. Some type need to mount in a near vertical position.

These relays are available in a compact form for printed-circuit board mounting. Multipole versions can be provided by putting additional capsules inside the coil. They are used for a great variety of switching applications such as are found in computers, business machines, machine tool control systems, and laboratory instruments.

Mercury-wetted switches can also come as a nonposition sensitive, mercury-wetted, reed relay that combines the desirable features of both dry reed and mercury-wetted capsules. This allows the user to place the reed relay in any position and is capable of withstanding shock and vibration limits usually associated with dry reed capsules. On the other hand, they retain the principal advantages of other mercury-wetted switches—no contact bounce and low stable contact resistance.

Operation of the nonposition-sensitive switch is made possible by the elimination of the pool of mercury at the bottom of the capsule. Its design captures and retains the mercury on contact and blade surfaces only. Due to the limited amount of mercury film, this switch should be restricted for use at low-level loads.

Mercury-wetted reed relays are a distinct segment of the reed relay family. They are different from the dry reed relays in the fact that contact between switch elements is made via a thin film of mercury. Thus, the most important special characteristics of mercury-wetted relays are:

- Contact resistance is essentially constant from operation to operation throughout life.
- Contacts do not exhibit bounce. The amount of mercury at the contacts is great enough to both cushion the impact of the underlying members and to electrically bridge any mechanical bounce that remains.
- Life is measured in billions of operations, due to constant contact surface renewal.
- Contacts are versatile. The same contacts, properly applied, can handle relatively high-power and low-level signals.
- Electrical parameters are constant. With contact wear eliminated, operating characteristics remain the same through billions of operations.

To preserve these characteristics, the rate of change of voltage across the contacts as they open must be limited to preclude damage to the contact surface under the mercury. For this reason, suppression should be specified for all but low-level applications.

Mounting Position. To ensure that distribution of mercury to the relay contacts is proper, position sensitive types should be mounted with switches oriented vertically. It is generally agreed that deviation from vertical by as much as 30° will have some effect on performance. The nonposition-sensitive mercury-wetted relay, which is the most common type today, is not affected by these limitations.

Bounce. Mercury-wetted relays do not bounce if operated within appropriate limits. However, if drive rates are increased, resonant effects in the switch may cause rebound to exceed the level that can be bridged by the mercury, and electrical bounce will result. Altered distribution of mercury to the contacts, caused by the high rate of operation, may also contribute to this effect.

Contact Resistance. Mercury-wetted relays have a terminal-to-terminal contact resistance that is somewhat lower than dry reed relays. Typical specification limit for maximum contact resistance is 0.150 Ω.

13.2.5.6 RF Relays

RF relays are used in high-frequency applications, usually in a 50 Ω circuit. The RF coaxial shielded relay in Fig. 13-17 can switch up to 200 Vdc at 0.5 A.
Insertion and Other Losses. In the past, the typical parameters used to quantify RF performance of reed relays were Insertion loss, isolation, and return loss (sometimes called reflection loss). These are frequency-related vector quantities describing the relative amount of RF power entering the relay and either being transmitted to the output or being reflected back to the source. For example, with the relay’s reed switch closed and 50% power being transmitted through the relay, the insertion loss would be 0.5 or $-3 \text{ dB}$. The frequency at which a $-3 \text{ dB}$ rolloff occurs is a convenient scalar (single-valued) quantity for describing insertion loss performance.

Isolation. The RF isolation of the reed relay can be determined by injecting an RF signal of known power amplitude with the reed switch open (coil unactivated). Sweeping the RF frequency and plotting the amount of RF energy exiting the relay allows the isolation curve to be plotted on a dB scale. At lower frequencies, the isolation may be $-40 \text{ dB}$ or greater, indicating that less than 0.01% of the incident power is leaking through the relay. The isolation decreases at higher frequencies, because of capacitive leakage across reed switch contacts.

Return Loss. Return loss represents the amount of RF power being reflected back to the source with the reed switch open and the output terminated with a standard impedance, normally 50 $\Omega$. If the relay was closely matched to 50 $\Omega$ at all frequencies, the reflected energy would be a very small fraction of the incident energy from low to high frequencies. In practice, return loss increases (more power is reflected) as frequency increases. High return loss (low reflective energy) is desirable for high-speed pulse transmission, since there is less risk of echoing signal collisions that can cause binary data corruption and increased bit error rates.

Return loss is calculated from the reflection coefficient ($\rho$), which is the ratio of the magnitude of signal power being reflected from a closed relay to the power input at a specified frequency

\[
\text{Return loss} = -20 \log \rho
\]

To determine the RF performance of a reed relay involves injecting a swept frequency RF signal of known power into the relay and measuring the amount of RF energy transmitted through or reflected back from it. These measurements can be conveniently made using a Vector Network Analyzer (VNA). These test instruments comprise a unified RF sweep frequency generator and quantitative receiver/detector. In the case of a Form A relay, the device is treated as a network with one input and one output port, and the amount of RF energy entering and being reflected from each port is recorded as a function of frequency. Thus a complete characterization of a Form A relay comprises four data vectors, designated as follows:

- $S_{11}$: power reflected from input port.
- $S_{12}$: power transmitted to input port from output port.
- $S_{21}$: power transmitted to output port from input port.
- $S_{22}$: power reflected from output port.

Voltage Standing Wave Ratio (VSWR). VSWR is a measurement of how much incident signal power is reflected back to the source when an RF signal is injected into a closed relay terminated with a 50 $\Omega$ impedance. It represents the ratio of the maximum amplitude of the reflected signal envelope amplitude divided by the minimum at a specified frequency. A VSWR of 1 indicates a perfect match between the source, relay, and output load impedance and is not achievable. VSWR at any particular frequency can be converted from y-axis return loss using Table 13-2.

### Table 13-4. Return Loss Versus VSWR

Rise Time. The rise time of a reed relay is the time required for its output signal to rise from 10% to 90% of its final value, when the input is changed abruptly by a step function signal. The relay can be approximated by
a simple first-order low-pass filter. The rise time is approximately

\[ T_r = RC \times \ln \frac{90\%}{10\%} = 2.3RC \]  

(13-17)

Substituting into the equation for the 50% roll-off frequency \( f_{3\,dB} = \frac{1}{2\pi RC} \) yields the relationship

\[ T_r = \frac{0.35}{f_{3\,dB}}. \]  

(13-18)

Therefore the relay’s rise time can be simply estimated from the \( S_{21} \) insertion loss curve by dividing the –3 dB rolloff frequency into 0.35. For example, the Coto Technology B40 ball grid relay has \( f_{3\,dB} = 11.5 \text{ GHz} \), from which the rise time can be estimated as 30 ps.

**Effect of Lead Form on High Frequency Performance.**

Surface mount (SMD) relays give better RF performance than those with through hole leads. SMD leadforms comprise gullwing, J-bend, and axial forms. Each has its advantages and disadvantages, but the RF performance point of view, axial relays generally have the best RF performance in terms of signal losses, followed by J-bend and gullwing. The straight-through signal path of axial relays minimizes capacitive and inductive reactance in the leads and minimizes impedance discontinuities in the relay, resulting in the highest bandwidth. However, the axial leadform requires a cavity in the printed circuit board to receive the body of the relay. An advantage is the effective reduced height of the axial relay, where space is at a premium.

J-bend relays provide the next-best RF performance and have the advantages of requiring slightly less area on the PCB. The gullwing form is the most common type of SMD relay. It has the longest lead length between the connection to the PCB pad and the relay body which results in slightly lower RF performance than the other lead types. Initial pick-and-place soldering is simple, as is rework, resulting in a broad preference for this lead type unless RF performance is critical.

Coto Technology’s new leadless relays have greatly enhanced RF performance. They do not have traditional exposed metal leads; instead, the connection to the user’s circuit board is made with ball-grid-array (BGA) attachment, so that the devices are essentially leadless. In the BGA relays, the signal path between the BGA signal input and output is designed as an RF transmission line, with an RF impedance close to 50 \( \Omega \) throughout the relay. This is achieved using a matched combination of coplanar waveguide and coaxial structures with very little impedance discontinuity through the relays. The Coto B10 and B40 reed relays, Fig. 13-18 achieve bandwidths greater than 10 GHz and rise times of 35 ps or less.

**Skin Effect in Reed Relays.** At high frequencies, RF signals tend to travel near the surface of conductors rather than through the bulk of the material. The skin effect is exaggerated in metals with high magnetic permeability, such as the nickel-iron alloy used for reed switch blades. In a reed switch, the same metal has to carry the switched current and also respond to a magnetic closure field. Skin effect does not appreciably affect the operation of reed relays at RF frequencies because the increase in ac resistance due to skin effect is proportional to the square root of frequency, whereas the losses due to increasing reactance are directly proportional to \( L \) and inversely proportional to \( C \). Also the external lead surfaces are coated with tin or solder alloys for enhanced solder-ability which helps to reduce skin effect losses.

**Selecting Reed Relays for High Frequency Service.**

High-speed switching circuits can be accomplished with reed relays, electromechanical relays (EMRs) specifically designed for high-frequency service, solid-state relays (SSRs), PIN diodes, and microelectromechanical systems (MEMS) relays. In many cases, reed relays are an excellent choice, particularly with respect to their unrivalled RC product. RC is a figure of merit expressed in \( \text{pF} \cdot \Omega \), where \( R \) is the closed contact resistance and \( C \) is the open contact capacitance. The lower this figure is, the better the high-frequency performance. The RC product of a Coto Technology B40 relay for example, is approximately 0.02 \( \text{pF} \cdot \Omega \). SSRs have \( \text{pF} \cdot \Omega \) products equal to about 6, almost 300 times
higher, plus, the breakdown voltage at these pF•Ω levels is much lower than that of a reed switch. The turn-off time for SSRs is also longer than the 50 µs needed by a reed relay to reach its typical $10^{12}$ Ω off resistance. Some feel that the reliability of reed relays compared to solid-state devices is largely unjustified, due to continuous technological improvements. Many reed relays have demonstrated MCBF values of several hundred million to several billion closure cycles at typical signal switching levels.

PIN diodes are occasionally used for HF switching. However, PIN diodes require relatively complex drive circuitry compared to the simple logic circuitry that drives reed relays. PIN diodes typically have a lower frequency cut-on of about 1 MHz, while a reed relay can switch from dc to its useful cut-off frequency. The high junction capacitance of PIN diodes results in lower RF isolation than a reed relay when the PIN diode is biased open. When biased closed, the higher on-resistance of the PIN diode can lead to Q-factor damping in the circuit to which it is connected. PIN diodes can exhibit significant nonlinearity, leading to gain compression, harmonic distortion, and intermodulation distortion, while reed relays are linear switching devices.

Electromechanical relays (EMRs) have been developed with bandwidths to about 6 GHz, and isolation of about −20 dB at that frequency. This isolation is better than that of a reed relay, since the contacts can be designed with bigger spacing, resulting in lower capacitive leakage. This advantage must be weighed against the increased size and cost of EMRs and lower reliability. The EMR has a complex structure with more moving parts than the simple blade flexure involved in closing a reed switch, resulting in a lower mechanical life. If higher isolation is required with a reed relay solution, two relays can be cascaded together with a combined reliability that is still higher than that of a typical EMR.

MEMS switches (relays) are being developed based on two technologies, electrostatic closure and pulsed magnetic toggling between open and closed states. They offer potential advantages in terms of small and low loss high-frequency switching. However, adequate contact reliability has not been demonstrated at the switching loads required by automated test equipment (ATE) applications. At present, though, MEMS relay technology is too immature for use in most applications addressed by reed relays.

13.2.5.7 Dry Reed Switches

A dry reed switch is an assembly containing ferromagnetic contact blades that are hermetically sealed in a glass envelope and are operated by an externally generated magnetic field. The field can be a coil or a permanent magnet. The switches in Figs. 13-19A and 13-19B can switch up to 175 Vdc at 350 mA or 140 Vac at 250 ma. The switch in Fig. 13-19C can switch 200 Vdc at 1 A or 140 Vac at 1 A.
Fig. 13-20 shows three methods of operating a reed switch using a coil. Fig. 13-21 shows four ways to operate a reed switch using permanent magnets.

13.2.6 Solid-State Relays

Solid-state relays (SSRs) utilize the on–off switching properties of transistors and SCRs for opening and closing dc circuits. They also use triacs for switching ac circuits.

13.2.6.1 Advantages

SSRs have several advantages over their electromechanical counterparts: no moving parts, arcing, burning, or wearing of contacts; and the capacity for high-speed, bounceless, noiseless operation. Many SSRs are available that feature optical coupling; thus, the signal circuit includes a lamp or light-emitting diode that shines on a phototransistor serving as the actuating device. In other types of SSRs, a small reed relay or transformer may serve as the actuating device. A third type is direct coupled and therefore not actually an SSR because there is no isolation between input and output. These are better called an amplifier. All three types are shown in Fig. 13-22.

Ac relays turn on and off at zero crossing; therefore, they have reduced \( \frac{dv}{dt} \). However, this does slow down the action to the operating frequency.

13.2.6.2 Disadvantages and Protection

Solid-state relays also have some inherent problems as they are easily destroyed by short circuits, high surge current, high \( \frac{dv}{dt} \), and high peak voltage across the power circuit.
Short-circuit and high-surge current protection is performed with fast blow fuses or series resistors. A standard fuse normally will not blow before the SCR or triac is destroyed since the fuses are designed to withstand surge currents. Fast blow fuses will act on high in-rush currents and usually protect solid-state devices.

Using a current-limiting resistor will protect the SSR; however, it creates a voltage drop that is current dependent and, at high current, dissipates high power.

A common technique for protecting solid-state switching elements against high $dv/dt$ transients is by shunting the switching element with an RC network (snubber), as shown in Fig. 13-23. The following equations provide effective results:

\[
R_1 = \frac{L}{V} \times \frac{dv}{dt} \tag{13-19}
\]

\[
R_2 = \frac{\sqrt{1 - (PF)^2}}{2\pi f} \times \frac{dv}{dt} \tag{13-20}
\]

\[
C = \frac{4L}{R_2} \tag{13-21}
\]

\[
C = \frac{4}{R_2} \times \frac{V}{I} \times \frac{\sqrt{1 - PF^2}}{2\pi F} \tag{13-22}
\]

where,

$L$ is the inductance in henrys,

$V$ is the line voltage,

$dv/dt$ is the maximum permissible rate of change of voltage in volts per microsecond,

$I$ is the load current,

$PF$ is the load power factor,

$C$ is the capacitance in microfarads,

$R_1, R_2$ are the resistance in ohms,

$f$ is the line frequency.

RC networks are often internal to SSRs.

13.2.6.3 High-Peak-Transient-Voltage Protection

Where high-peak-voltage transients occur, effective protection can be obtained by using metal-oxide varistors (MOV). The MOV is a bidirectional voltage-sensitive device that becomes low impedance when its design voltage threshold is exceeded.

Fig. 13-24 shows how the proper MOV can be chosen. The peak nonrepetitive voltage ($V_{DSM}$) of the selected relay is transposed to the MOV plot of peak voltage versus peak amperes. The corresponding current for that peak voltage is read off the chart. Using this value of current ($I$) in

\[
V_{DSM} = V_p - IR \tag{13-23}
\]

where,

$I$ is the current,

$V_p$ is the peak instantaneous voltage transient,

$R$ is the load plus source resistance.

It is important that the $V_{DSM}$ peak nonrepetitive voltage of the SSR is not exceeded.

The energy rating of the MOV must not be exceeded by the value of
13.2.6.4 **Low Load Current Protection**

If the load current is low, it may be necessary to take special precautions to ensure proper operation. Solid-state relays have a finite off-state leakage current. SSRs also need a minimum operating current to latch the output device.

If the off-state voltage across the load is very high, it could cause problems with circuit dropout and component overheating. In these applications a low-wattage incandescent lamp in parallel with the load offers a simple remedy. The nonlinear characteristics of the lamp allow it to be of lower resistance in the off state while conserving power in the on state. It must be remembered to size the SSR for the combined load.

### Figure 13-24. Metal-oxide varistor peak transient protector.

\[ E = V_{DSM} \times I \times t \]  

13.2.6.5 **Optically Coupled Solid-State Relays**

The optically coupled solid-state relay arrangement (SSR) shown in Fig. 13-22A is capable of providing the highest control/power-circuit isolation—many thousands of volts in compact, convenient form. The triac trigger circuit is energized by a phototransistor, a semiconductor device (encapsulated in transparent plastic) whose collector-emitter current is controlled by the amount of light falling on its base region.

A phototransistor is mounted in a light-tight chamber with a light-emitting diode, the separation between them being enough to give high isolation (thousands of volts) between the control and power circuit.

13.2.6.6 **Transformer-Coupled Solid-State Relays**

In Fig. 13-22B, the dc control signal is changed to ac in a converter circuit, the output of which is magnetically coupled to the triac trigger circuit by means of a transformer. Since there is no direct electrical connection between the primary and secondary of the transformer, control/power-circuit isolation is provided up to the voltage withstanding limit of the primary/secondary insulation.

13.2.6.7 **Direct-Coupled Solid-State Relays**

The circuit shown in Fig. 13-22C cannot truly be called a solid-state relay because it does not have isolation between input and output. It is the simplest configuration; no coupling device is interposed between the control and actuating circuits, so no isolation of the control circuit is provided. This circuit would be better called an amplifier.

One other variation of these solid-state circuits is occasionally encountered—the *Darlington* circuit. A typical arrangement is shown in Fig. 13-25. Actually a pair of cascaded power transistors, this circuit is used in
many solid-state systems to achieve very high power gain—1000 to 10,000 or more. Now marketed in single-transistor cases, it can be obtained as what appears to be a single transistor with high operating voltage ratings that control high amperage loads with only a few volts at the base connection and draw only a few milliamperes from the control circuit. It can be used for relay purposes in a dc circuit the same way, either by direct control signal coupling or with intermediate isolation devices like those described. It is not usable in ac power circuits.

13.2.6.8 Solid-State Time-Delay Relays

Solid-state time-delay relays, Fig. 13-26, can operate in many different modes since they do not rely on heaters or pneumatics. Simple ICs allow the relays to do standard functions plus totaling, intervals, and momentary action as described in the following.

**On-Delay.** Upon application of control power, the time-delay period begins. At the end of time delay, the output switch operates. When control power is removed, the output switch returns to normal, Fig. 13-26A.

**Nontotalizer.** Upon the opening of the control switch, the time-delay period begins. However, any control switch closure prior to the end of the time delay will immediately recycle the timer. At the end of the time-delay period, the output switch operates and remains operated until the required continuous power is interrupted, as shown in Fig. 13-26B.

**Totalizer/Preset Counter.** The output switch will operate when the sum of the individual control switch closure durations equal the preset time-delay period. There may be interruptions between the control switch closures without substantially altering the cumulative timing accuracy. The output switch returns to normal when the continuous power is interrupted, as shown in Fig. 13-26C.

**Off-Delay.** Upon closure of the control switch, the output switch operates. Upon opening of the control switch, the time-delay period begins. However, any control switch closure prior to the end of the time-delay period will immediately recycle the timer. At the end of the time-delay period, the output switch returns to
normal. Continuous power must be furnished to this timer, as shown in Fig. 13-26D.

**Interval.** Upon application of the control power, the output switch operates. At the end of the time-delay period, the output switch returns to normal. Control power must be interrupted in order to recycle, as shown in Fig. 13-26E.

**Momentary Actuation.** Upon closure of the control switch, the output switch operates, and the time-delay period begins. The time-delay period is not affected by duration of the control switch closure. At the end of the time-delay period, the output switch returns to normal. Continuous power must be furnished to this timer, as shown in Fig. 13-26F.

**Programmable Time-Delay Relay.** Programmable time-delay relays are available where the time and functions can be programmed by the user. The Magnecraft W211PROGX-1 relay in Fig. 13-27 is an example of this type. It plugs into an octal socket, has ±0.1% repeatability and four input voltage ranges. It has four programmable functions, On Delay, Off Delay, One Shot, and On Delay and Off Delay. There are 62 programmable timing ranges from 0.1 s to 120 min and the relay has 10 A DPDT contacts. An eight position DIP switch is used to program the timing function and a calibrated knob is used to set the timing.

14.1 Introduction

It was not long ago that wire was the only method to inexpensively and reliably transmit sound or pictures from one place to another. Today we not only have wire, but we also have fiber optics, and wireless radio frequency (RF) transmission from Blu-tooth to wireless routers, cell phones, and microwave and satellite delivery. RF transmission is discussed briefly in Chapter 16.10, Wireless Microphones. This chapter will discuss the various forms of wire and cable used in audio and video.

Wire is a single conductive element. Wire can be insulated or uninsulated. Cable, on the other hand, is two or more conductive elements. While they theoretically could be uninsulated, the chance of them touching each other and creating a short circuit requires that they are usually both insulated. A cable can be multiple insulated wires, called a multiconductor cable, or wires that are twisted together, called a twisted pair cable, or cables with one wire in the center, surrounded by insulation and then a covering of metal used as another signal path, called coaxial cable.

14.2 Conductors

Wire and cable are used to connect one circuit or component to another. They can be internal, connecting one circuit to another inside a box, or externally connecting one box to another.

14.2.1 Resistance and Wire Size

Wire is made of metal, or other conductive compounds. All wire has resistance which dissipates power through heat. While this is not apparent on cables with small signals, such as audio or video signals, it is very apparent where high power or high current travels down a cable, such as a power cord. Resistance is related to the size of the wire. The smaller the wire, the greater the resistance.

14.2.2 Calculating Wire Resistance

The resistance for a given length of wire is determined by:

\[ R = \frac{KL}{d^2} \]  \hspace{1cm} (14-1)

where,

- \( R \) is the resistance of the length of wire in ohms,
- \( K \) is the resistance of the material in ohms per circular mil foot,
- \( L \) is the length of the wire in feet,
- \( d \) is the diameter of the wire in mils.

The resistance, in ohms per circular mil foot (Ω/cir mil ft), of many of the materials used for conductors is given in Table 14-1. The resistance shown is at 20°C (68°F), commonly called room temperature.

</table>

When determining the resistance of a twisted pair, remember that the length of wire in a pair is twice the length of a single wire. Resistance in other construc-
tions, such as coaxial cables, can be difficult to determine from just knowing the constituent parts. The center conductor might be easy to determine but a braid or braid + foil shield can be difficult. In those cases, consult the manufacturer.

Table 14-1 show the resistance in ohms (Ω) per foot per circular mil area for various metals, and combinations of metals (alloys). Of the common metals, silver is the lowest resistance. But silver is expensive and hard to work with. The next material, copper, is significantly less expensive, readily available, and lends itself to being annealed, which is discussed in Section 14.2.4. Copper is therefore the most common material used in the manufacture of wire and cable. However, where price is paramount and performance not as critical, aluminum is often used. The use of aluminum as the conducting element in a cable should be an indication to the user that this cable is intended to be lower cost and possibly lower performance.

One exception to this rule might be the use of aluminum foil which is often used in the foil shielding of even expensive high-performance cables. Another exception is emerging for automobile design, where the weight of the cable is a major factor. Aluminum is significantly less weight than copper, and the short distances required in cars means that resistance is less of a factor.

Table 14-1 may surprise many who believe, in error, that gold is the best conductor. The advantage of gold is its inability to oxidize. This makes it an ideal covering for articles that are exposed to the atmosphere, pollution, or moisture such as the pins in connectors or the connection points on insertable circuit boards. As a conductor, gold does not require annealing, and is often used in integrated circuits since it can be made into very fine wire. But, in normal applications, gold would make a poor conductive material, closer to aluminum in performance than copper.

One other material on the list commonly found in cable is steel. As can be seen, this material is almost ten times the resistance of copper, so many are puzzled by its use. In fact, in the cables that use steel wires, they are coated with a layer of copper, called copper-clad steel and signal passes only on the copper layer, an effect called skin effect that will be discussed in Section 14.2.8. Therefore, the steel wire is used for strength and is not intended to carry signals.

Copper-clad steel is also found in cables where cable pulling strength (pulling tension) is paramount. Then a stranded conductor can be made up of many copper-clad steel strands to maximize strength. Such a cable would compromise basic resistive performance. As is often the case, one can trade a specific attribute for another. In this case, better strength at the cost of higher resistance.

### 14.2.3 Resistance and Gage Size

In the United States, wire is sized by the American Wire Gage (AWG) method. AWG was based on the previous Brown and Sharpe (B & S) system of wire sizes which dates from 1856. AWG numbers are most common in the United States, and will be referred to throughout this book. The wire most often used in audio ranges from approximately 10 AWG to 30 AWG, although larger and smaller gage sizes exist. Wire with a small AWG number, such as 4 AWG, is very heavy, physically strong but cumbersome, and has very low resistance, while wire of larger numbers, such as 30 AWG can be very light weight and fragile, and has high resistance. Resistance is an important factor in determining the appropriate wire size in any circuit. For instance, if an 8 Ω loudspeaker is being connected to an amplifier 500 ft away through a #19 wire, 50% of the power would be dropped in the wire in the form of heat. This is discussed in Section 14.2.5 regarding loudspeaker cable.

Each time the wire size changes three numbers, such as from 16 AWG to 19 AWG the resistance doubles. The reverse is also true. With a wire changed from 16 AWG to 13 AWG, the resistance halves. This also means that combining two identical wires of any given gage decreases the total gage of the combined wires by three units, and reduces the resistance. Two 24 AWG wires combined (twisted together) would be 21 AWG, for instance. If wires are combined of different gages, the resulting gage can be easily calculated by adding the circular mil area (CMA) shown in Tables 14-2 and 14-3. For instance, if three wires were combined, one 16 AWG (2583 CMA), one 20 AWG (1022 CMA) and one 24 AWG (404 CMA), the total CMA would be $2583 + 1022 + 404 = 4009$ CMA. Looking in Table 14-1, this numbers falls just under 14 AWG. While even number gages are the most common, odd number gages (e.g., 23 AWG) can sometimes be found. There are many Category 6 (Cat 6) premise/data cables that are 23 AWG, for instance. When required, manufacturers can even produce partial gages. There are coaxial cables with 28.5 AWG center conductors. Such specialized gage sizes might require equally special connectors.
There are two basic forms of wire, solid and stranded. A solid conductor is one continuous piece of metal. A stranded conductor is made of multiple smaller wires combined to make a single conductor. Solid wire has slightly lower resistance, with less flexibility and less flex-life (flexes to failure) than stranded wire.

### 14.2.4 Drawing and Annealing

Copper conductors start life as copper ore in the ground. This ore is mined, refined, and made into bars or rod. Five sixteenth inch copper rod is the most common form used for the making of wire and cable. Copper can be purchased at various purities. These commonly follow the ASTM (American Society for Testing and Materials) standards. Most of the high-purity copper is known as ETP, electrolytic tough pitch. For example, many cable products are manufactured with ASTM B115 ETP. This copper is 99.95% pure. Copper of higher purity can be purchased should the requirement arise. Many consumer audiophiles consider these to be oxygen free, when this term is really a discussion of copper purity and is determined by the number of nines of purity. The cost of the copper rises dramatically with each “9” that is added.

To turn \(\frac{5}{16}\) inch rod into usable wire, the copper rod is drawn through a series of dies. Each time it makes the rod slightly smaller. Eventually you can work the rod down to a very long length of very small wire. To take \(\frac{5}{16}\) inch rod down to a 12 AWG wire requires drawing the conductor through eleven different dies. Down to 20 AWG requires fifteen dies. To take that wire down to 36 AWG requires twenty-eight dies.

The act of drawing the copper work hardens the material making it brittle. The wire is run through an in-line annealing oven, at speeds up to 7000 feet per minute, and a temperature of 900 to 1000°F (482 to 537°C). This temperature is not enough to melt the wire, but it is enough to let the copper lose its brittleness and become flexible again, to reverse the work hardening. Annealing is commonly done at the end of the drawing process. However, if the next step requires more flexibility, it can be annealed partway through the drawing process. Some manufacturers draw down the wire and then put the entire roll in an annealing oven. In order to reduce oxygen content, some annealing ovens have inert atmospheres, such as nitrogen. This increases the purity of the copper by reducing the oxygen content. But in-line annealing is more consistent than a whole roll in an oven.

Lack of annealing, or insufficient annealing time or temperature, can produce a conductor which is stiff, brittle, and prone to failure. With batch annealing, the inner windings in a roll may not be heated as effectively as the outer windings. Cables made in other countries may not have sufficient purity for high-performance applications. Poor-quality copper, or poor annealing, are very hard to tell from initial visual inspection but often shows up during or after installation.

### 14.2.5 Plating and Tinning

Much of the wire manufactured is plated with a layer of tin. This can also be done in-line with the drawing and annealing by electroplating a layer on the wire. Tinning makes the wire especially resistant to pollutants, chemicals, salt (as in marine applications). But such a plated conductor is not appropriate for high-frequency applications where the signal travels on the skin of the conductor, called skin effect. In that case, bare copper conductors are used. The surface of a conductor used for high frequencies is a major factor in good performance and should have a mirror finish on that surface. Wires are occasionally plated with silver. While silver is slightly more conductive, its real advantage is that silver oxide is the same resistance as bare silver. This is not true with copper, where copper oxide is a semiconductor. Therefore, where reactions with a copper wire are predicted, silver plating may help preserve performance. So silver plating is sometimes used for marine cables, or cables used in similar outdoor environments.

Some plastics, when extruded (melted) onto wires, can chemically affect the copper. This is common, for instance, with an insulation of extruded TFE (tetrafluoroethylene), a form of Teflon™. Wires used inside these cables are often silver plated or silver-clad. Any oxidizing caused by the extrusion process therefore has no effect on performance. Of course, just the cost of silver alone makes any silver-plated conductor significantly more expensive than bare copper.

### 14.2.6 Conductor Parameters

Table 14-2 shows various parameters for solid wire from 4 AWG to 40 AWG. Table 14-3 shows the same parameters for stranded wire. Note that the resistance of a specific gage of solid wire is lower than stranded wire of the same gage. This is because the stranded wire is not completely conductive; there are spaces (interstices) between
400

Chapter 14

the strands. It takes a larger stranded wire to equal the
resistance of a solid wire.

14.2.6.1 Stranded Cables.
Stranded cables are more flexible, and have greater
flex-life (flexes to failure) than solid wire. Table 14-4
shows some suggested construction values. The two
numbers (65 × 34, for example) show the number of
strands (65) and the gage size of each strand (34) for
each variation in flexing.

for each 700 CMA. See also Section 14.2.9.


14.2.7 Pulling Tension

Pulling tension must be adhered to so the cable will not be permanently elongated. The pulling tension for annealed copper conductors is shown in Table 14-5.

Multiconductor cable pulling tension can be determined by multiplying the total number of conductors by the appropriate value. For twisted pair cables, there are two wires per pair. For shielded twisted pair cables, with foil shields, there is a drain wire that must be included in the calculations. Be cautious: the drain wire can sometimes be smaller gage than the conductors in the pair. The pulling tension of coaxial cables or other cables that are not multiple conductors is much harder to calculate. Consult the manufacturer for the required pulling tension.

14.2.8 Skin Effect

As the frequency of the signal increases on a wire, the signal travels closer to the surface of the conductor. Since very little of the area of the center conductor is used at high frequencies, some cable is made with a copper-clad-steel core center conductor. These are known as copper-clad, copper-covered, or Copperweld™ and are usually used by CATV/broadband service providers.

Copper-clad steel is stronger than copper cable so it can more easily withstand pulling during installation, or wind, ice, and other outside elements after installation. For instance, a copper-clad #18 AWG coaxial cable has a pull strength of 102 lbs while a solid copper #18 AWG coax would have a pull strength of 69 lbs. The main disadvantage is that steel is not a good conductor below 50 MHz, between four and seven times the resistance of copper, depending on the thickness of the copper layer.

This is a problem where signals are below 50 MHz such as DOCSIS data delivery, or VOD (video-on-demand) signals which are coming from the home to the provider. When installing cable in a system, it is better to use solid copper cable so it can be used at low frequencies as well as high frequencies.

This is also why copper-clad conductors are not appropriate for any application below 50 MHz, such as baseband video, CCTV, analog, or digital audio. Copper-clad is also not appropriate for applications such as SDI or HD-SDI video, and similar signals where a significant portion of the data is below 50 MHz.

The skin depth for copper conductors can be calculated with the equation

\[
D = \frac{2.61}{\sqrt{f}}
\]  

(14-2)

where,

\( D \) is the skin depth in inches,

\( f \) is the frequency in hertz.

Table 14-6 compares the actual skin depth and percent of the center conductor actually used in an RG-6 cable. The skin depth always remains the same no matter what the thickness of the wire is. The only thing that changes is the percent of the conductor utilized. Determining the percent of the conductor utilized requires using two times the skin depth because we are comparing the diameter of the conductor to its depth.

As can be seen, by the time the frequencies are high, the depth of the signal on the skin can easily be micro-inches. For signals in that range, such as high-definition video signals, for example, this means that the surface of the wire is as critical as the wire itself. Therefore, conductors intended to carry high frequencies should have a mirror finish.

Since the resistance of the wire at these high frequencies is of no consequence, it is sometimes asked why larger conductors go farther. The reason is that the surface area, the skin, on a wire is greater as the wire gets larger in size.

Further, some conductors have a tin layer to help prevent corrosion. These cables are obviously not intended for use at frequencies above just a few megahertz, or a significant portion of the signal would be traveling in the tin layer. Tin is not an especially good conductor as can be seen in Table 14-1.

14.2.9 Current Capacity

For conductors that will carry large amounts of electrical flow, large amperage or current from point to point, a general chart has been made to simplify the current carrying capacity of each conductor. To use the current capacity chart in Fig. 14-1, first determine conductor gage, insulation and jacket temperature rating, and number of conductors from the applicable product description for the cable of interest. These can usually be obtained from a manufacturer’s Web site or catalog.

Next, find the current value on the chart for the proper temperature rating and conductor size. To calculate the maximum current rating/conductor multiply the chart value by the appropriate conductor factor. The chart assumes the cable is surrounded by still air at an ambient temperature of 25°C (77°F). Current values are in amperes (rms) and are valid for copper conductors only. The maximum continuous current rating for an electronic cable is limited by conductor size, number of conductors contained within the cable, maximum temperature rating of the insulation on the conductors,
Transmission Techniques: Wire and Cable

and environment conditions such as ambient temperature and air flow. The four lines marked with temperatures apply to different insulation plastics and their melting point. Consult the manufacturer’s Web site or catalog for the maximum insulation or jacket temperature.

The current ratings of Fig. 14-1 are intended as general guidelines for low-power electronic communications and control applications. Current ratings for high-power applications generally are set by regulatory agencies such as Underwriters Laboratories (UL), Canadian Standards Association (CSA), National Electrical Code (NEC), and others and should be used before final installation.

Table 310-15(b)(2)(a) of the NEC contains amperage adjustment factors for whenever more than three current carrying conductors are in a conduit or raceway.

Section 240-3 of the NEC provides requirements for overload protection for conductors other than flexible cords and fixture wires. Section 240-3(d), Small Conductors, states that #14 to #10 conductors require a maximum protective overcurrent device with a rating no higher than the current rating listed in the 60°C column. These currents are 15 A for #14 copper wire, 20 A for #12 copper wire, and 30 A for #10 copper wire. These values are familiar as the breaker ratings for commercial installations.

When connecting wire to a terminal strip or another wire etc., the temperature rise in the connections must also be taken into account. Often the circuit is not limited by the current carrying capacity of the wire but of the termination point.

14.2.9.1 Wire Current Ratings

Current carrying capacity of wire is controlled by the NEC, particularly in Table 310-16, Table 310-15(b)(2)(a), and Section 240-3.

Table 310-16 of the NEC shows the maximum current carrying capacity for insulated conductors rated from 0 to 2000 V, including copper and aluminum conductors. Each conductor amperage is given for three temperatures: 60°C, 75°C, and 90°C. Copper doesn’t melt until almost 2000°C, so the current limit on a copper wire is not the melting point of the wire but the melting point of the insulation. This number is listed by most manufacturers in their catalog or on their Web site. For instance, PVC (polyvinyl chloride) can be formulated to withstand temperatures from 60°C to as high as 105°C. The materials won’t melt right at the specified temperature, but may begin to fail certain tests, such as cracking when bent.

14.3 Insulation

Wire can be bare, often called bus bar or bus wire, but is most often insulated. It is covered with a non-conducting material. Early insulations included cotton or silk woven around the conductor, or even paper. Cotton-covered house wiring can still be found in perfect operating condition in old houses. Today, most insulation materials are either some kind of rubber or some kind of plastic. The material chosen should be listed in the manufacturer’s catalog with each cable type. Table 14-7 lists some of the rubber-based materials with their properties. Table 14-8 lists the properties of various plastics. The ratings in both tables are based on average performance of general-purpose compounds. Any given property can usually be improved by the use of selective compounding.

14.3.1 Plastics and Dielectric Constant

Table 14-9 is a list of various insulation materials with details on performance, requirements, and special advantages. Insulation, when used on a cable intended to carry a signal, is often referred to as a dielectric. The performance of any material, its ability to insulate with minimal effect to the signal running on the cable is called the dielectric constant and can be measured in a

14.3.2 Wire Insulation Characteristics

The key difference between rubber compounds and plastic compounds is their recyclability. Plastic materials can be ground up, and re-melted into other objects. Polyethylene, for instance, can be recycled into plastic bottles, grocery bags, or even park benches. And, should the need arise, these objects could themselves be ground up and turned back into wire insulation, or many other uses.

The term thermoplastic means changed by heat and is the source of the common term plastic.

Rubber compounds, on the other hand, are thermoset. That is, once they are made, they are set, and the process cannot be reversed. Rubber, and its family, is cured in a process sometimes called vulcanizing. These compounds cannot be ground up and recycled into new products. There are natural rubber compounds (such as latex-based rubber) and artificial, chemical-based rubber compounds such as EPDM (ethylene-propylene-diene monomer).

The vast majority of wire and cable insulations are plastic-based compounds. Rubber, while it is extremely rugged, is considerably more expensive that most plastics, so there are fewer and fewer manufacturers offering rubber-based products. These materials, both rubber and plastic, are used in two applications with cable. The first application is insulation of the conductor(s) inside the cable. The second is as a jacket material to protect the contents of the cable.

14.4 Jackets

The jacket characteristics of cable have a large effect on its ruggedness and the effect of environment. A key consideration is often flexibility, especially at low temperatures. Audio and broadcast cables are manufactured in a wide selection of standard jacketing materials. Special compounds and variations of standard compounds are used to meet critical audio and broadcast application requirements and unusual environmental conditions. Proper matching of cable jackets to their working environment can prevent deterioration due to intense heat and cold, sunlight, mechanical abuse, impact, and crowd or vehicle traffic.

14.5 Plastics

Plastic is a shortened version of the term thermoplastic. Thermo means heat, plastic means change. Thermoplastic materials can be changed by heat. They can be melted and extruded into other shapes. They can be extruded around wires, for instance, forming an insulative (non-conductive) layer. There are many forms of plastic. Below is a list of the most common varieties used in the manufacture of wire and cable.

14.5.1 Vinyl

Vinyl is sometimes referred to as PVC or polyvinyl chloride, and is a chemical compound invented in 1928 by Dr. Waldo Semon (USA). Extremely high or low temperature properties cannot be found in one formulation, therefore, formulations may have −55°C to +105°C (−67°F to +221°F) rating while other common vinyls may have −20°C to +60°C (−4°F to +140°F). The many varieties of vinyl also differ in pliability and electrical properties fitting a multitude of applications. The price range can vary accordingly. Typical dielectric constant values can vary from 3.5 at 1000 Hz to 6.5 at 60 Hz, making it a poor choice if high performance is required.

PVC is one of the least expensive compounds, and one of the easiest to work with. Therefore, PVC is used with many cables that do not require high performance, or where cost of materials is a major factor. PVC is easy to color, and can be quite flexible, although it is not very rugged. In high-performance cables, PVC is often used as the jacket material, but not inside the cable.

14.5.2 Polyethylene

Polyethylene, invented by accident in 1933 by E.W. Fawcett and R.O. Gibson (Great Britain), is a very good insulation in terms of electrical properties. It has a low dielectric constant value over all frequencies and very high insulation resistance. In terms of flexibility, polyethylene can be rated stiff to very hard depending on molecular weight and density. Low density is the most
flexible and high density high molecular weight formulations are very hard. Moisture resistance is rated excellent. Correct brown and black formulations have excellent sunlight resistance. The dielectric constant is 2.3 for solid insulation and as low as 1.35 for gas-injected foam cellular designs. Polyethylene is the most common plastic worldwide.

14.5.3 Teflon®

Invented in 1937 by Roy Plunkett (USA) at DuPont, Teflon has excellent electrical properties, temperature range, and chemical resistance. It is not suitable where subjected to nuclear radiation, and it does not have good high voltage characteristics. FEP (fluorinated ethylene-propylene) Teflon is extrudable in a manner similar to vinyl and polyethylene, therefore, long wire and cable lengths are available. TFE (tetrafluoroethylene) Teflon is extrudable in a hydraulic ram-type process and lengths are limited due to amount of material in the ram, thickness of the insulation, and core size. TFE must be extruded over silver-coated or nickel-coated wire. The nickel and silver-coated designs are rated +260°C and +200°C maximum (500°F and 392°F), respectively, which is the highest temperature for common plastics. The cost of Teflon is approximately eight to ten times more per pound than vinyl insulations. The dielectric constant for solid Teflon is 2.1, the lowest of all solid plastics. Foam Teflon (FEP) has a dielectric constant as low as 1.35. Teflon is produced by and a trademark of DuPont Corporation.

14.5.4 Polypropylene

Polypropylene is similar in electrical properties to polyethylene and is primarily used as an insulation material. Typically, it is harder than polyethylene, which makes it suitable for thin wall insulations. UL maximum temperature rating may be 60°C or 80°C (140°F or 176°F). The dielectric constant is 2.25 for solid and 1.55 for cellular designs.

14.6 Thermoset Compounds

As the name implies, thermoset compounds are produced by heat (thermo) but are set. That is, the process cannot be reversed as in thermoplastics. They cannot be recycled into new products as thermoplastic materials can.

14.6.1 Silicone

Silicone is a very soft insulation which has a temperature range from −80°C to +200°C (−112°F to +392°F). It has excellent electrical properties plus ozone resistance, low moisture absorption, weather resistance, and radiation resistance. It typically has low mechanical strength and poor scuff resistance. Silicone is seldom used because it is very expensive.

14.6.2 Neoprene

Neoprene has a maximum temperature range from −55°C to +90°C (−67°F to +194°F). The actual range depends on the formulation used. Neoprene is both oil and sunlight resistant making it ideal for many outdoor applications. The most stable colors are black, dark brown, and gray. The electrical properties are not as good as other insulation materials; therefore, thicker insulation must be used for the same insulation.

14.6.3 Rubber

The description of rubber normally includes natural rubber and styrene-butadiene rubber (SBR) compounds. Both can be used for insulation and jackets. There are many formulations of these basic materials and each formulation is for a specific application. Some formulations are suitable for −55°C (−67°F) minimum while others are suitable for +75°C (+167°F) maximum. Rubber jacketing compounds feature exceptional durability for extended cable life. They withstand high-impact and abrasive conditions better than PVC and are resistant to degradation or penetration by water, alkali, or acid. They have excellent heat resistant properties, and also provide greater cable flexibility in cold temperatures.

14.6.4 EPDM

EPDM stands for ethylene-propylene-diene monomer. It was invented by Dr. Waldo Semon in 1927 (see Section 14.5.1). It is extremely rugged, like natural rubber, but can be created from petroleum byproducts ethylene and propylene gas.

14.7 Single Conductor

Single conductor wire starts with a single wire, either solid or stranded. It can be bare, sometimes called buss bar, or can be jacketed. There is no actual limit to how
small, or how large, a conductor could be. Choice of size (AWG) will be based on application and the current or wattage delivery required. If jacketed, the choice of jacket can be based on performance, ruggedness, flexibility, or any other requirement.

There is no single conductor plenum rating because the NEC (National Electrical Code) only applies to cables, more than one conductor. However, Articles 300 and 310 of the NEC are sometimes cited when installing single conductor wire for grounds and similar applications.

14.8 Multiconductor

Bundles of two or more insulated wires are considered multiconductor cable. Besides the requirements for each conductor, there is often an overall jacket, chosen for whatever properties would be appropriate for a particular application.

There are specialized multiconductor cables, such as power cordage used to deliver ac power from a wall outlet (or other source) to a device. There are UL safety ratings on such a cable to assure users will not be harmed.

There are other multiconductor applications such as VFD (variable frequency drive) cables, specially formulated to minimize standing waves and arcing discharge when running variable frequency motors. Since a multiconductor cable is not divided into pairs, resistance is still the major parameter to be determined, although reactions between conductors (as in VFD) can also be considered.

14.8.1 Multiconductor Insulation Color Codes

The wire insulation colors help trace conductors or conductor pairs. There are many color tables; Table 14-10 is one example.

14.9 Pairs and Balanced Lines

Twisting two insulated wires together makes a twisted pair. Since two conductive paths are needed to make a circuit, twisted pairs give users an easy way to connect power or signals from point to point. Sometimes the insulation color is different to identify each wire in each pair. Pairs can have dramatically better performance than multiconductor cables because pairs can be driven as a balanced line.

A balanced line is a configuration where the two wires are electrically identical. The electrical performance is referred to ground, the zero point in circuit design. Balanced lines reject noise, from low frequencies, such as 50/60 Hz power line noise, up to radio frequency signals in the Megahertz, or even higher.

When the two conductors are electrically identical, or close to identical, there are many other parameters, besides resistance, that come into play. These include capacitance, inductance, and impedance. And when we get to high-frequency pairs, such as data cables, we even measure the variations in resistance (resistance unbalance), variations in capacitance (capacitance unbalance, or even variations in impedance (return loss). Each of these has a section farther on in this chapter.

</table>

*Courtesy Belden*
Balanced lines work because they have a transformer at each end, a device made of two coils of wire wound together. Many modern devices now use circuits that act electrically the same as a transformer, an effect called *active balancing*. The highest-quality transformers can be extremely expensive, so high-performing balanced-line chips have been improving, some getting very close to the coils-of-wire performance.

It should be noted that virtually all professional installations use twisted pairs for audio because of their noise rejection properties. In the consumer world, the cable has one hot connection and a grounded shield around it and is called an unbalanced cable. These cables are effective for only short distances and have no other inherent noise rejection besides the shield itself.

### 14.9.1 Multipair

As the name implies, multipair cables contain more than one pair. Sometimes referred to as *multicores*, these can just be grouped bare pairs, or each pair could be individually jacketed, or each pair could be shielded (shielding is outlined below), or the pairs could even be individually shielded and jacketed. All of these options are easily available. Where there is an overall jacket, or individual jackets for each pair, the jacket material for each pair is chosen with regard to price, flexibility, ruggedness, color, and any other parameter required.

It should be noted that the jackets on pairs, or the overall jacket, has almost no effect on the performance of the pairs. One could make a case that, with individually jacketed pairs, the jacket moves the pairs apart and therefore improves crosstalk between pairs. It is also possible that poorly extruded jackets could leak the chemicals that make up the jacket into the pair they are protecting, an effect called *compound migration*, and therefore affect the performance of the pair.

Table 14-11 shows a common color code for paired cables where they are simply a bundle of pairs. The color coding is only to identify the pair and the coloring of the insulation has no effect on performance. If this cable were individually jacketed pairs, it would be likely that the two wires in the pair would be identical colors such as all black-and-red, and the jackets would use different colors to identify them as shown in Table 14-12.

### 14.9.2 Analog Multipair Snake Cable

Originally designed for the broadcast industry, hard-wire multipair audio snake cables feature individually shielded pairs, for optimum noise rejection, and sometimes with individual jackets on each pair for improved physical protection. These cables are ideal, carrying multiple line-level or microphone-level signals. They will also interconnect audio components such as multichannel mixers and consoles for recording studios, radio and television stations, postproduction facilities, and sound system installations. Snakes offer the following features:

- A variety of insulation materials, for low capacitance, ruggedness, or fire ratings.
- Spiral/serve, braid, French Braid™, or foil shields.
- Jacket and insulation material to meet ruggedness or NEC flame requirements.
- High temperature resistance in some compounds.
- Cold temperature pliability in some compounds.
- Low-profile appearance, based mostly on the gauge of the wires, but also on the insulation.

• Some feature overall shields to reduce crosstalk and facilitate star grounding.
• Allows easier and cheaper installs than using multiple single channel cables.

Snakes come with various terminations and can be specified to meet the consumer’s needs. Common terminations are male or female XLR (microphone) connectors and ¼ inch male stereo connectors on one end, and either a junction box with male or female XLR connectors and ¼ inch stereo connectors or pigtails with female XLR connectors and ¼ inch connectors on the other end.

For stage applications, multipair individually shielded snake cables feature lightweight and small diameter construction, making them ideal for use as portable audio snakes. Individually shielded and jacketed pairs are easier to install with less wiring errors. In areas that subscribe to the NEC guidelines, the need for conduit in studios is eliminated when CM-rated snake cable is used through walls between rooms. Vertically between floors, snakes rated CMR (riser) do not need conduit. In plenum areas (raised floors, drop ceilings) CMP, plenum rated snake cables can be used without conduit. Color codes for snakes are given in Table 14-12.

14.9.3 High Frequency Pairs

Twisted pairs were originally conceived to carry low-frequency signals, such as telephone audio. Beginning in the 1970s research and development was producing cables such as twinax that had reasonable performance to the megahertz. IBM Type 1 was the breakthrough product that proved that twisted-pairs could indeed carry data. This led directly to the Category premise/data cable of today.

There are now myriad forms of high-frequency, high-data rate cable including DVI, USB, HDMI, IEEE 1394 FireWire, and others. All of these are commonly used to transport audio and video signals, Table 14-13.

14.9.3.1 DVI

DVI (Digital Visual Interface) is used extensively in the computer-monitor interface market for flat panel LCD monitors.

The DVI connection between local monitors and computers includes a serial digital interface and a parallel interface format, somewhat like combining the broadcast serial digital and parallel digital interfaces.

Transmission of the TMDS (transition minimized differential signaling) format combines four differential, high-speed serial connections transmitted in a parallel bundle. DVI specifications that are extended to the dual mode operation allow for greater data rates for higher display resolutions. This requires seven parallel, differential, high-speed pairs. Quality cabling and connections become extremely important. The nominal DVI cable length limit is 4.5 m (15 ft). Electrical performance requirements are signal rise time of 0.330 ns, and a cable impedance of 100 Ω. FEXT is less than 5%, and signal rise time degradation is a maximum of 160 ps (picoseconds). Cable for DVI is application specific since the actual bit rate per channel is 1.65 Gbps.

Table 14-12. Color Codes for Snake Cables

Courtesy Belden.
Picture information or even the entire picture can be lost if any vital data is missing with digital video interfaces. DVI cable and its termination are very important and the physical parameters of the twisted pairs must be highly controlled as the specifications for the cable and the receiver are given in fractions of bit transmission.

Requirements depend on the clock rate or signal resolution being used. Transferring the maximum rate of $1600 \times 1200$ at 60 Hz for a single link system means that one bit time or 10 bits per pixel is $0.1(1/165 \text{ MHz})$ or 0.606 ns.

The DVI receiver specification allows $0.40 \times$ bit time, or 0.242 ns intrapair skew within any twisted pair. The pattern at the receiver must be very symmetrical. The interpair skew, which governs how bits will line up in time at the receiving decoder, may only be $0.6 \times$ pixel time, or 3.64 ns. These parameters control the transmission distances for DVI.

Also, the cable should be evaluated on its insertion loss for a given length. DVI transmitter output is specified into a cable impedance of 100 $\Omega$ with a signal swing of $\pm 780 \text{ mV}$ with a minimum signal swing of $\pm 200 \text{ mV}$. When determining DVI cable, assume minimum performance by the transmitter—i.e., 200 mV—and best sensitivity by the receiver which must operate on signals $\pm 75 \text{ mV}$. Under these conditions the cable attenuation can be no greater than 8.5 dB at 1.65 GHz (10 bits/pixel $\times$ 165 MHz clock) which is relatively difficult to maintain on twisted-pair cable.

DVI connections combine the digital delivery, described above, with legacy analog component delivery. This allows DVI to be the transition delivery scheme between analog and digital applications.

### 14.9.3.2 HDMI

HDMI (high definition multimedia interface) is similar to DVI except that it is digital-only delivery. Where DVI has found its way into the commercial space as well as consumer applications, HDMI is almost entirely consumer-based. It is configured into a 19 pin connector which contains four shielded twisted pairs (three pairs data, one pair clock) and seven wire for HDCP (copy protection), devices handshaking, and power. The standard versions of HDMI are nonlocking connector, attesting to its consumer-only focus.

### 14.9.3.3 IEEE -1394 or FireWire Serial Digital

FireWire, or IEEE -1394, is used to upload DV, or digital video, format signals to computers etc. DV, sometimes called DV25, is a serial digital format of 25 Mbps. IEEE 1394 supports up to 400 Mbps. The specification defines three signaling rates, S100 (98.304 Mbps), S200 (196.608 Mbps), and S400 (393.216 Mbps).

IEEE 1394 can interconnect up to sixty three devices in a peer-to-peer configuration so audio and video can be transferred from device to device without a computer, D/A, or A/D conversion. IEEE 1394 is hot pluggable from the circuit while the equipment is turned on.

$^{1}$ Transmission distances may vary widely depending on cabling and the specific equipment involved. STP = shielded twisted pair, UTP = unshielded twisted pair, n/a = not applicable
The IEEE 1394 system uses two shielded twisted pairs and two single wires, all enclosed in a shield and jacket, Fig. 14-2. Each pair is shielded with 100% coverage foil and a minimum 60% coverage braid. The outer shield is 100% coverage foil and a minimum 90% coverage braid. Each pair is shielded with aluminum foil and is equal to or greater than 60% braid. The twisted pairs handle the differential data and strobe (assists in clock regeneration) while the two separate wires provide the power and ground for remote devices. Signal level is 265 mV differential into 110 Ω.

Nominal impedance for the data pair is 90 Ω. The maximum cable length is determined by the signal propagation delay which must be less than 26 ns from end to end. Table 14-15 lists some common plastics and the theoretical distance each could go based on 26 ns. With an additional allowance of 4 ns, which is split between the sending device connection and the receiver connection/response function, the entire one-way delay is a maximum of 30 ns. The cable velocity of propagation must be less than 5.2 ns/m and the length and twist of the data pair must be matched so time skew is no more than 0.10 ns between bit polarities. The nominal differential signal level is 800 mV.

14.9.3.5 DisplayPort

DisplayPort is an emerging protocol for digital video. Its original intention was the transfer of images from a PC or similar device to a display. It has some significant advantages over DVI and HDMI. DisplayPort is by design backward-compatible to single link DVI and HDMI. Those are both severely distance-limited by the delay skew of the three data pairs when compared to the clock pair. With DisplayPort the clock is embedded with one twisted pair for data and two untwisted wires for powering downstream appliances. A full-speed cable includes a #28 gage twisted pair, and an untwisted pair of #28 to #20 gage power conductors, all enclosed in an aluminized polyester shield with a drain wire.
the video, much as the clock is embedded with the audio bit stream in AES digital audio, so the distance limitations on DisplayPort are less likely to involve clock timing problems.

However, display port is also a nonlocking connector, of 20 pins, and is intended for maximum distance 15 m (50 ft). These cables are, like HDMI and DVI, only available in assemblies. Raw cable and connectorization in the field do not currently look like an option for the professional installer. All these factors make it less likely to be embraced by the professional broadcast video arena.

14.9.3.6 Premise/Data Category Cables

While premise/data category cables were never intended to be audio or video cables, their high performance and low cost, and their ubiquitous availability, have seen them pressed into service carrying all sorts of non-data signals.

It should also be noted that high-speed Ethernet networks are routinely used to transport these audio and video signals in data networks. The emergence of 10GBase-T, 10 gigabit networks, will allow the transport of even multiple uncompressed 1080p/60 video images. The digital nature of most entertainment content, with the ubiquitous video server technology in use today, makes high-bandwidth, high-data-rate networks in audio, video, broadcast, and other entertainment facilities, an obvious conclusion.

14.9.3.6.1 Cabling Definitions

- **Telcom Closet** (TC). Location where the horizontal cabling and backbone cabling are made.
- **Main Cross-Connect** (M XC). Often called the equipment room and is where the main electronics are located.
- **Intermediate Cross-Connect** (IXC). A room between the TC and the MXC are terminated. Rarely used in LANs.
- **Horizontal Cabling**. The connection from the telcom closet to the work area.
- **Backbone Cabling**. The cabling that connect all of the hubs together.
- **Hub**. The connecting electronic box that all of the horizontal cables connect to which are then connected to the backbone cable.
- **Ethernet**. A 10, 100, or 1000 Mb/s LAN. The 10 Mbps version is called 10Base-T. The 100 Mbps version is called Fast Ethernet and 1000 Mbps version is called Gigabit Ethernet.

14.9.3.6.2 Structured Cabling

Structured cabling, also called communications cabling, data/voice, low voltage, or limited energy is the standardized infrastructure for telephone and local area network (LAN) connections in most commercial installations. The architecture for the cable is standardized by Electronic Industries Association and Telecommunications Industry Association (EIA/TIA), an industry trade association. EIA/TIA 568, referred to as 568, is the main document covering structured cabling. IEEE 802.3 also has standards for structured cabling.

The current standard, as of this writing, is EIA/TIA 568-B.2-10 that covers all active standards up to 10GbaseT, 10 gigabit cabling.

14.9.3.6.3 Types of Structured Cables

Following are the types of cabling, Category 1 though Category 7, often referred to as Cat 1 through Cat 7. The standard TIA/EIA 568A no longer recognizes Cat 1, 2, or 4. As of July 2000, the FCC mandated the use of cable no less than Cat 3 for home wiring. The naming convention specified by ISO/IEC 11801 is shown in Fig. 14-3.

Table 14-16 gives the equivalent TIA and ISO classifications for structured cabling.

SF = braid and foil shielded

Figure 14-3. ISO/IEC 11801 cable naming convention.
**Category 1.** Meets the minimum requirements for analog voice or plain old telephone service (POTS). This category is not part of the EIA/TIA 568 standard.

**Category 2.** Defined as the IBM Type 3 cabling system. IBM Type 3 components were designed as a higher grade 100 Ω UTP system capable of operating 1 Mb/s Token Ring, 5250, and 3270 applications over shortened distances. This category is not part of the EIA/TIA 568 standard.

**Category 3.** Characterized to 16 MHz and supports applications up to 10 Mbps. Cat 3 conductors are 24 AWG. Applications range from voice to 10Base-T.

**Category 4.** Characterized to 20 MHz and supports applications up to 16 Mb/s. Cat 4 conductors are 24 AWG. Applications range from voice to 16 Mbps Token Ring. This category is no longer part of the EIA/TIA 568 standard.

**Category 5.** Characterized to 100 MHz and supports applications up to 100 Mbps. Cat 5 conductors are 24 AWG. Applications range from voice to 100Base-T. This category is no longer part of the EIA/TIA 568 standard.

**Category 5e.** Characterized to 100 MHz and supports applications up to 1000 Mbps/1 Gbps. Cat 5e conductors are 24 AWG. Applications range from voice to 1000Base-T. Cat 5e is specified under the TIA standard ANSI/TIA/EIA-568-B.2. Class D is specified under ISO standard ISO/IEC 11801, 2nd Ed.

**Category 6.** Characterized to 250 MHz, in some versions bandwidth is extended to 600 MHz, and supports 1000 Mbps/1 Gbps and future applications and is backward compatible with Cat 5 cabling systems. Cat 6 conductors are 23 AWG. This gives improvements in power handling, insertion loss, and high-frequency attenuation. Fig. 14-4 shows the improvements of Cat 6 over Cat 5e. Cat 6 is specified under the TIA standard ANSI/TIA/EIA-568-B.2-1. Class E is specified under ISO standard ISO/IEC 11801, 2nd Ed. Amendment 1. Cat 6a is available most commonly in the United States as UTP.

**Category 6a.** Cat 6a (Augmented Category 6) is characterized to 500 MHz, and in special versions to 625 MHz, has lower insertion loss, and has more immunity to noise. Cat 6a is often larger than the other cables. 10GBase-T transmission uses digital signal processing (DSP) to cancel out some of the internal noise created by NEXT and FEXT between pairs. Cat 6a is specified under the TIA standard ANSI/TIA/EIA 568-B.2-10. Class EA is specified under ISO standard ISO/IEC 11801, 2nd Ed. Amendment 1.

**Category 7 S/STP.** Cat 7 S/STP (foil shielded twisted-pair) cable is sometimes called PiMF (pairs in metal foil). Shielded-twisted pair 10Base-T cable dramatically reduces alien crosstalk. Shielding reduces electromagnetic interference (EMI) and radio-frequency interference (RFI). This is particularly important as the airways are getting more congested. The shield reduces signal leakage and makes it harder to tap by an outside source. Shield termination at 14.16 Class F will be specified under ISO standard ISO/IEC 11801, 2nd Ed. Class FA will be specified under ISO standard ISO/IEC 11801, 2nd Ed. Amendment 1.

14.9.3.6.4 Comparisons

Table 14-17 compares network data rates for Cat 3 through Cat 6a and Table 14-18 compares various characteristics of Cat 5e, 6, and 6a. Fig. 14-6 compares the

Figure 14-6. Comparison of media distance to bandwidth

New cable designs can affect size and pathway load so consult the manufacturer. Note that cable density is continually changing with newer, smaller cable designs. Numbers in Table 14-18 should be considered worst case. Designers and installers of larger systems should get specific dimensional information from the manufacturer.

Fig. 14-7 shows various problems that can be found in UTP cabling. Fig. 14-8 gives the maximum distances for UTP cabling as specified by ANSI/TIA.

![Fig. 14-7. Paired wiring faults. Courtesy Belden.](image)

Four (4) pair 100 Ω ±15% UTP Cat 5e cabling is the recommended minimum requirement for residential and light commercial installations because it provides excellent flexibility. Pair counts are four pair for desktop and twenty five pair for backbone cabling. The maximum length of cable is 295 ft (90 m) with another 33 ft (10 m) for patch cords.

Unshielded twisted pairs (UTP) and shielded twisted pairs (STP) are used for structured cabling. Unshielded twisted pairs (UTP) are the most common today. These cables look like the POTS cable, however, their construction makes them usable in noisy areas and at high frequencies because of the short, even twisting of the two wires in each pair. The twist must be even and tight so complete noise cancellation occurs along the entire length of the cable. To best keep the twist tight and even, better cable has the two wires bonded together so they will not separate when bent or flexed. Patch cable is flexible so twist and impedance are not as well controlled. The color codes for the pairs are given in Table 14-19.

Cable diameter varies for the different types of cable. TIA recommends that two Cat 6 cables but only one Cat 6a cable can be put in a ¾ inch (21 mm) conduit at 40% fill. The diameter and the stiffness of the cables determine their bend radius and therefore the bend radius of conduits and trays, Table 14-20.

Fig. 14-9 shows the construction of UTP and screened UTP cable.

14.9.3.6.5 Critical Parameters

Critical parameters for UTP cable are: NEXT, PS-NEXT, FEXT, ELFEXT, PS-ELFEXT, RL, ANEXT.

NEXT. NEXT, or near-end crosstalk, is the unwanted signal coupling from the near end of one sending pair to a receiving pair.
PS-NEXT. PS-NEXT, or power-sum near-end crosstalk, is the crosstalk between all of the sending pairs to a receiving pair. With four-pair cable, this is more important than NEXT.

FEXT. FEXT, or far-end crosstalk, is the measure of the unwanted signal from the transmitter at the near end coupling into a pair at the far end.

EL-FEXT. EL-FEXT, or equal level far-end crosstalk, is the measure of the unwanted signal from the transmitter end to a neighboring pair at the far end relative to the received signal at the far end. The equation is

$$EL - FEXT = FEXT - Attenuation$$

(14-3)

Power sum equal-level far-end crosstalk is the computation of the unwanted signal coupling from multiple transmitters at the near end into a pair measured at the far end relative to the received signal level measured on the same pair.

Return Loss (RL). RL is a measure of the reflected energy from a transmitted signal and is expressed in −dB, the higher the value, the better. The reflections are caused by impedance mismatch caused by connectors, improper installation such as stretching the cable or too sharp a bend radius, improper manufacturing, or improper load.

Broadcasters are very familiar with return loss, calling it by a different name, SWR (standing wave ratio) or VSWR (voltage standing wave ratio). In fact, return loss measurements can easily be converted into VSWR values, or vice versa. Return loss can be found with the equation

$$RL = 20\log \frac{Difference}{Sum}$$

(14-4)

where,

Difference is the difference (absolute value) between the desired impedance and the actual measured impedance,

Sum is the desired impedance and the actual measured impedance added together.

- The desired impedance for all UTP data cables (Cat 5, 5e, 6, 6a) is 100 Ω.
- The desired impedance for all passive video, HD, HD-SDI or 1080p/60 components is 75 Ω.
- The desired impedance for all digital audio twisted pairs is 110 Ω.

Cable diameters are nominal values.
The desired impedance for all digital audio on coaxial cable is 75 Ω.

With 1000Base-T systems, the pairs simultaneously transmit and receive. As the transmitter sends data, it is also listening for data being sent from the opposite end of the same pair. Any reflected signal from the sending end that reflects back to the sending end mixes with the sending signal from the far end, reducing intelligibility. With 10Base-T or 100Base-T data networks, one pair transmits while another receives, so reflections (RL, return loss) are not a major consideration and were not required to be measured. Now, with pairs simultaneously transmitting and receiving, called duplex mode, RL is a critical measurement for data applications.

**Delay Skew.** Since every pair (and every cable) takes a specific amount of time to deliver a signal from one end to the other, there is a delay. Where four pairs must deliver data to be recombined, the delay in each pair should, ideally, be the same. However, to reduce crosstalk, the individual pairs in any Category cable have different twist rates. This reduces the pair-to-pair crosstalk but affects the delivery time of the separate parts. This is called delay skew.

While delay skew affects the recombining of data, in 1000Base-T systems, for instance, the same delay skew creates a problem when these UTP data cables are used to transmit component video or similar signals, since the three colors do not arrive at the receiving end at the same time, creating a thin bright line on the edge of dark images. Some active baluns have skew correction built in, see Section 14.12.5.

**ANEXT.** ANEXT, or alien crosstalk, is coupling of signals between cables. This type of crosstalk cannot be cancelled by DSP at the switch level. Alien crosstalk can be reduced by overall shielding of the pairs, or by inserting a nonconducting element inside that cable to push away the cables around it.

**14.9.3.6.6 Terminating Connectors**

All structured cabling use the same connector, an RJ-45. In LANs (local area networks) there are two possible pin-outs, 568A and 568B. The difference is pair 2 and pair 3 are reversed. Both work equally well as long as they are not intermixed. The termination is shown in Fig. 14-10.

In the past decade, the B wiring scheme has become the most common. However, if you are adding to or extending and existing network, you must determine which wiring scheme was used and continue with that scheme. A mixed network is among the most common causes of network failure.

It is very important that the pairs be kept twisted as close to the connector as possible. For 100Base-T (100 MHz, 100 Mbps) applications, a maximum of ½ inch should be untwisted to reduce crosstalk and noise pickup. In fact, with Cat 6 (250 MHz) or Cat 6a (500 MHz) it is safe to say that any untwisting of the pairs will affect performance. Therefore there are many connectors, patch panels, and punch-down blocks that minimize the untwisting of the pairs.

**Baluns**

Baluns (Balanced-Unbalanced) networks are a method of connecting devices of different impedance and different formats. Baluns have been commonly used to convert unbalanced coax, to balanced twinlead for television antennas, or to match coaxial data formats (coaxial Ethernet) to balanced line systems (10Base-T, 100Base-T etc.). Other balun designs can allow unbalanced sources, such as video or consumer audio, for instance, to be carried on balanced lines, such as UTP Cat 5e, 6, etc.

Since there are four pairs in a common data cable, this can carry four channels. Since category cables are rarely tested below 1 MHz, the audio performance was originally suspect. Crosstalk at audio frequencies in UTP has been measured and is consistently better than −90 dB even on marginal Cat 5. On Cat 6, the crosstalk at audio frequencies is below the noise floor of most network analyzers.

Baluns are commonly available to handle such signals as analog and digital audio, composite video, S-video, RGB or other component video (VGA, Y/R-Y/B-Y,Y/Cr/Cb), broadband RF/CATV, and even DVI and HDMI. The limitations to such applications
are the bandwidth specified on the cable and the performance of the cable (attenuation, return loss, crosstalk, etc.) at those higher frequencies.

Passive baluns can also change the source impedance in audio devices. This dramatically extends the effective distance of such signals from only a few feet to many hundreds of feet. Consult the balun manufacturer for the actual output impedance of their designs.

Some baluns can include active amplification, equalizations, or skew (delivery timing) compensation. While more expensive, these active baluns can dramatically increase the effective distance of even marginal cable.

14.9.3.6.8 Adaptors

Users and installers should be aware there are adaptors, often that fit in wall plates, where keystone data jacks are intended to be snapped in place. These adaptors often connect consumer audio and video (RCA connectors) to 110 blocks or other twisted pair connection points. However, there is no unbalanced-to-balanced device in these, so the noise rejection inherent in twisted pairs when run as a balanced line is not provided. These adaptors simply unbalance the twisted pair and offer dramatically short effective distances. Further, baluns can change the source impedance and extend distance. Adaptors with no transformers or similar components cannot extend distance and often reduce the effective distance. These devices should be avoided unless they contain an actual balun.

14.9.3.6.9 Power Over Ethernet (PoE)

PoE supplies power to various Ethernet services as VoIP (Voice over Internet Protocol) telephones, wireless LAN access points, Blu-tooth access points, and Web cameras. Many audio and video applications will soon use this elegant powering system. IEEE 802.3af-2003 is the IEEE standard for PoE. IEEE 802.3af specifies a maximum power level of 15.4 W at the power sourcing equipment (PSE) and a maximum of 12.95 W of power over two pairs to a powered device (PD) at the end of a 100 m (330 ft) cable.

The voltage supplied is nominally 48 Vdc with a minimum of 44 Vdc, a maximum of 57 Vdc, and the maximum current per pair is 350 mAdc, or 175 mAdc per conductor. For a single solid 24 AWG wire, common to many category cable designs, of 100 m length (328 ft) this would be a resistance of 8.4 Ω. Each conductor would dissipate 0.257 W or 1.028 W per conductor (0.257 W × 4 conductors). This causes a temperature rise in the cable and conduit which must be taken into consideration when installing PoE.

14.9.3.6.10 Power Over Ethernet Plus (PoE Plus)

PoE Plus is defined in IEEE 802.3at and is capable of delivering up to 30 W. Work is being done to approach 60 W or even greater. This requires the voltage supply to be 50 to 57 Vdc. Assuming a requirement of 42 W of power at the endpoint at 50 Vdc, the total current would be 0.84 A, or 0.21 A per pair, or 0.105 A (105 mA) per conductor, or a voltage drop of only 0.88 V in one 24 AWG wire.
14.10 Coaxial Cable

Coaxial cable is a design in which one conductor is accurately centered inside another with both conductors carrying the desired signal currents (source to load and return), as shown in Fig. 14-12. Coaxial cable is so called because if you draw a line through the center of a cross-sectional view, you will dissect all parts of the cable. All parts are on the same axis, or coaxial.

14.10.1 History of Coaxial Cable

It has been argued that the first submarine telegraph cable (1858) was coaxial, Fig. 14-13. While this did have multiple layers, the outer layer was not part of the signal-carrying portion. It was a protective layer.

Modern coaxial cable was invented on May 23, 1929 by Lloyd Espenscheid and Herman Affel of Bell Laboratories. Often called coax, it is often used for the transmission of high-frequency signals. At high frequencies, above 100 kHz, coax has a dramatically better performance than twisted pairs. However, coax lacks the ability to reject noise that twisted pairs can do when configured as balanced lines. Coaxial cable was first installed in 1931 to carry multiple telephone signals between cities.

14.10.2 Coaxial Cable Construction

The insulation between the center conductor and the shield of a coaxial cable affects the impedance and the durability of the cable. The best insulation to use between the center conductor and the shield would be a vacuum. The second best insulation would be dry air, the third, nitrogen. The latter two are familiar insulators in hard-line transmission line commonly used to feed high-power antenna in broadcasting.

A vacuum is not used, even though it has the lowest dielectric constant of "1," because there would be no conduction of heat from the center conductor to the outer conductor and such a transmission line would soon fail. Air and nitrogen are commonly used under pressure in such transmission lines. Air is occasionally used in smaller, flexible cables.

Polyethylene (PE) was common as the core material in coaxial cables during WW II. Shortly after the war, polyethylene was declassified and most early cable designs featured this plastic. Today most high-frequency coaxial cables have a chemically formed foam insulation or a nitrogen gas injected foam. The ideal foam is high-density hard cell foam, which approaches the density of solid plastic but has a high percentage of nitrogen gas. Current state-of-the-art polyethylene foam velocity is 86% (dielectric constant: 1.35) although most digital video cables are 82–84% velocity of propagation. High-density foam of this velocity resists conductor migration when the cable is bent, keeping impedance variations to a minimum. This high velocity improves the high-frequency response of the cable.

A problem with soft foam is it easily deforms, which changes the distance between the center conductor and the shield, changing the cable impedance. This can be caused by bending the cable too sharply, or running over it, or pulling it too hard, or any other possibility. To reduce this problem, a hard cell foam is used. Some cable that is rated as having a very high velocity of propagation might use very soft foam. A simple test can be performed where the user squeezes the foam dielec-
Transmission Techniques: Wire and Cable

The density (crush resistance) of various cables. It will be immediately apparent that some cables have a density double that of other designs. Soft foam can lead to conductor migration over time which will change timing, impedance, return loss, and bit errors over distance.

Coaxial cable is used quite extensively with various types of test equipment. When such cable is replaced, the capacitance per foot, which is determined by the dielectric constant of the insulator, must be taken into consideration, particularly for oscilloscope probes.

### 14.10.2.1 CCTV Cable

CCTV (closed circuit television) cable has a 75 Ω characteristic impedance. CCTV is a baseband signal comprised of low-frequency vertical and horizontal sync pulse information and high-frequency video information. Since the signal is broadband, only cable with a center conductor of solid copper should be used.

If the cable is constantly in motion as in pan and tilt operation, a stranded center conductor should be used as a solid conductor will work-harden and break. There are also robotic coaxes designed to flex millions of times before failure for intense flexing applications.

Shielding for CCTV cable should have a copper or tinned-copper braid of at least 80% coverage, for low-frequency noise rejection. If an aluminum foil shield is used in conjunction with a braid, either tinned copper or aluminum only may be used for the shield. A bare copper braid will result in a galvanic reaction.

#### 14.10.2.1.1 CCTV Distances

For common CCTV 75 Ω cables, their rule-of-thumb transmission distances are shown in Table 14-21. These distances can be extended by the use of in-line booster amplifiers.

#### 14.10.2.2 CATV Broadband Cable

For higher-frequency applications, such as carrying radio frequencies or television channels, only the skin of the conductor is working (see Section 14.2.8, Skin Effect). Television frequencies in the United States, for instance, start with Channel 2 (54 MHz) which is definitely in the area of skin effect. So these cables can use center conductors that have a layer of copper over a steel wire, since only the copper layer will be working.

If one uses a copper-clad steel conductor for applications below 50 MHz, the conductor has a dc resistance from four to seven times that of a solid copper conductor. If a copper-clad cable is used on a baseband video signal, for instance, the sync pulses may be attenuated too much. If such a cable is used to carry audio, almost the entire audio signal will be running down the steel wire.

CATV/broadband cable should have a foil shield for good high-frequency noise rejection. CATV cable should also have a braid shield to give the connector something to grab onto, 40% to 60% aluminum braid being the most common. Multiple layer shields are also available such as tri-shielded (foil-braid-foil) and quad shields (foil-braid-foil-braid). Assumptions that quad shields give the best shield effectiveness are erroneous, there being single foil/braid and tri-shield configurations that are measurably superior. Refer to Section 14.8.6 on shield effectiveness.

Modern CATV/broadband cable will use a foamed polyethylene or foamed FEP dielectric, and preferably one with gas injected foam. This will reduce the losses in the cable. The jacket material is determined by the environment that the cable will be working in (see Sections 14.4, 14.5, 14.6).

### 14.10.3 Coaxial Cable Installation Considerations

#### 14.10.3.1 Indoor Installation

Indoor environments are the most common for coaxial cable installations. A few tips on installing coaxial cable are as follows:

1. First and foremost, follow all NEC requirements when installing coaxial cables.
2. Distribute the pulling tension evenly over the cable and do not exceed the minimum bend radius of ten times the diameter. Exceeding the maximum pulling tension or the minimum bend radius of a cable can cause permanent damage both mechanically and electrically to the cable.
3. When pulling cable through conduit, clean and deburr the conduit completely and use proper lubricants in long runs.
14.10.3.2 Outdoor Installation

Outdoor installations require special installation techniques that will enable the cable to withstand harsh environments. When using cable in an aerial application, lash the cable to a steel messenger, or buy cable with a built-in steel messenger. This will help support the cable and reduce the stress on the cable during wind, snow, and ice storms. When direct burying a cable, lay the cable without tension so it will not be stressed when earth is packed around it. When burying in rocky soil, fill the trench with sand. Lay the cable and then place pressure-treated wood or metal plates over the cable. This will prevent damage to the cable from rocky soil settling; in cold climate areas, bury the cable below the frost line. Buy direct burial cable designed to be buried.

14.10.4 Coaxial Cable Termination Techniques

14.10.4.1 Soldering

Soldering offers several advantages as it can be used on solid or stranded conductors and it creates both a solid mechanical and electrical connection. The disadvantage is that it takes more time to terminate than other methods and cold solder joints can cause problems if the connector is not soldered to the cable properly. The use of lead-based solder might also be a consideration if RoHS (reduction of hazardous substances) requirements are part of the installation. Soldering is not recommended for high-frequency applications, such as HD-SDI or 1080p/60 as the variations in dimensions will show up as variations in impedance and contribute to return loss (see Section 14.10.5).

14.10.4.2 Crimping

Crimping is probably the most popular method of terminating BNC and F connectors on coax cable. Like the solder method, it can be used on solid or stranded conductors and provides a good mechanical and electrical connection. This method is the most popular because there is no need for soldering so installation time is reduced. It is very important to use the proper size connector for a tight fit on the cable. Always use the proper tool. Never use pliers as they are not designed to place the pressure of the crimp evenly around the connector. Pliers will crush the cable and can degrade the electrical properties of the cable.

14.10.4.3 Twist-On Connectors

Twist-on connectors are the quickest way of terminating a coaxial cable; however, they do have some drawbacks. When terminating the cable with this type of connector, the center conductor is scored by the center pin on the connector, thus too much twisting can cause damage to the center conductor. It is not recommended for pan and tilt installations as the constant movement of the cable may work the connector loose. Because there is no mechanical or electrical crimp or solder connection, this connector is not as reliable as the other methods.

14.10.4.4 Compression Connectors

There are connectors, often a one-piece connector, that fit over the stripped cable and fasten by having two parts squeeze or compress together. This is a very simple and reliable way of connecting cable. However, the very high-frequency performance (beyond 500 MHz) has yet to be proven and so these connectors are not recommended for professional digital applications. A compression connector that is measured with a return loss of −20 dB at 2 GHz would be acceptable for professional broadcast HD applications.

14.10.5 Return Loss

At high frequencies, where cable and connectors are a significant percentage of a wavelength, the impedance variation of cable and components can be a significant source of signal loss. When the signal sees something other than 75 Ω, a portion of the signal is reflected back to the source. Table 14-22 shows the wavelength and quarter wavelength at various frequencies. One can see that this was a minor problem with analog video (quarter wave 59 ft) since the distances are so long. However, with HD-SDI and higher signals, the quarter wave can be 1 inch or less, meaning that everything in the line is critical: cable connectors, patch panels, patch cords, adaptors, bulkhead/feet through connectors, etc.

### Table 14-22. Wavelength and Quarter Wavelength of Various Signals at Various Frequencies

<table>
<thead>
<tr>
<th>Signal</th>
<th>Clock Frequency</th>
<th>Third Harmonic</th>
<th>Wavelength</th>
<th>Quarter Wavelength</th>
</tr>
</thead>
<tbody>
<tr>
<td>Analog video analog (4.2 MHz)</td>
<td>analog</td>
<td>234 ft</td>
<td>59 ft</td>
<td></td>
</tr>
</tbody>
</table>
In fact, Table 14-22 above is not entirely accurate. The distances should be multiplied by the velocity of propagation of the cable or other component, to get the actual length, so they are even shorter still.

Since everything is critical at high frequencies, it is appropriate to ask the manufacturers of the cable, connectors, patch panels, and other passive components, how close to 75Ω their products are. This can be established by asking for the return loss of each component. Table 14-23 will allow the user to roughly translate the answers given.

<table>
<thead>
<tr>
<th>Return Loss</th>
<th>% of Signal Received</th>
<th>% Reflected</th>
</tr>
</thead>
<tbody>
<tr>
<td>–50 dB</td>
<td>99.999%</td>

<td>90.0%</td>
<td>100.0%</td>
</tr>
</tbody>
</table>

Most components intended for HD can pass –20 dB return loss. In fact, –20 dB return loss at 2 GHz is a good starting point for passive components intended for HD-SDI. Better components will pass –30 dB at 2 GHz. Better still (and rarer still) would be –30 dB at 3 GHz. There are currently no components that are consistently –40 dB return loss at any reasonable frequency. In Table 14-22, it can be seen that 1080p/60 signals need to be tested to 4.5 GHz. This requires expensive custom-built matching networks. As of this writing, only one company (Belden) has made such an investment.

Note that the number of nines in the Signal Received column is the same as the first digit of the return loss (i.e., –30 dB = 3 nines = 99.9%). There are similar tests, such as SRL (structural return loss). This test only partially shows total reflection. Do not accept values measured in any way except return loss. The SMPTE maximum amount of reflection on a passive line (with all components measured and added together) is –15 dB or 96.84% received, 3.16% reflected. A line with an RL of –10 dB (10% reflected) will probably fail.

### 14.10.6 Video Triaxial Cable

Video triaxial cable is used to interconnect video cameras to their related equipment. Triaxial cable contains a center conductor and two isolated shields, allowing it to support many functions on the one cable. The center conductor and outer shield carry the video signals plus intercoms, monitoring devices, and camera power. The center shield carries the video signal ground or common. Triax cable is usually of the RG-59 or RG-11 type.

### 14.10.7 S-Video

S-video requires a duplex (dual) coaxial cable to allow separate transmission of the luminance (Y) and the chrominance (C). The luminance signal is black or white or any gray value while the chrominance signal contains color information. This transmission is sometimes referred to as Y-C. Separating signals provides greater picture detail and resolution and less noise interference.

S-video is sometimes referred to as S-VHS™ (Super-Video Home System). While its intention was for improved consumer video quality, these cameras were also used for the lower end of the professional area, where they were used for news, documentaries, and other less-critical applications.

### 14.10.8 RGB

RGB stands for red-green-blue, the primary colors in color television. It is often called component video since the signal is split up to its component colors. When these analog signals are carried separately much better image resolution can be achieved. RGB can be carried on multiple single video cables, or in bundles of cables made for this application. With separate cables, all the cables used must be precisely the same electrical length. This may or may not be the same as the physical length. Using a vectorscope, it is possibly to determine the electrical length and compare the RGB components. If the cables are made with poor quality control, the electrical length of the coaxes may be significantly different (i.e., one cable may have to be physically longer than the others to align the component signals). Cables made with very good quality control can simply be cut at the same physical length.

Bundles of RGB cables should be specified by the amount of timing error, the difference in the delivery
time on the component parts. For instance, all Belden bundled coax cables are guaranteed to be 5 ns (nano-second) difference per 100 ft of cable. Other manufacturers should have a similar specification and/or guarantee. The de facto timing requirement for broadcast RGB is a maximum of 40 ns. Timing cables by hand with a vectorscope allows the installer to achieve timing errors of >1 ns. Bundled cables made for digital video can also be used for RGB analog, and similar signals (Y, R–Y, B–Y or Y, Pb, Pr or YUV or VGA, SVGA, XGA, etc.) although the timing requirements for VGA and that family of signals has not been established.

These bundled coaxes come in other version besides just three coax RGB. Often the horizontal and vertical synchronizing signals (H and V) are carried with the green video signal on the green coax. For even greater control, these signals can be carried by a single coax (often called RGBS) or five coaxes, one for each signal (called RGBHV). These cables are becoming more common in the home, where they are often referred to as five-wire video. There are also four-pair UTP data cables made especially to run RGB and VGA signals. Some of these have timing tolerance (called delay skew in the UTP world) that is seriously superior to bundled coaxes. However, the video signals would have to be converted from 75 Ω to 100 Ω, and the baluns to do this, one for each end of the cable, would be added to the cost of the installation. Further, the impedance tolerance of coax, even poorly made coax, is dramatically superior to twisted pairs. Even bonded twisted pairs are, at best, ±7 Ω, where most coaxial cables are ±3 Ω, with precision cables being twice as good as that, or even better.

### 14.10.9 VGA and Family

VGA stands for video graphics array. It is an analog format to connect progressive video source to displays, such as projectors and screens. VGA comes in a number of formats, based on resolution. These are shown in Table 14-24.

There are many more variations in resolution and bandwidth than the ones shown in Table 14-24.

### 14.11 Digital Video

There are many formats for digital video, for both consumer, commercial and professional applications. This section concentrates on the professional applications, mainly SD-SDI (standard definition—serial digital interface) and HD-SDI (high-definition—serial digital interface.) There are sections on related consumer standards such as DVI (Section 14.9.4.1) and HDMI (Section 14.9.4.2).

### 14.11.1 Digital Signals and Digital Cable

Control communications, or data communications, uses digital signals. Digital video signals require wide bandwidth cabling. Control communications and data communications use lower-performance cabling because they carry less information, requiring less bandwidth. High-speed data communications systems have significant overhead added to handle error correction so if data is lost, it can be re-sent. Digital video has some error correction capabilities, however, if all of the data bits required to make the system work are not received, picture quality is reduced or lost completely. Table 14-25 compares various digital formats.

### 14.11.2 Coax and SDI

Most professional broadcast formats (SDI and HD-SDI) are in a serial format and use a single coaxial cable with BNC connectors. Emerging higher resolution formats, such as 1080p/60, are also BNC based. Some work with smaller connectors for dense applications, such as patch panels and routers, which use subminiature connectors such as LCC, DIN 1.0/2.3 or DIN 1.0/2.5. Proprietary miniature BNC connectors are also available.

### 14.11.3 Cables and SDI

The most common form of SDI, component SDI, operates at data rates of 270 Mbps (clock 135 MHz). Cable loss specifications for standard SDI are specified in SMPTE 259M and ITUR BT.601. The maximum cable length is specified as 30 dB signal loss at one-half the
clock frequency and is acceptable because serial digital receivers have signal recovery processing.

HD-SDI, whose cable loss is governed by SMPTE 292M, operates at a data rate of 1.5 Gbps (clock 750 MHz). The maximum cable length is specified at 20 dB signal loss at one-half the clock frequency. These are Manchester Coded signals and the bit rate is therefore double the clock rate. Emerging 1080p/60 applications are covered under SMPTE 424M. The data rate is 3 Gbps (clock 1.5 GHz).

### 14.11.4 Receiver Quality

The quality of the receiver is important in the final performance of a serial digital system. The receiver has a greater ability to equalize and recover the signal with SDI signals. SMPTE 292M describes the minimum capabilities of a type A receiver and a type B receiver. SDI receivers are considered adaptive because of their ability to amplify, equalize, and filter the information. Rise time is significantly affected by distance, and all quality receivers can recover the signal from a run of HD-SDI RG-6 (such as Belden 1694A) for a minimum distance of 122 m (400 ft). The most important losses that affect serial digital are rise time/fall time degradation and signal jitter. Serial digital signals normally undergo reshaping and reclocking as they pass through major network hubs or matrix routers.

Table 14-26 gives the specifications mandated in SMPTE 259M and SMPTE 292M in terms of rise/fall time performance and jitter. If the system provides this level of performance at the end of the cable run, the SDI receiver should be able to decode the signal, swept at 2.25 GHz. RL can be no greater than 15 dB at

### 14.11.5 Serial Digital Video

Serial digital video (SDI) falls under standards by the Society of Motion Picture and Television Engineers (SMPTE) and ITU and falls under the following categories:

ITU-R BT.601 International standard for PAL transmissions of 177 Mb/s

These standards can work with standard analog video coax cables, however, the newer digital cables provide the more precise electrical characteristics required for high-frequency transmission.

SDI cable utilizes a solid bare-copper center-conductor which improves impedance stability and reduced return loss (RL). Digital transmissions contain both low-frequency and high-frequency signals so it is imperative that a solid-copper center-conductor is used rather than a copper-clad steel center conductor. This allows the low frequencies to travel down the center of the conductor and the high frequencies to travel on the outside of the conductor due to the skin effect. Since digital video consists of both low and high frequencies, foil shields work best. All SDI cable should be sweep tested for return loss to the third harmonic of the fundamental frequency. For HD-SDI which is 1.485 Gb/s or has a 750 MHZ bandwidth, the cable is this frequency.
BNC 50 Ω connectors are often used to terminate digital video lines. This is probably acceptable if only one or two connectors are used. However, if more connectors are used, 75 Ω connectors are required to eliminate RL. Connectors should exhibit a stable 75 Ω impedance out to 2.25 GHz, the third harmonic of 750 MHz.

### 14.12 Radio Guide Designations

From the late 1930s the U.S. Army and Navy began to classify different cables by their constructions. Since the intent of these high-frequency cables, both coaxes and twisted pairs, was to guide radio frequency signals, they carried the designation RG for radio guide.

There is no correlation between the number assigned and any construction factor of the cable. Thus an RG-8 came after an RG-7 and before an RG-9, but could be completely different and unrelated designs. For all intents and purposes, the number simply represents the page number in a book of designs. The point was to get a specific cable design, with predictable performance, when ordered for military applications.

As cable designs changed, with new materials and manufacturing techniques, variations on the original RG designs began to be manufactured. Some of these were specific targeted improvement, such as a special jacket on an existing design. These variations are noted by an additional letter on the designation. Thus RG-58C would be the third variant on the design of RG-58.

The test procedure for many of these military cables is often long, complicated, and expensive. For the commercial user of these cables, this is a needless expense. So many manufacturers began to make cables that were identical to the original RG specification except for testing. These were then designated utility grade and a slash plus the letter U is placed at the end. RG-58C/U is the utility version of RG-58C, identical in construction but not in testing.

Often the word *type* is included in the RG designation. This indicates that the cable under consideration is based on one of the earlier military standards but differs from the original design in some significant way. At this point, all the designation is telling the installer is that the cable falls into a family of cables. It might indicate the size of the center conductor, the impedance, and some aspects of construction, with the key word being *might*.

By the time the RG system approached RG-500, with blocks of numbers abandoned in earlier designs, the system became so unwieldy and unworkable that the military abandoned it in the 1970s and instituted MIL-C-17 (Army) and JAN C-17 (Navy) designations that continue to this day. RG-6, for instance, is found under MIL-C-17G.

### 14.13 Velocity of Propagation

*Velocity of propagation*, abbreviated $V_p$, is the ratio of the speed of transmission through the cable versus the speed of light in free space, about 186,282 miles per second (mi/s) or 299,792,458 meters per second (m/s). For simplicity, this is usually rounded up to 300,000,000 meters per second (m/s). Velocity of propagation is a good indication of the quality of the cable. Solid polyethylene has a $V_p$ of 66%. Chemically formed foam has a

Velocity of propagation is the velocity of the signal as it travels from one end of the line to the other end. It is caused because a transmission line, like all electrical circuits, possesses three inherent properties: resistance, inductance, and capacitance. All three of these properties will exist regardless of how the line is constructed. Lines cannot be constructed to eliminate these characteristics.

Under the foregoing conditions, the velocity of the electrical pulses applied to the line is slowed down in its transmission. The elements of the line are distributed evenly and are not localized or present in a lumped quantity.

The velocity of propagation ($V_p$) in flexible cables will vary from 50% to a $V_p$ of 86%, depending on the insulating composition used and the frequency. $V_p$ is directly related to the dielectric constant (DC) of the insulation chosen. The equation for determining the velocity of propagation is

$$V_p = \frac{100}{\sqrt{\text{DC}}} \quad (14-5)$$

where,

- $V_p$ is the velocity of propagation,
- DC is the dielectric constant.

Velocity can apply to any cable, coax or twisted pairs, although it is much more common to be expressed for cables intended for high-frequency applications. The velocity of propagation of coaxial cables is the ratio of the dielectric constant of a vacuum to the square root of the dielectric constant of the insulator, and is expressed in percent.

$$\frac{V_L}{V_S} = \frac{1}{\sqrt{\varepsilon}} \quad (14-6)$$

or

$$V_L = \frac{V_S}{\sqrt{\varepsilon}} \quad (14-7)$$

where,

- $V_L$ is the velocity of propagation in the transmission line,
- $V_S$ is the velocity of propagation in free space,
- $\varepsilon$ is the dielectric constant of the transmission line insula-

14.14 Shielding

From outdoor news gathering to studios and control rooms to sound reinforcement systems, the audio industry faces critical challenges from EM/RF interference (EMI and RFI). Shielding cable and twisting pairs insures signal integrity and provides confidence in audio and video transmissions, preventing downtime and maintaining sound and picture clarity.

Cables can be shielded or unshielded, except for coaxial cable which is, by definition, a precise construction of a shielded single conductor. There are a number of shield constructions available. Here are the most common.

14.14.1 Serve or Spiral Shields

Serve or spiral shield are the simplest of all wire-based shields. The wire is simply wound around the inner portions of the cable. Spiral shields can be either single or double spirals. They are more flexible than braided shields and are easier to terminate. Since spiral shields are, in essence, coils of wire, they can exhibit inductive effects which make them ineffective at higher frequencies. Therefore, spiral/serve shields are relegated to low frequencies and are rarely used for frequencies above analog audio. Serve or spiral shields tend to open up when the cable is bent or flexed. So shield effectiveness is less than ideal, especially at high frequencies.

14.14.2 Double Serve Shields

Serve or spiral shields can be improved by adding a second layer. Most often, this is run at a 90° angle to the original spiral. This does improve coverage although the tendency to open up is not significantly improved and so this is still relegated to low-frequency or analog audio applications. This double serve or spiral construction is also called a Reussen shield (pronounced roy-sen).
14.14.3 French Braid™

The French Braid shield by Belden is an ultraflexible double spiral shield consisting of two spirals of bare or tinned copper conductors tied together with one weave. The shield provides the long flex life of spiral shields and greater flexibility than braided shields. It also has about 50% less microphonic and triboelectric noise. Because the two layers are woven along one axis, they cannot open up as dual spiral/serve constructions can. So French Braid shields are effective up to high frequencies, and are used up to the Gigahertz range of frequencies.

14.14.4 Braid

Braid shields provide superior structural integrity while maintaining good flexibility and flex life. These shields are ideal for minimizing low-frequency interference and have lower dc resistance than foil. Braid shields are effective at low frequencies, as well as RF ranges. Generally, the higher the braid coverage, the more effective the shield. The maximum coverage of a single braid shield is approximately 95%. The coverage of a dual braid shield can be as much as 98%. One hundred percent coverage with a braid is not physically possible.

14.14.5 Foil

Foil shields can be made of bare metal, such as a bare copper shield layer, but more common is an aluminum-polyester foil. foil shields can offer 100% coverage. Some cables feature a loose polyester-foil layer. Other designs can bond the foil to either the core of the cable or to the inside of the jacket of the cable. Each of these presents challenges and opportunities.

The foil layer can either face out, or it can be reversed and face in. Since foil shields are too thin to be used as a connection point, a bare wire runs on the foil side of the shield. If the foil faces out, the drain wire must also be on the outside of the foil. If the foil layer faces in, then the drain wire must also be inside the foil, adjacent to the pair.

Unbonded foil can be easily removed after cutting or stripping. Many broadcasters prefer unbonded foil layers in coaxial cable to help prevent thin slices of foil that can short out BNC connectors. If the foil is bonded to the core, the stripping process must be much more accurate to prevent creating a thin slice of core-and-foil.

However, with F connectors, which are pushed onto the end of the coax, unbonded foil can bunch up and prevent correct seating of these connectors. This explains why virtually all coaxes for broadband/CATV applications have the foil bonded to the core—so F connectors easily slip on.

In shielded paired cables, such as analog or digital audio paired cables, the foil shield wraps around the pair. Once the jacket has been stripped off, the next step is to remove the foil shield. These cables are also available where the foil is bonded (glued) to the inside of the jacket. When the jacket is removed, the foil is also removed, dramatically speeding up the process.

A shorting fold technique is often used to maintain metal-to-metal contact for improved high-frequency performance. Without the shorting fold, a slot is created through which signals can leak. A isolation fold also helps prevent the shield of one pair contacting the shield of an adjacent pair in a multipair construction. Such contact significantly increases crosstalk between these pairs.

An improvement on the traditional shorting fold used by Belden employs the Z-Fold™, designed for use in multipair applications to reduce crosstalk, Fig. 14-14. The Z-Fold combines an isolation fold and a shorting fold. The shorting fold provides metal-to-metal contact while the isolation fold keeps shields from shorting to one another in multipair, individually shielded cables.

Since the wavelength of high frequencies can eventually work through the holes in a braid, foil shields are most effective at those high frequencies. Essentially, foil shields represent a skin shield at high frequencies, where skin effect predominates.

14.14.6 Combination Shields

Combination shields consist of more than one layer of shielding. They provide maximum shield efficiency
across the frequency spectrum. The combination foil-braid shield combines the advantages of 100% foil coverage and the strength and low dc resistance of a braid. Other combination shields available include various foil-braid-foil, braid-braid, and foil-spiral designs.

14.14.6.1 Foil + Serve

Because of the inductive effects of serve/spiral shields, which relegate them to low-frequency applications, this combination is rarely seen.

14.14.6.2 Foil + Braid

This is the most common combination shield. With a high-coverage braid (95%) this can be extremely effective over a wide range of frequencies, from 1 kHz to many GHz. This style is commonly seen on many cables, including precision video cable.

14.14.6.3 Foil + Braid + Foil

Foil-braid-foil is often called a tri-shield. It is most commonly seen in cable television (CATV) broadband coaxial applications. The dual layers of foil are especially effective at high frequencies. However, the coverage of the braid shield in between is the key to shield effectiveness. If it is a reasonably high coverage (>80%) this style of braid will have excellent shield effectiveness.

One other advantage of tri-shield coax cable is the ability to use standard dimension F connectors since the shield is essentially the same thickness as the common foil + braid shield of less expensive cables.

14.14.6.4 Foil + Braid + Foil + Braid

Foil-braid-foil-braid is often called quad-shield or just quad (not to be confused with starquad microphone cable or old POTS quad hookup cable). Like tri-shield above, this is most common in cable television (CATV) broadband coaxial applications. Many believe this to be the ultimate in shield effectiveness. However, this is often untrue.

If the two braids in this construction are high coverage braids (>80%) then, yes, this would be an exceptional cable. But most quad-shield cable uses two braids that are 40% and 60% coverage, respectively. With that construction, the tri-shield with an 80%+ braid is measurably superior. Further, quad-shield coaxial cables are considerably bigger in diameter and therefore require special connectors.

Table 14-27 shows the shield effectiveness of different shield constructions at various frequencies. Note that all the braids measured are aluminum braids except for the last cable mentioned. That last cable is a digital precision video (such as Belden 1694A) and is many times the cost of any of the other cables listed.

14.15 Shield Current Induced Noise

There is significant evidence that constructions that feature bonded foil with an internal drain wire may affect the performance of the pairs, especially at high frequencies. Since an ideal balanced line is one where the two wires are electrically identical, having a drain wire in proximity would certainly seem to affect the symmetry of the pair. This would be especially critical where strong RF fields are around audio cables.

Despite this evidence, there are very few cables made with appropriate symmetry. This may be based on lack of end-user demand, as manufacturers would be glad to redesign their cables should the demand arise. The drain wire could be easily substituted with a symmetrical low-coverage braid, for instance.

14.16 Grounds of Shields

With any combination shield, the braid portion is the part that is making the connection. Even if we are shielding against high-frequency noise, in which case the foil is doing the actual work, the noise gets to ground by way of the braid which is much lower in resistance than the foil.

Where the foil uses a drain wire, it is that drain wire that is the shield connection. Therefore, that drain wire must be bare so it can make contact with the foil. If the foil is floating, not glued or bonded to the core of the cable, then another plastic layer is used to carry the foil.
The foil itself is much too thin and weak to even be applied in the factory by itself. The second plastic layer adds enough strength and flex-life (flexes until failure) to allow the foil to be used.

The drain wire, therefore, must be in contact with the foil. In some cables, the foil faces out, so the drain wire must be on the outside of the foil, between the foil and the jacket. If the foil faces in, then the drain wire must be on the inside of the foil, adjacent to the pair (or other components) inside the cable.

With an internal drain wire, there are a number of additional considerations. One is SCIN, shield current induced noise, mentioned earlier in Section 14.8.5.1. Another is the ability to make a multipair shielded cable where the shields are facing in and the plastic facing out. This allows the manufacturer to color code the pairs by coloring the plastic holding the foil.

If you have a multipair cable, with individual foil shields, it is important that these foil shields do not touch. If the shields touch, then any signal or noise that is on one foil will be instantly shared by the other. You might as well put a foil shield in common around both pairs. Therefore, it is common to use foil shields facing in which will help prevent them from touching. These can then be color coded by using various colors of plastic with each foil to help identify each pair.

However, simply coiling the foil around the pair still leaves the very edge of the foil exposed. In a multipair cable with many individual foils, where the cable is bent and flexed to be installed, it would be quite easy for the edge of one foil to touch the edge of another foil, thus compromising shield effectiveness. The solution for this is a Z-fold invented by Belden in 1960, shown in Fig. 14-14. This does not allow any foil edge to be exposed no matter how the cable is flexed.

### 14.16.1 Ground Loops

In many installations, the ground potential between one rack and another, or between one point in a building and another, may be different. If the building can be installed with a star ground, the ground potential will be identical throughout the building. Then the connection of any two points will have no potential difference.

When two points are connected that do have a potential difference, this causes a ground loop. A ground loop is the flow of electricity down a ground wire from one point to another. Any RF or other interference on a rack or on an equipment chassis connected to ground will now flow down this ground wire, turning that foil or braid shield into an antenna and feeding that noise into the twisted pair. Instead of a small area of interference, such as where wires cross each other, a ground loop can use the entire length of the run to introduce noise.

If one cannot afford the time or cost of a star ground system, there are still two options. The first option is to cut the ground at one end of the cable. This is called a telescopic ground.

#### 14.16.2 Telescopic Grounds

Where a cable has a ground point at each end, disconnecting one end produces a telescopic ground. Installers should be cautioned to disconnect only the destination (load) end of the cable, leaving the source end connected.

For audio applications, the effect of telescopic grounds will eliminate a ground loop, but at a 50% reduction in shield effectiveness (one wire now connected instead of two). If one disconnects the source end, which in analog audio is the low-impedance end, and maintains the destination (load) connection, this will produce a very effective R-L-C filter at audio frequencies.

At higher frequencies, such as data cables, even a source-only telescopic shield can have some serious problems. Fig. 14-15 shows the effect of a telescopic ground on a Cat 6 data cable. The left column shows the input impedance, the impedance presented to any RF traveling on the shield, at frequency $f_k$ (bottom scale) in MHz.

You will note that at every half-wavelength, the shield acts like an open circuit. Since most audio cables are foil shielded, and the foil is effective only at high
frequencies, this means that even a correctly terminated telescopic shield is less effective at RF frequencies.

14.17 UTP and Audio

One other solution for ground loops is to have no ground connection. For the seasoned audio and video professional, this solution may require a leap of faith. In can clearly be seen that, with a cable that has no shield, no drain wire, and no ground wire, so no ground loop can develop. This is a common form of data cable called UTP, unshielded twisted pairs.

With such a cable, having no shield means that you are totally dependent on the balanced line to reject noise. This is especially true, where you wish to use the four pairs in a Cat 5e, 6, or 6a cable to run four unrelated audio channels. Tests were performed on low-performance (stranded) Cat 5e patch cable (Belden 1752A) looking at crosstalk between the pairs. This test shows the average of all possible pair combinations, the worst possible case, and covered a bandwidth of 1 kHz to 50 kHz. The results are shown in Fig. 14-16.

You will note that the worst case is around 40 kHz where the crosstalk is slightly better than −95 dB. In the range of common audible frequencies (20 kHz) the pair-to-pair crosstalk approaches −100 dB. Since a noise floor of −90 dB is today considered wholly acceptable, a measurement of −95 dB or −100 dB is even better still.

A number of data engineers questioned these numbers based on the fact that these measurements were FEXT, far-end crosstalk, where the signals are weakest in such a cable. So measurements were also taken of NEXT, near-end crosstalk, where the signals are strongest. Those measurements are shown in Fig. 14-17.

The NEXT measurements are even better than the previous FEXT measurements. In this case, the worst case is exactly −95 dB at just under 50 kHz. At 20 kHz and below, the numbers are even better than the previous graph, around −100 dB or better.

There were attempts made to test a much better cable (Belden 1872A MediaTwist). This unshielded twisted-pair cable is now a Cat 6 bonded-pair design. After weeks of effort, it was determined that the pair-to-pair crosstalk could not be read on an Agilent 8714ES network analyzer. The crosstalk was somewhere below the noise floor of the test gear. The noise floor of that instrument is −110 dB. With a good cable, the crosstalk is somewhere below −110 dB.

14.17.1 So Why Shields?

These experiments with unshielded cable beg the question, why have a shield? In fact, the answer is somewhat reversed. The pairs in data cables are dramatically improved over the historic audio pairs. The bandwidth alone, 500 MHz for Cat 6a, for instance, indicates that these are not the same old pairs but something different. In fact, what has happened is that the wire and cable (and data) industries have fixed the pairs.

Before, with a poorly manufactured pair, a shield would help prevent signals from getting into, or leaking out of, a pair. The fact that either effect, ingress or egress, occurred indicated the poor balance, the poor performance of the pair.

This does not mean shields are dead. There are data cables with overall shields (FTP), even individually shielded pairs (Cat 7) common in Europe. However, these are subject to the same problems as all shielded, grounded cables in terms of ground loops and wavelength effects as shown in Sections 14.8.6.5 and 14.8.6.6.

The truth to the efficacy of unshielded twisted pairs running audio, video, data and many other signals is commonplace today. Many audio devices routinely use...
UTP for analog and digital connections. Where the source is not a balanced line, a device must change from balanced (UTP) to unbalanced (coax, for instance). Such a device matches Balanced-to-Unbalanced and is therefore called a balun. There is more on baluns in Section 14.9.3.6.7, Baluns.

14.18 AES/EBU Digital Audio Cable

Digital audio technology has been around for many years, even decades, but until recently it has not been used much for audio. This has now changed and digital audio is overtaking analog audio. For this reason it is important that the cable used for digital signals meet the digital requirements. To set a standard, the Audio Engineering Society (AES) and the European Broadcast Union (EBU) have set standards for digital audio cable. The most common sampling rates and equivalent bandwidth are shown in Table 14-28.

It is important that the line impedance be maintained to eliminate reflections that degrade the signal beyond recovery. Standard analog cable can be used for runs under 50 ft (15 m) but beyond that, reliability decreases. The impedance and capacitance of analog cable is 40 to 70 \( \Omega \) and 20 to 50 pF/ft. The impedance and capacitance for digital cable is 110 \( \Omega \) and 13 pF/ft with a velocity of propagation of 78%. Proper impedance match and low capacitance are required so the square wave signal is not distorted, reflected, or attenuated.

Broadcast cable is most often #24 (7 × 32) tinned copper wire with short overall twist lengths, low-loss foam insulation, and 100% aluminum polyester foil shield for permanent installations. Braided shields are also available for portable use. If required, #22 to #26 wire can be obtained. Digital audio cable also comes in multiple pairs with each pair individually shielded, and often jacketed, allowing each pair and its shield to be completely isolated from the others. One pair is capable of carrying two channels of digital audio. Cables are terminated with either XLR connectors or are punched down or soldered in patch panels.

14.18.1 AES/EBU Digital Coaxial Cable

Digital audio requires a much wider bandwidth than analog. As the sampling rate doubles, the bandwidth also doubles, as shown in Table 14-28.

Digital audio can be transmitted farther distances over coax than over twisted pairs. The coax should have a 75 \( \Omega \) impedance, a solid copper center conductor, and have at least 90% shield coverage. When transmitting audio over an unbalanced coax line, the use of baluns may be required to change from balanced to unbalanced and back unless the device contains AES/EBU unbalanced coax inputs and outputs. The baluns change the impedance from 110 \( \Omega \) balanced to 75 \( \Omega \) unbalanced and back.

14.19 Triboelectric Noise

Noise comes in a variety of types such as EMI (electromagnetic interference) and RFI (radio frequency interference). There are also other kinds of noise problems that concern cables. These are mechanically generated or mechanically induced noise, commonly called triboelectric noise.

Triboelectric noise is generated by mechanical motion of a cable causing the wires inside the shield to rub against each other. Triboelectric noise is actually small electrical discharges created when conductors position changes relative to each other. This movement sets up tiny capacitive changes that eventually pop. Highly amplified audio can pick this up.

Fillers, nonconductive elements placed around the conductors, help keep the conductor spacing constant while semiconductive materials, such as carbon-impregnated cloth or carbon-plastic layers, help dissipate charge buildup. Triboelectric noise is measured through low noise test equipment using three low noise standards: NBS, ISA-S, and MIL-C-17.

Mechanically induced noise is a critical and frequent concern in the use of high-impedance cables such as guitar cords and unbalanced microphone cables that are constantly moving. The properties of special conductive tapes and insulations are often employed to help prevent mechanically induced noise. Cable without fillers can often produce triboelectric noise. This is why premise/data category cables are not suitable for flexing, moving audio applications. There are emerging flexible tactical data cables, especially those using bonded pairs, that might be considered for these applications.
14.20 Conduit Fill

To find the conduit size required for any cable, or group of cables, do the following:

1. Square the OD (outside diameter) of each cable and total the results.
2. To install only one cable: multiply that number by 0.5927.
3. To install two cables: multiply by 1.0134.
4. To install three or more cables: multiply the total by 0.7854.
5. From step #2 or #3 or #4, select the conduit size with an area equal to or greater than the total area. Use the ID (inside diameter) of the conduit for this determination.

This is based on the NEC ratings of

- single cable       53% fill
- two cables         31% fill
- three or more cables 40% fill

If the conduit run is 50 ft to 100 ft, reduce the number of cables by 15%. For each 90° bend, reduce the conduit length by 30 ft. Any run over 100 ft requires a pull box at some midpoint.

14.21 Long Line Audio Twisted Pairs

As can be seen in Table 14-29, low frequency signals, such as audio, rarely go a quarter-wavelength and, therefore, the attributes of a transmission line, such as the determination of the impedance and the loading/matching of that line, are not considered.

However, long twisted pairs are common for telephone and similar applications, and now apply for moderate data rate, such as DSL. A twisted-pair transmission line is loaded at stated intervals by connecting an inductance in series with the line. Two types of loading are in general usage—lumped and continuous. Loading a line increases the impedance of the line, thereby decreasing the series loss because of the conductor resistance.

Although loading decreases the attenuation and distortion and permits a more uniform frequency characteristic, it increases the shunt losses caused by leakage. Loading also causes the line to have a cutoff frequency above which the loss becomes excessive. In a continuously loaded line, loading is obtained by wrapping the complete cable with a high-permeability magnetic tape or wire. The inductance is distributed evenly along the line, causing it to behave as a line with distributed constants.

In the lumped loading method, toroidal wound coils are placed at equally spaced intervals along the line, as shown in Fig. 14-18. Each coil has an inductance on the order of 88 mH. The insulation between the line conductors and ground must be extremely good if the coils are to function properly.

![Figure 14-18. Loading coil connected in a balanced transmission line.](image)

Loading coils will increase the talking distance by 35 to 90 miles for the average telephone line.

If a high-frequency cable is not properly terminated, some of the transmitted signal will be reflected back toward the transmitter, reducing the output.

14.22 Delay and Delay Skew

The fact that every cable has a velocity of propagation, obviously means that it takes time for a signal to go down a cable. That time is called delay, normally measured in nanoseconds (Dn). \( V_p \) can easily be converted into delay. Since \( V_p \) is directly related to dielectric constant (DC), they are all directly related as shown in Eq. 14-8 and determine the delay in nanoseconds-per-foot (ns/ft).

\[
Dn = \frac{100}{V_p} = \sqrt{DC}
\]  

(14-8)

While these equations will give you a reasonable approximate value, the actual equations should be

\[
Delay = \frac{101.67164}{V_p} = 1.0167164\sqrt{DC}.
\]  

(14-9)

Delay becomes a factor in broadcasting when multiple cables carry a single signal. This commonly occurs in RGB or other component video delivery systems. Delay also appears in high-data rate UTP, such
a 1000Base-T (1GBase-T) and beyond where data is split between the four pairs and combined at the destination device.

Where signals are split up and recombined, the different cables supplying the components will each have a measurable delay. The trick is for all the component cables to have the same delay to deliver their portions at the same time. The de facto maximum timing variation in delay for RGB analog is delivery of all components within 40 ns. Measuring and adjusting cable delivery is often called timing. By coincidence, the maximum delay difference in the data world is 45 ns, amazingly close. In the data world, this is called skew or delay skew, where delivery does not line up.

In the RGB world, where separate coax cables are used, they have to be cut to the same electrical length. This is not necessarily the same physical length. Most often, the individual cables are compared by a Vector-scope, which can show the relationship between components, or a TDR (time domain reflectometer) that can establish the electrical length (delay) of any cable.

Any difference in physical versus electrical length can be accounted for by the velocity of propagation of the individual coaxes, and therefore, the consistency of manufacture. If the manufacturing consistency is excellent, then the velocity of all coaxes would be the same, and the physical length would be the same as the electrical length. Where cables are purchased with different color jackets, to easily identify the components, they are obviously made at different times in the factory. It is then a real test of quality and consistency to see how close the electrical length matches the physical length.

Where cables are bundled together, the installer then has a much more difficult time in reducing any timing errors. Certainly in UTP data cables, there is no way to adjust the length of any particular pair. In all these bundled cables, the installer must cut and connectorize.

This becomes a consideration when four-pair UTP data cables (category cables) are used to deliver RGB, VGA, and other nondata component delivery systems. The distance possible on these cables is therefore based on the attenuation of the cables at the frequency of operation, and on the delay skew of the pairs. Therefore, the manufacturers measurement and guarantee (if any) of delay skew should be sought if nondata component delivery is the intended application.

### 14.23 Attenuation

All cable has attenuation and the attenuation varies with frequency. Attenuation can be found with the equation

\[ A = 4.35 \frac{R_t}{Z_o} + 2.78 \rho f \sqrt{\varepsilon} \]  

where,

- \( A \) is the attenuation in dB/100 ft,
- \( R_t \) is the total dc line resistance in \( \Omega/100 \) ft,
- \( \varepsilon \) is the dielectric constant of the transmission line insulation,
- \( \rho \) is the power factor of the dielectric medium,
- \( f \) is the frequency,
- \( Z_o \) is the impedance of the cable.

Table 14-29 gives the attenuation for various 50 \( \Omega \), 52 \( \Omega \), and 75 \( \Omega \) cables. The difference in attenuation is due to either the dielectric of the cable or center-conductor diameter.

### 14.24 Characteristic Impedance

The characteristic impedance of a cable is the measured impedance of a cable of infinite length. This impedance is an ac measurement, and cannot be measured with an ohmmeter. It is frequency-dependent, as can be seen in Fig. 14-19. This shows the impedance of a coaxial cable from 10 Hz to 100 MHz.

At low frequencies, where resistance is a major factor, the impedance is changing from a high value (approximately 4000 \( \Omega \) at 10 Hz) down to a lower impedance. This is due to skin effect (see Section 14.2.8), where the signal is moving from the whole conductor at low frequencies to just the skin at high frequencies. Therefore, when only the skin is carrying the signal, the resistance of the conductor is of no importance. This can be clearly seen in the equations for impedance, Eq. 14-13, for low frequencies, shows \( R \), the resistance, as a major component. For high frequencies, Eq. 14-14, there is no \( R \), no resistance, even in the equation.

Once we enter that high-frequency area where resistance has no effect, around 100 kHz as shown in Fig. 14-19, we enter the area where the impedance will not change. This area is called the characteristic impedance of the cable.

The characteristic impedance of an infinitely long cable does not change if the far end is open or shorted. Of course, it would be impossible to test this as it is impossible to short something at infinity. It is important to terminate coaxial cable with its rated impedance or a portion of the signal can reflect back to the input, reducing the efficiency of the transmission. Reflections can be caused by an improper load, using a wrong connector—i.e., using a 50 \( \Omega \) video BNC connector at
Transmission Techniques: Wire and Cable

High frequencies rather than a 75 \( \Omega \) connector—a flattened cable, or too tight a bend radius, which changes the spacing between the conductors. Anything that affects the dimensions of the cable, will affect the impedance and create reflective losses. It would just be a question of how much reflection is caused. Reflections thus caused are termed return loss.

The characteristic impedance of common coaxial cable can be between 30 \( \Omega \) and 200 \( \Omega \). The most common values are 50 \( \Omega \) and 75 \( \Omega \). The characteristic \( Z_0 \) is the average impedance of the cable equal to

\[
Z_0 = \frac{138 \log D}{\sqrt{\varepsilon}} \quad (14-11)
\]

where,
\( \varepsilon \) is the dielectric constant,
\( D \) is the diameter of the inner surface of the outer coaxial conductor (shield) in inches,
\( d \) is the diameter of the center conductor in inches.

The true characteristic impedance, at any frequency, of a coaxial cable is found with the equation

\[
Z_0 = \sqrt{\frac{R + j2\pi fL}{G + j2\pi fC}} \quad (14-12)
\]

where,
\( R \) is the series resistance of the conductor in ohms per unit length,
\( f \) is the frequency in hertz,
\( L \) is the inductance in henrys,
\( G \) is the shunt conductance in mhos per unit length,
\( C \) is the capacitance in farads.

At low frequencies, generally below 100 kHz, the equation for coaxial cable simplifies to

\[
Z_0 = \sqrt{\frac{R}{j2\pi fC}} \quad (14-13)
\]

At high frequencies, generally above 100 kHz, the equation for coaxial cable simplifies to

\[
Z_0 = \sqrt{\frac{L}{\sqrt{\varepsilon}}} \quad (14-14)
\]

### 14.25 Characteristic Impedance

The characteristic impedance of a transmission line is equal to the impedance that must be used to terminate the line in order to make the input impedance equal to the terminating impedance. For a line that is longer than a quarter-wavelength at the frequency of operation, the input impedance will equal the characteristic impedance of the line, irrespective of the terminating impedance.
This means that low-frequency applications often have quarter-wavelength distance way beyond common practical applications. Table 14-30 shows common signals, with the wavelength of that signal and the quarter-wavelength. To be accurate, given a specific cable type, these numbers would be multiplied by the velocity of propagation.

The question is very simple: will you be going as far as the quarter-wavelength, or farther? If so, then the characteristic impedance becomes important. As that distance gets shorter and shorter, this distance becomes critical. With smaller distances, patch cords, patch panels, and eventually the connectors themselves become just as critical as the cable. The impedance of these parts, especially when measured over the desired bandwidth, becomes a serious question. To be truly accurate, the quarter-wavelength numbers in Table 14-28 need to be multiplied by the velocity of propagation of each cable. So, in fact, the distances would be even shorter than what is shown.

</tbody>
</table>

It is quite possible that a cable can work fine with lower-bandwidth applications and fail when used for higher-frequency applications. The characteristic impedance will also depend on the parameters of the pair or coax cable at the applied frequency. The resistive component of the characteristic impedance is generally high at the low frequencies as compared to the reactive component, falling off with an increase of frequency, as shown in Fig. 14-19. The reactive component is high at the low frequencies and falls off as the frequency is increased.

The impedance of a uniform line is the impedance obtained for a long line (of infinite length). It is apparent, for a long line, the current in the line is little affected by the value of the terminating impedance at the far end of the line. If the line has an attenuation of 20 dB and the far end is short circuited, the characteristic impedance as measured at the sending end will not be affected by more than 2%.

14.26 Twisted-Pair Impedance

For shielded and unshielded twisted pairs, the characteristic impedance is

$$Z_0 = \frac{101670}{C(V_p)} \quad (14-15)$$

where,

- $Z_0$ is the average impedance of the line,
- $C$ is found with Eqs. 14-16 and 14-17,
- $V_p$ is the velocity of propagation.

For unsheilded pairs

$$C = \frac{3.68\varepsilon}{\log \left[ \frac{2(ODi)}{DC(Fs)} \right]} \quad (14-16)$$

For sheilded pairs

$$C = \frac{3.68\varepsilon}{\log \left[ \frac{1.06(ODi)}{DC(Fs)} \right]} \quad (14-17)$$

where,

- $\varepsilon$ is the dielectric constant,
- $ODi$ is the outside diameter of the insulation,
- $DC$ is the conductor diameter,
- $Fs$ is the conductor stranding factor (solid = 1, 7 strand = 0.939, 19 strand = 0.97).

The impedance for higher-frequency twisted-pair data cables is

$$Z_0 = 276\left(\frac{V_p}{100}\right) \times \log \left[ 2\left(\frac{h}{DC \times Fs} \right) \times \frac{1 - \frac{h}{DC + Fb}}{1 + \frac{h}{DC + Fb}} \right] \quad (14-18)$$
where,
\( h \) is the center to center conductor spacing,
\( F_b \) is very near 0. Neglecting \( F_b \) will not introduce appreciable error.

### 14.26.1 Transmission Line Termination

All lines do not need to be terminated. Knowing when to terminate a transmission line is a function of the frequency/wavelength of the signal and the length of the transmission line. Table 14-30 can be guideline, especially where the signal is long compared to the length of the line. If the wavelength of the signal is small compared to the transmission-line length, for instance a 4.5 GHz signal, a terminator is required to prevent the signal from reflecting back toward the source and interfering with forward traveling signals. In this case the line must be terminated for any line longer than a quarter of a wavelength.

Transmission-line termination is accomplished using parallel or series termination. Parallel termination connects a resistor between the transmission line and ground at the receiving end of the transmission line while series termination connects a resistor in series with the signal path near the beginning of the transmission line, Fig. 14-20.

Transmission-line termination is accomplished using parallel or series termination. Parallel termination connects a resistor between the transmission line and ground at the receiving end of the transmission line while series termination connects a resistor in series with the signal path near the beginning of the transmission line, Fig. 14-20.

Figure 14-20. Basic termination of transmission lines.

Resistive termination requires a resistor value that matches the characteristic impedance of the transmission line, most commonly a 50 \( \Omega \) or 75 \( \Omega \) characteristic impedance. The termination resistance is matched to the transmission line characteristic impedance so the electrical energy in the signal does not reflect back from the receiving end of the line to the source. If the resistor is perfectly matched to the characteristic impedance, at all frequencies within the desired bandwidth, all of the energy in the signal dissipates as heat in the termination resistor so no signal reflects backwards down the line to the source causing cancellations.

### 14.27 Loudspeaker Cable

Much has been said about wire for connecting loudspeakers to amplifiers. Impedance, inductance, capacitance, resistance, loading, matching, surface effects, etc. are constantly discussed.

Most home and studio loudspeaker runs are short (less than 50 ft, or 15 m) and therefore do not constitute a transmission line. When runs are longer, it is common to connect the loudspeakers as a 70 V, or 100 V system to reduce line loss caused by the wire resistance so the power lost in the line does not appreciably effect the power delivered to the loudspeaker. For instance, if a 4 \( \Omega \) loudspeaker is connected to an amplifier with a cable which measures 4 \( \Omega \) resistance, 50% of the power will be dissipated in the cable. If the loudspeaker was connected to a 70 V system, and the loudspeaker was taking 50 W from the amplifier, the loudspeaker/transformer impedance would be 100 \( \Omega \); therefore, the 4 \( \Omega \) line resistance would dissipate 4% of the power.

When using a 70.7 V loudspeaker system, the choice of wire size for loudspeaker lines is determined by an economic balance of the cost of copper against the cost of power lost in the line. Power taken from the amplifier is calculated from the equation

\[
P = \frac{V^2}{Z}
\]

where,
\( P \) is the power delivered by the amplifier,
\( V \) is the voltage delivered by the amplifier,
\( Z \) is the impedance of the load.

For a 70 V system

\[
P = \frac{5000}{Z}
\]

If the voltage is 70.7 V and the load is 50 \( \Omega \), the power would be 100 W. However, if the amplifier was connected to a 50 \( \Omega \) load with 1000 ft of #16 wire (2000 ft round trip) or 8 \( \Omega \) of wire resistance the power from the amplifier would be

\[
P = \frac{5000}{50 \Omega + 8 \Omega} = 86.2 \text{ W}
\]
The current through the system is found with

\[ I = \frac{\sqrt{P}}{\sqrt{R}} \]  

(14-21)

or in this case

\[ I = \frac{\sqrt{86.2}}{\sqrt{58}} \]

\[ = \frac{86.2}{\sqrt{58}} \]

\[ = 1.21 \text{ A} \]

The power to the 50 Ω load would be found with

\[ P = I^2 R \]  

(14-22)

or in this case

\[ P = (1.21)^2 R \]

\[ = 74.3 \text{ W} \]

or 26% less power than assumed.

Only 11.7 W are lost to the line, the other 14 W cannot be taken from the amplifier because of the impedance mismatch. While high-power amplifiers are relatively inexpensive, it is still practical to use heavy enough wire so the amplifier can output almost its full power to the loudspeakers. Table 14-31 shows the characteristics of various cables which could be used for loudspeaker wire and Table 14-32 is a cable selection guide for loudspeaker cable.

The following explains how to use Table 14-29:

1. Select the appropriate speaker impedance column.
2. Select the appropriate power loss column deemed to be acceptable.
3. Select the applicable wire gauge size and follow the row over to the columns determined in steps one and two. The number listed is the maximum cable run length.
4. The maximum run for 12 AWG in a 4 Ω loudspeaker system with 11% or 0.5 dB loss is 140 ft.
14.27.1 Damping Factor

The damping factor of an amplifier is the ratio of the load impedance (loudspeaker plus wire resistance) to the amplifier internal output impedance. The damping factor of the amplifier acts as a short circuit to the loudspeaker, controlling the overshoot of the loudspeaker. Present day amplifiers have an output impedance of less than 0.05 \( \Omega \) which translates to a damping factor over 150 at 10 kHz, for instance, so they effectively dampen the loudspeaker as long as the loudspeaker is connected directly to the amplifier. Damping factor is an important consideration when installing home systems, studios, or any system where high-quality sound, especially at the low frequencies, is desired. As soon as wire resistance is added to the circuit, the damping factor reduces dramatically, reducing its affect on the loudspeaker. For instance, if a #16 AWG 50 ft loudspeaker cable (100 ft round trip) is used, the wire resistance would be 0.4 \( \Omega \) making the damping factor only 18, considerably less than anticipated.

It is not too important to worry about the effect the damping factor of the amplifier has on the loudspeakers in a 70 V system as the 70 V loudspeaker transformers wipe out the effects of the wire resistance.

Consider the line as a lump sum, Fig. 14-21. The impedance of the line varies with wire size and type. Table 14-33 gives typical values of \( R, C, \) and \( L \) for 33 ft (10 m) long cables. Note, the impedance at 20 kHz is low for all but the smallest wire and the \(-3\) dB upper frequency is well above the audio range. The worst condition is with a capacitive load. For instance, with a 4 \( \mu\)F load, resonance occurs around 35 kHz.

The results of the above are as follows:

1. Make the amplifier to loudspeaker runs as short as possible.
2. Use a wire gage that represents less than 5% of the loudspeaker impedance at any frequency.
3. Use twisted pairs on balanced 70 or 100 V distributed systems to reduce crosstalk (amplifier output is often fed back into the amplifier as negative feedback).
4. Use good connectors to reduce resistance.

Table 14-34 gives the length of cable run you can have for various loudspeaker impedances.

14.27.2 Crosstalk

When a plurality of lines, carrying different programs or signals, are run together in the same conduit, or where multiple pairs or multiple coax cables are bundled, they tend to induce crosstalk currents into each other. Crosstalk is induced by two methods:

1. Electromagnetically through unbalanced coupling between one circuit and others.
2. Electrostatically through unbalanced capacitance to other circuits, or to the conduit if it carries current. This develops a voltage difference between one circuit and the others, or to its own or other shields carrying current.

If the line is less than a quarter-wavelength at the frequency of operation, then the cable does not have to have a specific impedance, or be terminated in a specific impedance. The terminating impedance could then be small compared to the open line characteristic impedance. The net coupling with unshielded pairs would then be predominantly magnetic. If the terminating impedance is much larger than the characteristic impedance of the wires, the net coupling will be predominantly electric.

Two wires of a pair must be twisted; this insures close spacing and aids in canceling pickup by transposition. In the measurements in Fig. 14-22, all pickup was

capacitive because the twisting of the leads effectively eliminated inductive coupling.

One application that is often ignored regarding crosstalk is speaker wiring, especially 70 V distributed loudspeaker wiring. You will note in the first drawing that the two wires are not a balanced line. One is hot the other is ground. Therefore, that pair would radiate some of the audio into the adjoining pair, also unbalanced. Twisting the pairs in this application would do little to reduce crosstalk.

The test was made on a 250 ft twisted pair run in the same conduit with a similar twisted pair, the latter carrying signals at 70.7 V. Measurements made for half this length produced half the voltages, therefore the results at 500 ft and 1000 ft were interpolated.

The disturbing line was driven from the 70 V terminals of a 40 W amplifier and the line was loaded at the far end with 125 Ω, thus transmitting 40 W. The crosstalk figures are for 1 kHz. The voltages at 100 Hz and 10 kHz are one-tenth and ten times these figures, respectively.

There are two ways to effectively reduce crosstalk. One is to run signals only on balanced-line twisted pairs. Even shielding has a small added advantage compared to the noise and crosstalk rejection of a balanced line. The second way to reduce crosstalk is to move the two cables apart. The inverse-square law tells us that doubling the distance will produce four times less interference. Further, if cables cross at right angles, this is the point where the magnetic fields have minimum interaction. Of course, the latter solution is not an option in a prebundled cable, or in cable trays or installations with multiple cables run from point to point.

14.28 National Electrical Code

The National Electrical Code (NEC) is a set of guidelines written to govern the installation of wiring and equipment in commercial buildings and residential areas. These guidelines were developed to insure the safety of humans as well as property against fires and electrical hazards. Anyone involved in specifying cable for installation should be aware of the basics of the code.

The NEC code book is made up of nine chapters, with each chapter divided into separate articles pertaining to specific subjects. Five articles pertain to communication and power-limited cable. The NEC book is written by and available from the NFPA (National Fire Protection Association), 11 Tracy Drive, Avon, MA 02322. They can be reached at 1-800-344-3555 or www.nfpa.org.

**Article 725—Class 1, Class 2, Class 3, Remote-Control, Signaling, and Power-Limited Circuits.**

Article 725 covers Class 1, Class 2, and Class 3 remote control and signaling cables as well as power-limited tray cable. Power-limited tray cable can be used as a Class 2 or Class 3 cable. Cable listed multipurpose, communications, or power-limited fire protective can be used for Class 2 and Class 3 applications. A Class 3 listed cable can be used as a Class 2 cable.

**Article 760—Fire Protective Signaling Systems.** Article 760 covers power-limited fire-protective cable. Cable listed as power-limited fire-protective cable can also be used as Class 2 and Class 3 cable. Cable listed as communications and Class 3 can be used as power-limited fire protective cable with restrictions to conductor material and type gage size and number of conductors.

Article 770—Fiber Optic Systems. Article 770 covers three general types of fiber optic cable: nonconductive, conductive, and composite. Nonconductive type refers to cable containing no metallic members and no other electrically conductive materials. Conductive type refers to cable containing noncurrent carrying conductive members such as metallic strength members, etc. Composite type refers to cable containing optical fibers and current carrying electrical conductors. Composite types are classified according to the type of electrical circuit that the metallic conductor is designed for.

Article 800—Communication Circuits. Article 800 covers multipurpose and communication cable. Multipurpose cable is the highest listing for a cable and can be used for communication, Class 2, Class 3, and power-limited fire-protective cable. Communication cable can be used for Class 2 and Class 3 cable and also as a power-limited fire protective cable with restrictions.

Article 820—Community Antenna Television. Article 820 covers community antenna television and RF cable. CATV cable may be substituted with multipurpose or communication listed coaxial cable.

14.28.1 Designation and Environmental Areas

The NEC has designated four categories of cable for various environments and they are listed from the highest to the lowest listing. A higher listing can be used as a substitute for a lower listing.

Plenum—Suitable for use in air ducts, plenums, and other spaces used for environmental air without conduit and has adequate fire-resistant and low-smoke produc-
ing characteristics. It can also be substituted for all applications below.

**Riser**—Suitable for use in a vertical run, in a shaft, or from floor to floor, and has fire-resistant characteristics capable of preventing the spread of fire from floor to floor. It can also be substituted for all applications below.

**General Purpose**—Suitable for general-purpose use, with the exception of risers, ducts, plenums, and other space used for environmental air, and is resistant to the spread of fire. It can be substituted for the applications below.

**Restricted Applications**—Limited use and suitable for use in dwellings and in raceways and is flame retardant. Restricted use is limited to nonconcealed spaces of 10 ft or less, fully enclosed in conduit or raceway, or cable with diameters less than 0.25 inches for a residential dwelling.

### 14.28.2 Cable Types

Signal cable used for audio, telephone, video, control applications, and computer networks of less than 50 V is considered low-voltage cabling and is grouped into five basic categories by the NEC, Table 14-35.

**Table 14-35. The Five Basic NEC Cable Groups**

<table>

</tbody>
</table>

All computer network and telecommunications cabling falls into the CM class. The A/V industry primarily uses CM and CL2 cabling.

Table 14-36 defines the cable markings for various applications. Note plenum rated cable is the highest level because it has the lowest fire load which means it does not readily support fire.

### 14.28.3 NEC Substitution Chart

NEC cable hierarchy, Fig. 14-23 defines which cables can replace other cables. The chart starts with the highest listed cable on the top and descends to the lowest listed cable on the bottom. Following the arrows defines which cable can be substituted for others. Fig. 14-24 defines the Canadian Electrical Code (CEC) substitution chart.

### 14.28.4 Final Considerations

The National Electrical Code is widely accepted as the suggested regulations governing the proper installation of wire and cable in the United States. The code is revised every three years to keep safety in the forefront in wire and cable manufacturing and installation. Even though the code is generally accepted, each state, county, city, and municipality has the option to adopt all of the code, part of the code, or develop one of its own. The local inspectors have final authority of the installation. Therefore, the NEC is a good reference when questions arise about the proper techniques for a particular installation, but local authorities should be contacted for verification.

When choosing cable for an installation, follow these three guidelines to keep problems to a minimum:

1. The application and environment determine which type of cable to use and what rating it should have. Make sure the cable meets the proper ratings for the application.
2. If substituting a cable with another, the cable must be one that is rated the same or higher than what the code calls for. Check with the local inspector as to what is allowed in the local area.
3. The NEC code is a general guideline that can be adopted in whole or in part. Local state, county, city, or municipal approved code is what must be followed. Contact local authorities for verification of the code in the area.

The local inspector or fire marshal has the final authority to approve or disapprove any installation of cable based on the National Electric Code or on the local code.
Plenum cable is used in ceilings where the air handling system uses the plenum as the delivery or the return air duct. Because of its flame-resistant and low smoke-emission properties, the special compound used in plenum cable jackets and insulations has been accepted under the provisions of the NEC and classified by Underwriters Laboratories Inc. (UL) for use without conduit in air plenums.

In a typical modern commercial building, cables are installed in the enclosed space between drop ceilings and the floors from which they are suspended. This area is also frequently used as a return air plenum for a building’s heating and cooling system. Because these air ducts often run across an entire story unobstructed,
they can be an invitation to disaster if fire breaks out. Heat, flames, and smoke can spread rapidly throughout the air duct system and building if the fire is able to feed on combustible materials (such as cable insulations) in the plenum. To eliminate this problem and to keep fumes from entering the air handling system, the NEC requires that conventional cables always be installed in metal conduit when used in plenums.

Plenums, with their draft and openness between different areas, cause fire and smoke to spread, so the 1975 NEC prohibited the use of electrical cables in plenums and ducts unless cables were installed in metal conduit. In 1978, Sections 725-2(b) (signaling cables), 760-4(d) (fire-protection cable), and 800-3(d) (communication/telephone cables) of the NEC allowed that cables “listed as having adequate fire-resistance and low-smoke producing characteristics shall be permitted for ducts, hollow spaces used as ducts, and plenums other than those described in Section 300-22(a).”

While plenum cable costs more than conventional cable, the overall installed cost is dramatically lower because it eliminates the added cost of conduit along with the increased time and labor required to install it.

In 1981 the jacket and insulation compound used in plenum cables was tested and found acceptable under the terms of the NEC and was classified by UL for use without conduit in air return ducts and plenums. Fig. 14-25 shows the UL standard 910 plenum flame test using a modified Steiner tunnel equipped with a special rack to hold test cables.

Virtually any cable can be made in a plenum version. The practical limit is the amount of flammable material in the cable and its ability to pass the Steiner Tunnel Test, shown in Fig. 14-25. Originally plenum cable was all Teflon inside and out. Today most plenum cables have a Teflon core with a special PVC jacket which meets the fire rating. But there are a number of compounds such as Halar® and Solef® that can also be used.

### 14.2.8.6 Power Distribution Safety

Electricity kills! No matter how confident we are we must always be careful around electricity. Fibrillation is a nasty and relatively slow death so it is important that Defibrillators are accessible when working around electricity. Table 14-37 displays the small amounts of current that is required to hurt or kill a person.

#### 14.2.8.6.1 Ground-Fault Interrupters

Ground-fault circuit interrupters (GFCIs) are sometimes called earth leakage or residual-current circuit breakers. GFCIs sense leakage current to earth ground from the hot or neutral leg and interrupt the circuit automatically within 25 ms if the current exceeds 4 to 6 ma. These values are determined to be the maximum safe levels before a human heart goes into ventricular fibrillation. GFCIs do not work when current passes from one line to the other line through a person, for instance. They do not work as a circuit breaker.

One type of GFCI is the core-balance protection device, Fig. 14-26. The hot and neutral power conduc-
tors pass through a toroidal (differential) current transformer. When everything is operating properly, the vector sum of the currents is zero. When the currents in the two legs are not equal, the toroidal transformer detects it, amplifies it, and trips an electromagnetic relay. The circuit can also be tested by depressing a test button which unbalances the circuit.

</table>

**14.28.7 AC Power Cords and Receptacles**

Ac power cords, like other cables come with a variety of jacket materials for use in various environments. All equipment should be connected with three-wire cords. Never use ground-lift adapters to remove the ground from any equipment. This can be dangerous, even fatal, if a fault develops inside the equipment, and there is no path to ground.

A common European plug, with a rating of 250 Vac and 10 A, is shown in Fig. 14-27.

The color codes used in North America and Europe for three conductors are shown in Table 14-38.

Cables should be approved to a standards shown in Table 14-39.

The UL listing signifies that all elements of the cords and assembly methods have been approved by the Underwriters Laboratories, Inc. as meeting their appli-
cable construction and performance standards. UL listed has become a symbol of safety to millions of Americans and their confidence in it results in easier sales of electrical products.

The U.S. NEMA configurations for various voltage and current general purpose plugs and receptacles are shown in Fig. 14-28.

### 14.28.8 Shielded Power Cable

Shielding the power cord is an effective means of minimizing the error-generating effects of ambient electrical interference. However, the shield effectiveness of most constructions is mostly medium to high-frequency. For instance, braid shields, even high-density high-coverage braids, have little effectiveness below 1000 Hz. So, if the intent is to shield the 50/60 Hz from adjacent cables or equipment, buying a shielded power cord will not be effective. In that case, steel conduit is recommended. But even solid steel conduit, perfectly installed, only has an effectiveness of approximately 30 dB at 50/60 Hz.

The standard power cable shielding consists of aluminum polyester film providing 100% shield coverage and radiation reduction. A spiral-wound drain wire provides termination to ground. These shields are highly effective at high frequencies, generally above...
10 MHz. Power cords used in applications involving extremely high EMI and RFI environments require shield constructions such as Belden Z-Fold™ foil providing 100% coverage, plus another layer of tinned copper braid of 85% coverage, or greater. This provides the maximum shielding available in a flexible power cord.

Shield effectiveness is an important benefit where interference-sensitive electronic devices, such as computer and laboratory test equipment are concerned. However, any designer or installer should realize that the ultimate protection between power cable and other cables or equipment is distance. The inverse square law clearly states that double the distance results in four times less interference. Double that distance is sixteen times less, etc.

### 14.28.9 International Power

Table 14-40 gives the current characteristics for various countries. These are for the majority of the cities in each country, however some countries have different currents in different cities or areas.

15.1 History

Fiber optics is the branch of optical technology concerned with the transmission of light through fibers made of transparent materials, such as glass, fused silica, or plastic, to carry information.

Fiber optics has been used by the telephone industry for over thirty years, and has proved itself as being the transmission medium for communications. Past history shows audio follows the telephone industry, therefore fiber optics will soon be a force in audio.

The founder of fiber optics was probably the British physicist, John Tyndall. In 1870 Tyndall performed an experiment before the Royal Society that showed light could be bent around a corner as it traveled in a rush of pouring water. Tyndall aimed a beam of light through the spout along with the water and his audience saw the light follow a zigzag path inside the curved path of the water. His experiment utilized the principle of total internal reflection, which is also applied in today’s optical fibers.

About ten years later, William Wheeler, an engineer from Concord, Massachusetts invented a scheme for piping light through buildings. He used a set of pipes with a reflective lining and diffusing optics to transmit light (bright electric arc) through a building, then diffuse it into other rooms. Although Wheeler’s light pipes probably didn’t reflect enough light to illuminate the rooms, his idea kept coming up again and again until it finally coalesced into the optical fiber.

At about the same time Alexander Graham Bell invented the photophone, Fig. 15-1. Bell demonstrated that a light ray could carry speech through the air. This was accomplished by a series of mirrors and lenses directing light onto a flat mirror attached to a mouthpiece. Speech vibrating the mirror caused the light to modulate. The receiver included a selenium diode detector whose resistance varied with the intensity of light striking it. Thus the modulated light (sunlight, etc.) striking the selenium detector varied the amount of current through the receiver and reproduced speech that could be transmitted over distances of approximately 200 meters.

In 1934, an American, Norman R. French, while working with AT&T, received a patent for his optical telephone system. French’s patent described how speech signals could be transmitted via an optical cable network. Cables were to be made out of solid glass rods or a similar material with a low attenuation coefficient at the operating wavelength.

Interest in glass waveguides increased in the 1950s, when research turned to glass rods for unmodulated transmission of images. One result was the invention of the fiber scope, widely used in the medical field for viewing the internal parts of the body. In 1956 Brian O’Brien, Sr., in the United States, and Harry Hopkins and Narinder Kapany, in England, found the way to guide light. The key concept was making a two-layer fiber. One layer was called the core the other layer was called the cladding (see section on light). Kapany then coined the term fiber optics.

An efficient light source was needed but it wasn’t until 1960 when the first laser light was invented that it became available. A Nobel Prize was awarded to Arthur Schawlow and Charles H. Townes of Bell Laboratories for developing the laser, which was first successfully operated by Theodor H. Maiman of Hughes Research Laboratory. The manufacturing process of lasers from semiconductor material was recognized in 1962. At the same time semiconductor photodiodes were developed for receiver elements. Now the only thing left was to find a suitable transmission medium.

Then in 1966 Charles H. Kao and George A. Hockham, of Standard Telecommunication Labs, England, published a paper proposing that optical fibers could be used as a transmission medium if their losses could be reduced to 20 dB/km. They knew that high losses of over 1000 dB/km were the result of impurities in the glass, not of the glass itself. By reducing these impurities a low-loss fiber could be produced for telecommunications.

Finally in 1970, Robert Maurer and associates at Corning Glass Works, New York, developed the first fiber with losses under 20 dB/km, and by 1972 lab samples were revealed as low as 4 dB/km. Since then the Corning Glass Works and Bell Telephone Labs of the United States; Nippon Sheet Glass Company and Nippon Electric Company of Japan; and at AEG-Telefunken, Siemens and Halske in Germany, have developed glass fibers with losses at about 0.2 dB/km. There is also some plastic materials as well as glass being used for shorter distances.
The practical use of fiber optics for communications began in the mid- and late 1970s with test trials. However, the popularization of fiber optics wasn’t until the 1980 Winter Olympics at Lake Placid, New York, when the joint effort of New York Telephone, AT&T, Western Electric, and Bell Labs installed a fiber optic system. Its purpose was to transform the Lake Placid telephone facility into a professional communications center capable of handling a wide range of telecommunications services necessary to support the Olympic events. Today fiber optics is an established technology.

### 15.2 Advantages of Using Fiber Optics for Audio

There are at least four advantages in using fiber over hardwired systems. One is the superb performance in transmission, allowing extremely large bandwidths and low loss which minimizes the need for preamplifying a signal for long haul applications. Digital data can be easily transmitted with rates of 100 Mb/s or higher showing more information handling capability and greater efficiency. Since the optical fiber is nonmetallic (made of glass, plastic, etc.), it is immune to problems caused by electromagnetic interference (EMI) and radio frequency interference (RFI). Also the problem of crosstalk is eliminated—a quality advantage.

With optical fiber one no longer needs to worry about impedance matching, electrical grounding or shorting problems, or no ground loops. Safety is an important feature of fiber optics because a broken cable will not spark, possibly causing shock or an explosion in a dangerous environment.

Another plus is fiber optic cable weighs about 9 lbs/1000 ft and takes up less space than wire, useful especially when running in conduits. Cost is now less than or comparable to copper. And finally an optical fiber system cannot be easily tapped, which allows for better security.

#### 15.2.1 Applications for Audio

Telephone companies have many fiber links which can connect Japan and Europe to the United States. Think of the many possibilities of doing a multitrack recording from many different places all over the world over a fiber optic cable without worrying about SNR, interference, distortion, etc. Top-of-the-line compact disc and DAT players already provide an optical fiber link output. Also, there are companies like Klotz Digital of Germany and Wadia Digital Corporation of the United States who are manufacturing fiber optic digital audio links, which employ an AES/EBU input and output at each end.

Many recording studios are located in high rise apartment buildings. A perfect application of a digital audio fiber optic link is to connect, for instance, studio A which is located on the 21st floor, to studio B which is located on the 24th floor. This is ideal because the user doesn’t have to worry about noise and interference caused by fluorescent lighting and elevator motors, to name a few. Another perfect use is to connect MIDI stations together.

Another recent advance is a recording studio can record in real time by using DWDM (dense wavelength division multiplexing) lasers and erbium doped optical fibers to send the AES3 audio channels over the Atlantic or Pacific Ocean and then to the appropriate recording studio. The Internet is also being used to establish a fiber optic end-to-end recording session.

### 15.3 Physics of Light

Before discussing optical fiber, we must understand the physics on light.

**Light.** Light is electromagnetic energy, as are radio waves, x-rays, television, radar, and electronic digital pulses. The frequencies of light used in fiber optic data transmission are around 200 THz–400 THz (400 × 10^12), several orders of magnitude higher on the electromagnetic energy spectrum than the highest radio waves, see Fig. 15-2. Wavelength, a more common way of describing light waves, are correspondingly shorter than radio wavelengths. Visible light, with wavelengths from about 400 nm for deep violet to 750 nm for deep red, is only a small portion of the light spectrum. While fiber optic data transmission sometimes uses visible light in the 600 nm to 700 nm range, the near infrared region extending from 750 nm to 1550 nm is of greater interest because fibers propagate the light of these wavelengths more efficiently.

The main distinction between different waves lies in their frequency or wavelength. Frequency, of course, defines the number of sine-wave cycles per second and is expressed in hertz (Hz). Wavelength is the distance between the same points on two consecutive waves (or it is the distance a wave travels in a single cycle). Wavelength and frequency are related. The wavelength (\( \lambda \)) equals

\[
\lambda = \frac{v}{f} \quad \text{(15-1)}
\]
The velocity of electromagnetic energy in free space is generally called the speed of light, \(186,000 \text{ mi/s} \) \([300,000 \text{ km/s}]\). The equation clearly shows that the higher the frequency, the shorter the wavelength.

Light travels slower in other media than a vacuum, and different wavelengths travel at different speeds in the same medium. When light passes from one medium to another, it changes speed, causing a deflection of light called refraction. A prism demonstrates this principle. White light entering a prism is composed of all colors which the prism refracts. Because each wavelength changes speed differently, each is refracted differently, therefore the light emerges from the prism divided into the colors of the visible spectrum, as shown in Fig.15-3.

![Figure 15-3. Light prism.](image)

**The Particle of Light.** Light and electrons both exhibit wave- and particlelike traits. Albert Einstein theorized that light could interact with electrons so that the light itself might be considered as bundles of energy or quanta (singular, quantum). This helped explain the photoelectric effect.

In this concept, light rays are considered to be particles that have a zero rest mass called photons.

The energy contained in a photon depends on the frequency of the light and is expressed in Planck’s Law, as

\[ E = hf \]  

(15-2)

where,

- \( E \) is the energy in watts,
- \( h \) is Planck’s constant, equal to \( 6.624 \times 10^{-34} \) joule-second,
- \( f \) is its frequency.

As can be seen from this equation, light energy is directly related to frequency (or wavelength). As the frequency increases, so does the energy, and vice versa. Photon energy is proportional to frequency. Because most of the interest in photon energy is in the part of the spectrum measured in wavelength, a more useful equation which gives energy in electron volts when wavelength is measured in micrometers (\(\mu m\)) is

\[ E \text{ in } eV = \frac{1.2406}{\lambda \text{ in } \mu m}. \]

(15-3)

Treating light as both a wave and a particle aids investigation of fiber optics. We switch back and forth.
between the two descriptions, depending on our needs. For example the characteristics of many optical fibers vary with wavelength, so the wave description is used. On the other hand, the emission of a light by a source, a light emitting diode (LED), or its absorption by a positive-intrinsic-negative detector (PIN), is best treated by particle theory.

**Light Rays.** The easiest way to view light in fiber optics is by using light ray theory, where the light is treated as a simple ray drawn by a line. The direction of propagation is shown on the line by an arrow. The movement of light through the fiber optic system can be analyzed with simple geometry. This approach simplifies the analysis and makes the operation of an optical fiber simple to understand.

**Refraction and Reflection.** The index of refraction \( n \) is a dimensionless number expressing the ratio of the velocity of light in free space \( c \) to its velocity in a specific medium \( v \)

\[
 n = \frac{c}{v} \tag{15-4}
\]

The following are typical indices of refraction:

- Vacuum: 1.0
- Air: 1.0003 (generalized to 1)
- Water: 1.33
- Fused Quartz: 1.46
- Glass: 1.5
- Diamond: 2.0
- Gallium Arsenide: 3.35
- Silicon: 3.5
- Aluminum Gallium Arsenide: 3.6
- Germanium: 4.0

Although the index of refraction is affected by light wavelength, the influence of wavelength is small enough to be ignored in determining the refractive indices of optical fibers.

Refraction of a ray of light as it passes from one material to another depends on the refractive index of each material. In discussing refraction, three terms are important. The normal is an imaginary line perpendicular to the interface of the two materials. The angle of incidence is the angle between the incident ray and the normal. The angle of refraction is the angle between the normal and the refracted ray.

When light passes from one medium to another that has a higher refractive index, the light is refracted toward the normal as shown in Fig. 15-4A. When the index of the first material is higher than that of the second, most of the light is refracted away from the normal, Fig. 15-4B. A small portion is reflected back into the first material by Fresnel reflection. The greater the difference in the indices of two materials the greater the reflection. The magnitude of the Fresnel reflection at the boundary between any two materials is approximately

\[
 R = \left(\frac{n_1 - n_2}{n_1 + n_2}\right)^2 \tag{15-5}
\]

where,

- \( R \) is the Fresnel reflection,
- \( n_1 \) is the index of refraction of material 1,
- \( n_2 \) is the index of refraction of material 2.

In decibels, this loss of transmitted light is

\[
 L_F = -10\log(1 - R) \text{ dB} \tag{15-6}
\]

As the angle of incidence increases, the angle of refraction approaches 90° with the normal. The angle of incidence that yields a 90° angle of refraction is called the critical angle, Fig. 15-4C. If the angle of incidence is increased past the critical, the light is totally reflected back into the first material and does not enter the second material and the angle of reflection equals the angle of incidence, Fig. 15-4D.

A single optical fiber is comprised of two concentric layers. The inner layer, the core, contains a very pure glass (very clear glass); it has a refractive index higher than the outer layer, or cladding, which is made of less pure glass (not so clear glass). Fig. 15-5 shows the arrangement. As a result, light injected into the core and striking the core-to-cladding interface at an angle greater than the critical is reflected back into the core. Since the angles of incidence and reflection are equal, the ray continues zigzagging down the length of the core by total internal reflection, as shown in Fig. 15-6. The light is trapped in the core, however, the light striking the interface at less than the critical angle passes into the cladding and is lost. The cladding is usually surrounded by a third layer, the buffer, whose purpose is to protect the optical properties of the cladding and core.

Total internal reflection forms the basis for light propagation in optical fiber. Most analyses of light propagation in a fiber evaluate meridional rays—those which pass through the fiber axis each time they are reflected. To help you to understand how an optical fiber works, let us look at Snell’s Law which describes
the relationship between incident and reflected light as shown in Fig. 15-6.

Snell’s Law equation is

\[ n_1 \sin \theta_1 = n_2 \sin \theta_2 \]  

(15-7)

where,

- \( n_1 \) is the refractive index of the core,
- \( n_2 \) is the refractive index of the cladding,
- \( \theta_1 \) is the angle of incidence,
- \( \theta_2 \) is the angle of reflection.

The critical angle of incidence, \( \theta_c \), (where \( \theta_2 = 90^\circ \)) is

\[ \theta_c = \sin^{-1}\left(\frac{n_2}{n_1}\right) \]  

(15-8)

At angles greater than \( \theta_c \), the light is reflected. Because reflected light means that \( n_1 \) and \( n_2 \) are equal (since they are in the same material), \( \theta_1 \) and \( \theta_2 \), the angles of incidence and reflection are equal. These simple principles of refraction and reflection form the basis of light propagation through an optical fiber.

Fibers also support skew rays, which travel down the core without passing through the fiber axis. In a straight fiber, the patch of a skew ray is typically helical. Because skew rays are very complex to analyze, they...
are usually not included in practical fiber analysis. The exact characteristics of light propagation depend on the fiber size, construction, and composition, and on the nature of the light source injected.

Fiber performance and light propagation can be reasonably approximated by considering light as rays. However, more exact analysis must deal in field theory and solutions to Maxwell’s electromagnetic equations. Maxwell’s equations show that light does not travel randomly through a fiber; it is channeled into modes, which represent allowed solutions to electromagnetic field equations. In simple terms, a mode is a possible path for a light traveling down a fiber.

The characteristics of the glass fiber, in an extreme sense, can be compared to light as seen through crystal clear water, turbid water, and water containing foreign objects. These conditions are characteristics of water and have quite different effects on light traveling (propagating) through them. The glass fibers are no different, splices, breaks, boundary distortion, bubbles, core out-of-round, etc., all influence the amount of light that reaches the distant end. The main objective is to receive maximum intensity with little or no distortion.

15.4 Fiber Optics

15.4.1 Types of Fiber

Optical fibers are usually classified by their refractive index profiles and their core size. There are three main types of fibers:

1. Single mode.
2. Multimode stepped index.
3. Multimode graded index.

Single Mode Fiber. Single mode fiber contains a core diameter of 8 to 10 microns, depending on the manufacturer. A highly concentrated source such as a laser or high-efficient LED must be used to produce a single mode for radiation into the fiber. The index of refraction in single mode fiber is very low because the highly concentrated beam and extremely small core prevent blossoming (officially referred to as scattering) of the ray.

The small core tends to prevent the entry of extraneous modes into the fiber, as illustrated in Fig. 15-7. Loss in a single mode fiber is very low and permits the economy of longer repeater (telephone amplifier) spacing. This optical fiber has the capability of propagating 1310 nm and 1550 nm wavelengths. It is well suited for intracity and intercity applications where long repeater spacing is desired.

Multimode Step Index Fiber. The production of optical fiber includes layer deposition of core glass inside a started tube. If the glass core layers exhibit the same optical properties the fiber is classed a step index fiber. The core layers contain uniform transmission characteristics. The fanout of the rays and their refraction at the core-clad boundary give them the appearance of stepping through the glass, Fig. 15-8. Notice also that as the individual rays step their way through, some travel farther and take longer to reach the far end; the reason for the rounded output pulse shown. This optical fiber requires repeaters-regenerators located at short intervals.

Multimode Graded Index Fiber. The process of manufacturing graded index fiber involves depositing different grades of glass in the starting tube to provide a core with various transmission characteristics; the outer portion does not impede the passage of modes as much as the center.

In graded index fiber, the core axis contains a higher-density glass of slow wave (ray, mode) propagation in this path for coordination with arrival of the waves in the longest path. The grades of core glass deposited from axis to perimeter are progressively less impeding.
to let all waves arrive in unison and greatly increase the received intensity (power).

Notice in Fig. 15-9 how each mode is bent (and slowed) in proportion to its entry point in the optical fiber, keeping them in phase. When the rays arrive in phase their powers add. This technique provides maximum signal strength over the greatest distance without regeneration because out-of-phase modes subtract from the total power.

Notice in Fig. 15-9 how each mode is bent (and slowed) in proportion to its entry point in the optical fiber, keeping them in phase. When the rays arrive in phase their powers add. This technique provides maximum signal strength over the greatest distance without regeneration because out-of-phase modes subtract from the total power.

*Dispersion per nanometer of source width.
†PCS (Plastic-clad silica: plastic cladding and glass core).
(Courtesy AMP Incorporated)

Dispersion. Dispersion is the spreading of a light pulse as it travels down the length of an optical fiber. Dispersion limits the bandwidth or information-carrying capacity of a fiber. In a digital modulated system, this causes the received pulse to be spread out in time. No power is actually lost due to dispersion, but the peak power is reduced as shown in Fig. 15-10. Dispersion can be canceled to zero in single-mode fibers but with multimode it often imposes the system design limit. The units for dispersion are generally given in ns/km.

Loose Tube and Tight Buffer Fiber Jackets. There are basically two types of fiber jacket protection called loose tube and tight buffer, Fig. 15-11.

The loose tube is constructed to contain the fiber in a plastic tube that has an inner diameter much larger than the fiber itself. The plastic loose tube is then filled with a gel substance. This allows the fiber to have less stress from the exterior mechanical forces due to the running or pulling of the cable. In multiple fiber loose tube or single fiber loose tube extra strength members are added to keep the fibers free of stress and to help minimize elongation and contraction. Thus, varying the amount of fibers inside the loose tube, the degree of shrinkage can be controlled due to temperature change. This allows for more consistent attenuation over temperature.

The second type, tight buffer, protects the fiber by a direct extrusion of plastic over the basic fiber coating. These tight buffer cables can withstand much greater crush and impact forces without fiber breakage. While the tight buffer has better crush capabilities and is more flexible, it lacks the better attenuation figure of the loose tube due to temperature variations which cause microbending due to sharp bends and twisting of the cable.
Strength members provide for better tensile load parameters similar to coax or electrical audio cables. An optical fiber doesn’t stretch very far before it breaks, so the strength members must employ low elongation at the expected tensile loads.

A common strength member used in fiber optic cables for harsh environments is Kevlar™. Kevlar is the material used in bulletproof vests and has the best performance for optical fiber strength members. These strength members are also referred to as tactical optical fiber. They were first used for military communications and were popularized in Operation Desert-Storm in the Iraq and Kuwait war of 1991. These tactical optical fiber cables are impervious to tanks, trucks and bomb explosions. In today’s audio applications involving broadcast sports events and news, tactical optical fiber cables have found a niche.

15.4.3 Signal Loss

15.4.3.1 Fiber Optic Transmission Loss (FOTL)

In addition to physical changes to the light pulse which result from frequency or bandwidth limitations, there are also reductions in level of optical power as the light pulse travels to and through the fiber. This optical power loss, or attenuation, is expressed in dB/km (decibels per kilometer). The major causes of optical attenuation in optical fiber systems are:

1. Optical fiber loss.
2. Microbending loss.
3. Connector loss.
5. Coupling loss.

In the ANSI/IEEE Standard 812-1984 the Definition of Terms Relating to Fiber Optics defines attenuation and attenuation coefficient as follows:

**Attenuation.** In an optical waveguide, the diminution of average optical power. Note: In optical waveguides, attenuation results from absorption, scattering, and other radiation. Attenuation is generally expressed in decibels (dB). However, attenuation is often used as a synonym for attenuation coefficient, expressed as dB/km. This assumes the attenuation coefficient is invariant with length. Also see—attenuation coefficient; coupling loss; differential mode attenuation; equilibrium mode distribution; extrinsic joint loss; leaky modes; macrobend loss; material scattering; microbend loss; Rayleigh scattering; spectral window; transmission loss; waveguide scattering.

**Attenuation Coefficient.** The rate of diminution of average optical power with respect to distance along the waveguide. Defined by the equation

\[
P(z) = P(0)10^{-\frac{\alpha z}{10}}
\]

(15-9)

where,

- \(P(z)\) is the power at distance \(z\) along the guide,
- \(P(0)\) is the power at \(z = 0\),
- \(\alpha\) is the attenuation coefficient in dB/km if \(z\) is in km.

From this equation,

\[
\alpha z = -10\log\left[\frac{P(z)}{P(0)}\right]
\]

(15-10)

This assumes that \(\alpha\) is independent of \(z\); if otherwise, the definition shall be given in terms of incremental attenuation as

\[
P(z) = P(0)10^{\int_0^z \frac{\alpha(x)dx}{10}}
\]

(15-11)

or, equivalently,

\[
\alpha z = -10\frac{d}{dz}\log\left[\frac{P(z)}{P(0)}\right]
\]

(15-12)

15.4.3.2 Optical Fiber Loss

Attenuation varies with the wavelength of light. Windows are low-loss regions, where fibers carry light with little attenuation. The first generation of optical fibers operated in the first window, around 820 nm to 850 nm. The second window is the zero-dispersion region of 1300 nm, and the third window is the 1550 nm region. A typical 50/125 graded-index fiber offers attenuation of 4 dB/km at 850 nm and 2.5 dB/km at 1300 nm, a 30% increase in transmission efficiency. Attenuation is very high in the regions of 730 nm, 950 nm, 1250 nm, and 1380 nm; therefore, these regions should be avoided.

Evaluating loss in an optical fiber must be done with respect to the transmitted wavelength. Fig. 15-12 shows a typical attenuation curve for a low-loss multimode fiber. Fig. 15-13 does the same for a single-mode fiber; notice the high loss in the mode-transition region, where the fiber shifts from multimode to single-mode
operation. Making the best use of the low-loss properties of the fiber requires that the source emit light in the low-loss regions of the fiber. Plastic fibers are best operated in the visible-light area around 650 nm.

One important feature of attenuation in an optical fiber is that it is constant at all modulation frequencies within the bandwidth. In a copper cable, attenuation increases with the signal’s frequency. The higher the frequency, the greater the attenuation. A 30 MHz signal will be attenuated in a copper cable more than a 15 MHz signal. As a result, signal frequency limits the distance a signal can be sent before a repeater is needed to regenerate the signal. In an optical fiber, both signals will be attenuated the same.

Attenuation in a fiber has three main causes:

1. Scattering.
2. Absorption.
3. Bending (Microbending).

Scattering. Scattering is the loss of optical energy due to imperfections in the fiber and from the basic structure of the fiber. Scattering does just what the term implies: it scatters the light in all directions. The light is no longer directional.

Rayleigh scattering is the same phenomenon that causes a red sky at sunset. The shorter blue wavelengths are scattered and absorbed while the longer red wavelengths suffer less scattering and reach our eyes, so we see a red sunset. Rayleigh scattering comes from density and compositional variations in a fiber that are natural byproducts of manufacturing. Ideally, pure glass has a perfect molecular structure and, therefore, uniform density throughout. In real glass, the density of the glass is not perfectly uniform. The result is scattering.

Since scattering is inversely proportional to the fourth power of the wavelength ($\frac{1}{\lambda^4}$), it decreases rapidly at longer wavelengths. Scattering represents the theoretical lower limits of attenuation, which are as follows:

- 2.5 dB at 820 nm
- 0.24 dB at 1300 nm
- 0.012 dB at 1550 nm

Absorption. Absorption is the process by which impurities in the fiber absorb optical energy and dissipate it as a small amount of heat. The light becomes dimmer. The high-loss regions of a fiber result from water bands, (where hydroxyl molecules significantly absorb light). Other impurities causing absorption include ions of iron, copper, cobalt, vanadium, and chromium. To maintain low losses, manufacturers must hold these ions to less than one part per billion. Fortunately, modern manufacturing techniques, including making fibers in a very clean environment, permit control of impurities to the point that absorption is not nearly as significant as it was a few years ago.

Microbend Loss. Microbend loss is that loss resulting from microbends, which are small variations or bumps in the core to cladding interface. As shown in Fig. 15-14, microbends can cause high-order modes to reflect at angles that will not allow further reflection. The light is lost.

Microbends can occur during the manufacture of the fiber, or they can be caused by the cable. Manufacturing and cabling techniques have advanced to minimize microbends and their effects.

New Reduced Bend Radius Fibers. Fiber optic cable manufacturers have now significantly reduced the bend radius of the fiber. The reduced bend radius allows for more flexibility allowing installers to bend the fiber
around tight corners without any discernible increase in the fiber’s attenuation. There are several names given to these optical fibers such as bend insensitive or bend resistant that can be somewhat misleading when it comes to the selection of the fiber. The user may tend to believe that the reduction of the bend radius will also eliminate any mishandling, temperature extremes, improper routing, or other external forces on the fiber. However, the user should be aware that these factors may not always be true. Selecting a reduced-bend radius-fiber really achieves the improvements of bending the fibers for tighter bends in fiber panels, frames and routing pathways like conduits, raceways and risers.

There is a common basic rule of thumb that the maximum bend radius should be ten times the outside diameter of the cable or approximately 1.5 inches, whichever is greater. This reduced bend radius of the fiber decreases the standard by about 50%, or to 15 mm, without changing the fiber’s attenuation.

There have been fiber demonstrations showing a reduced bend radius fiber patch cord and tying a tight knot within the patch cord. Then the patch cord was tested with the tight knot and revealed that no light escaped and also no increase of attenuation was present. These improvements for patch cords have been tremendous, but when it comes to using reduced bend radius for other applications such as in routing in higher densities or easy connector access they will become more critical. Thus, always consult with the manufacturer’s guidelines and specifications when selecting reduced bend radius fibers.

**Connector Loss.** Connector loss is a function of the physical alignment of one fiber core to another fiber core. Scratches and dirt can also contaminate connector surfaces and severely reduce system performance, but most often the connector loss is due to misalignment or end separation.

Several styles of fiber optic connectors are available from major connector suppliers. Typically, each manufacturer has its own design and is generally not compatible with those of other manufacturers. However, things are constantly changing for the better so now all SMA- and ST-type connectors are compatible.

Depending on connector type, different terminating techniques are used:

- Epoxy and Polish— the fiber is epoxied in place in an alignment sleeve, then polished at the ferrule face.
- Optical and Mechanical—both lenses and rigid alignment tubes are commonly used. In addition, index matching mediums may be employed.

The optical power loss of a connector-to-connector interface typically runs between 0.1 dB and 2 dB, depending on the style of the connector and the quality of the preparation.

**splice Loss.** Two fibers may be joined in a permanent fashion by fusion, welding, chemical bonding, or mechanical joining. A splice loss that is introduced to the system may vary from as little as 0.01 dB to 0.5 dB.

**Coupling Loss.** Loss between the fiber and the signal source or signal receiver is a function of both the device and the type of fiber used. For example, LEDs emit light in a broad spectral pattern when compared to laser diodes. Therefore, LEDs will couple more light when a larger core fiber is used, while lasers can be effective with smaller core diameters such as in single-mode systems.

Fiber core size is, therefore, a major factor in determining how much light can be collected by the fiber. Coupled optical power increases as a function of the square of the fiber core diameter.

The numerical aperture (NA) is the light gathering ability of a fiber. Only light injected into the fiber at angles greater than the critical angle will be propagated. The material NA relates to the refractive indices of the core and cladding

\[
NA = \frac{1}{\sin \theta} \tag{15-13}
\]

where,

- \( NA \) is a unitless dimension.

We can also define the angles at which rays will be propagated by the fiber. These angles form a cone, called the acceptance cone, that gives the maximum angle of light acceptance. The acceptance cone is related to the \( NA \)

\[
\theta = \sin^{-1}(NA) \tag{15-14}
\]

\( NA = \sin\theta \)

where,

\( \theta \) is the half-angle of acceptance, Fig. 15-15.

The NA of a fiber is important because it gives an indication of how the fiber accepts and propagates light. A fiber with a large NA accepts light well; a fiber with a low NA requires highly directional light.

In general, fibers with a high bandwidth have a lower NA; thus, they allow fewer modes. Fewer modes mean less dispersion and, hence, greater bandwidth. NAs range from about 0.50 for plastic fibers to 0.21 for
graded-index fibers. A large NA promotes more modal dispersion, since more paths for the rays are provided.

Sources and detectors also have an NA. The NA of the source defines the angles of the exiting light. The NA of the detector defines the angles of light that will operate the detector. Especially for sources, it is important to match the NA of the source to the NA of the fiber so that all the light emitted by the source is coupled into the fiber and propagated. Mismatches in NA are sources of loss when light is coupled from a lower NA to a higher one.

15.4.3.3 Attenuation Measurement

In an optical fiber, attenuation measurements require comparison of input and output power $P_{in}$ and $P_{out}$, respectively. It is measured in decibels as

$$L_{FOP} = -10 \log \left( \frac{P_{out}}{P_{in}} \right) \text{ in dB}$$  \hspace{1cm} (15-15)

where,

the negative sign is added to give attenuation a positive value because the output power is always less than the input power for passive devices,

$L_{FOP}$ is the level of fiber optic power expressed in dB.

Remember these are optical powers, and they are dependent on the wavelength. Optical power digital meters make their measurements readings in either dB or dBm, and also display the wavelength. The optical power level $L_{OP}$ is computed with the equation

$$L_{OP} = 10 \log \left( \frac{P_s}{P_r} \right) \text{ in dB}$$  \hspace{1cm} (15-16)

where,

$P_s$ is the power of the signal,

$P_r$ is the reference power.

If the reference power is 1 mW, then the equation for the optical power level $L_{OP}$ becomes

$$L_{OP} = 10 \log \left( \frac{P_s}{1 \text{ mW}} \right) \text{ in dB}$$  \hspace{1cm} (15-17)

Notice when we know the reference power is 1 mW the unit of level changes to dBm. When the reference power is not specified the unit of level is in dB.

Precise fiber attenuation measurements are based on the cut-back method test shown in Fig. 15-16. Here a light source is used to put a signal into the optical fiber; a mode filter is used in graded index or multimode fiber to establish a consistent launch condition to allow consistency of measurements. Although modal conditioning (using mode filter) is beyond the scope of this discussion, it is a very important topic for making measurements in multimode fiber because of the effects of modal conditioning on the values one will measure in this test. Measure the amount of light that comes out at the far end, then cut the fiber back (about 1 to 2 meters) to just past the mode filter. Measure the amount of light that comes out the new end. The difference in the light at one end and that at the other end divided by the length of the fiber gives you the loss per unit length, or the attenuation of the fiber. This is the method used by all manufacturers for testing their fiber.

Be aware, however, that this will not accurately measure the loss that light will experience in short multimode fibers because that loss depends on propagation of high-order modes that are eliminated from measurements by adding a mode filter.

Similar measurements can be made on fiber optic cables with mounted connectors by replacing the short cut-back fiber segment with a short jumper cable (including a mode filter if desired). That approach simplifies measurements by avoiding the need to cut fibers at a modest sacrifice in accuracy. One special problem with single-mode fibers is that light can propagate short distances in the cladding, throwing off measurement results by systematically underestimating input coupling losses. To measure true single-mode transmission and coupling, fiber lengths should be at least 20 to 30 m (65 to 100 ft).
Testing fiber optic continuity is important for system function checks. This test for continuity is simple and doesn’t require elaborate equipment. A technician on one end shines a flashlight into the fiber, and the technician on the other end looks to see if any light emerges. That quick test can be checked by measuring cable attenuation. Sites of discontinuities can be located with optical time domain reflectometers (OTDRs), as well as attenuation measurements of the cable.

The OTDR contains a high-power laser source and a sensitive photodetector coupled to a signal amplifier that has a wide dynamic range. The output signal is displayed on an integral oscilloscope. OTDRs use the fundamental reflection or backscatter properties of optical fibers by launching a well-defined optical pulse shape into the fiber and measuring and displaying the return level. However, OTDRs are more elaborate and expensive. The alternative for the audio engineer might be an optical fault finder like the one by Tektronix® (Model TOP300) in Fig. 15-17. The TOP300 is a hand-held unit which weighs about one pound and incorporates easy to read LEDs. No experience is necessary for the user, just push the buttons and read the LEDs. The strong laser light shows where the fault is located. There are other test instruments for fiber optics which is beyond the scope of this chapter.

15.4.3.4 Advancements in OTDR Testing

The optical time domain reflectometer (OTDR) is designed to troubleshoot fiber breaks and fiber losses. In the past the OTDR was very elaborate and extremely expensive. Fiber optic manufacturers finally have made the OTDR’s measurement less complicated. An example of one such device is the OptiFiber® Advanced OTDR by Fluke Networks, Fig. 15-18.

Figure 15-18. OptiFiber Advanced Certifying OTDR. Courtesy of Fluke Networks.

The OptiFiber Advanced OTDR Package will test the fiber link/span, certify it, diagnose it, and document it. This is one of the first certifying OTDRs designed for network owners and installers.

The use of fiber optics in audio and broadcast networks is continually growing, and so are the requirements for testing and certifying. To insure the performance of these optical networks/LANs, network owners are demanding more information that gives them a complete picture of the fiber links. Using this type of OTDR provides a more complete picture.

The OptiFiber is the first test instrument specifically designed to keep network owners and installers on top of the latest requirements for testing and certifying fiber networks. OptiFiber integrates insertion loss and fiber length measurement, OTDR analysis, and fiber connector end face imaging to provide a higher standard
of fiber certification and diagnostics. The companion PC software documents, reports, and manages all test data. OptiFiber enables audio network owners of all experience levels to certify fiber to industry and customer specifications, and troubleshoot short-haul connection links and thoroughly document their results.

15.5 Sources

Sources are transmitters of light that can be coupled into fiber optic cables. Basically the two major sources used in fiber optic communications are light emitting diodes (LEDs) and laser diodes. Both are made from semiconductor materials.

LEDs and laser diodes are created from layers of P- and N-type semiconductor materials, forming a junction. Applying a small voltage across the junction causes electrical current, consisting of electrons and holes, to flow. Light photons are emitted from the junction when the electrons and holes combine internal to the junction.

Although the LED provides less power and operates at slower speeds, it is amply suited to applications requiring speeds to several hundred megabits and transmission distances of several kilometers. It is also more reliable, less expensive, has a longer life expectancy, and is easier to use. For higher speeds or longer transmission distances, the laser diode must be considered.

You might have seen LEDs being used in VU or peak-reading meter displays, or as simple status indicators. LEDs used in fiber optics are designed somewhat differently than a simple display LED. The complexities arise from the desire to construct a source having characteristics compatible with the needs of a fiber optic system. Principal among these characteristics are the wavelength and pattern of emission. There are special packaging techniques for LEDs to couple maximum light output into a fiber, Fig. 15-19.

There are three basic types of designs for fiber optic LEDs:

- Surface emitting LED.
- Edge emitting LED.
- Microlensed LED.

Surface Emitting LED. Surface emitting LEDs, Fig. 15-20A, are the easiest and cheapest to manufacture. The result is a low-radiance output whose large emission pattern is not well suited for use with optical fibers. The problem is that only a very small portion of the light emitted can be coupled into the fiber core.

The Burrus LED, named after its inventor Charles A. Burrus of Bell Labs, is a surface-emitting LED with a hole etched to accommodate a light collecting fiber, Fig. 15-21. However, the Burrus LED is not frequently used in modern systems.

Edge Emitting LED. The edge emitting LEDs, Fig. 15-20B, use an active area having stripe geometry. Because the layers above and below the stripe have different refractive indices, carriers are confined by the waveguide effect produced. (The waveguide effect is the same phenomenon that confines and guides the light in the core of an optical fiber.) The width of the emitting area is controlled by etching an opening in the silicon oxide insulating area and depositing metal in the opening. Current through the active area is restricted to the area below the metal film. The result is a high-radiance elliptical output which couples much more light into small fibers than surface emitting LEDs.

Microlensed LED. More recently, technology has advanced such that it is possible, under production con-
conditions, to place a microscopic glass bead that acts as a lens on top of the diode’s microchip structure. This microlensed device has the advantage of direct compatibility with a very wide range of possible fibers. There are also double-lensed versions which allow light to be concentrated into the output fiber pigtail.

**Dominant Wavelengths.** Most LEDs will have a maximum power at a dominant wavelength lying somewhere within the range of 800 to 850 nm (first window). Some LEDs are available for other wavelengths: either around...
Transmission Techniques: Fiber Optics

1300 nm (second window) or around 1550 nm (third window). The choice is dictated by:

1. Windows—i.e., loss minima, in optical fibers.
2. Availability of suitable detectors.
3. Cost.
4. Minimization of pulse spreading (dispersion) in a fiber.
5. Reliability.

Also the facility for wavelength-division multiplexing (WDM) can also be a factor influencing choice.

15.5.2 Laser Diodes

Laser is an acronym for light amplification by the stimulated emission of radiation. The main difference between an LED and a laser is that the laser has an optical cavity required for lasing, see Fig. 15-22. This cavity, called a Fabry-Perot cavity, is formed by cleaving the opposite end of the chip to form highly parallel, reflective mirrorlike finishes.

At low electrical drive currents, the laser acts like an LED and emits light spontaneously. As the drive current increases, a threshold level is reached, above which lasing action begins. A laser diode relies on high current density (many electrons in the small active area of the chip) to provide lasing action. Some of the photons emitted by the spontaneous action are trapped in the Fabry-Perot cavity, reflecting back and forth from end mirror to end mirror. These photons have an energy level equal to the band gap of the laser material. If one of these photons influences an excited electron, the electron immediately recombines and gives off a photon. Remember that the wavelength of a photon is a measure of its energy. Since the energy of the stimulated photon is equal to the original stimulating photon, its wavelength is equal to that of the original stimulating photon. The photon created is a clone of the first photon. It has the same wavelength, phase, and direction of travel. In other words, the incident photon has stimulated the emission of another photon. Amplification has occurred, and emitted photons have stimulated further emission.

The high drive current in the chip creates population inversion. Population inversion is the state in which a high percentage of the atoms move from the ground state to the excited state so that a great number of free electrons and holes exist in the active area around the junction. When population inversion is present, a photon is more likely to stimulate emission than be absorbed. Only above the threshold current does population inversion exist at a level sufficient to allow lasing.

Although some of the photons remain trapped in the cavity, reflecting back and forth and stimulating further emissions, others escape through the two cleaved end faces in an intense beam of light. Since light is coupled into the fiber only from the front face, the rear face is often coated with a reflective material to reduce the amount of light emitted. Light from the rear face can also be used to monitor the output from the front face. Such monitoring can be used to adjust the drive current to maintain constant power level on the output.

Thus, the laser differs from an LED in that laser light has the following attributes:

1. Nearly monochromatic: The light emitted has a narrow band of wavelengths. It is nearly monochromatic, that is, of a single wavelength. In contrast to the LED, laser light is not continuous across the band of its special width. Several distinct wavelengths are emitted on either side of the central wavelength.
2. Coherent: The light wavelengths are in phase, rising and falling through the sine-wave cycle at the same time.
3. Highly directional: The light is emitted in a highly directional pattern with little divergence. Divergence is the spreading of a light beam as it travels from a source.

**15.5.3 Superluminescent Diodes (SLDs)**

A source called the superluminescent diode (SLD) is now available for use. The performance and cost of the SLD fall somewhere in between the LED and the laser. The SLD was first investigated in 1971 by the Soviet physicist, Kurbatov. The SLD may operate like a edge-emitting LED at low currents, while at high-injection currents, the output power increases superlinearly and the spectral width narrows as a result of the onset of optical gain.

**15.5.4 Vertical Cavity Surface Emitting Laser (VCSEL)**

A more recent source is the vertical cavity surface emitting laser (VCSEL). It is a specialized laser diode that promises to revolutionize fiber optic communications by improving efficiency and increasing data speed. The acronym VCSEL is pronounced vixel. It is typically used for the 850 nm and 1300 nm windows in fiber optic systems.

**15.5.5 LED and Laser Characteristics**

**15.5.5.1 Output Power**

Both LEDs and laser diodes have VI voltage versus current characteristic curves similar to regular silicon diodes. The typical forward voltage drop across LEDs and laser diodes is 1.7 volts.

In general, the output power of sources decreases in the following order: laser diodes, edge emitting LEDs, surface emitting LEDs. Fig. 15-23 shows some curves of relative output power versus input current for LEDs, SLDs, and laser diodes.

**15.5.5.2 Output Pattern**

The output or dispersion pattern of light is an important concern in fiber optics. As light leaves the chip, it spreads out. Only a portion of light actually couples into the fiber. A smaller output pattern allows more light to be coupled into the fiber. A good source should have a small emission diameter and a small NA. The emission diameter defines how large the area of emitted light is, and the NA defines at what angles the light is spreading out. If either the emitting diameter or the NA of the source is larger than those of the receiving fiber, some of the optical power will be lost. Fig. 15-24 shows typical emission patterns for the LED, SLD, and laser.

**15.5.5.3 Wavelength**

Optical fibers are sensitive to wavelength, therefore the spectral (optical) frequency of a fiber optic source is important. LEDs and laser diodes do not emit a single wavelength; they emit a range of wavelengths. This range is known as the spectral width of the source. It is measured at 50% of the maximum amplitude of the peak wavelength. As an example, if a source has a peak
wavelength of 820 nm and a spectral width of 30 nm, its output ranges from 805 nm to 835 nm from the spectral width curve specs. The spectral width of a laser diode is about 0.5 nm to 6 nm; the spectral width of LEDs is much wider—around 20 nm to 60 nm.

15.5.5.4 Speed

A source must turn on and off fast enough to meet the bandwidth requirements of the system. The source speed is specified by rise and fall times. Lasers have rise times of less than 1 ns, whereas LEDs have slower rise times of about 5 ns. A rough approximation of bandwidth for a given rise time is

\[ BW = \frac{0.35}{t_r} \]  

(15-18)

where,

- \( BW \) is the bandwidth in hertz,
- \( t_r \) is the rise time in seconds.

15.5.5.5 Lifetime

The expected operating lifetime of a source runs into the millions of hours. Over time, however, the output power decreases due to increasing defects in the device’s crystal-line structure. The lifetime of the source is normally considered the time where the peak output power is reduced 50% or 3 dB. In general LEDs have a longer lifetime than laser diodes. As an example, an LED emitting a peak power of 1 mW is considered at the end of its lifetime when its peak power becomes 500 \( \mu \)W or 0.5 mW.

15.5.5.6 Safety

There are a few main precautions to take in the field of fiber optics. Most important is to never look directly into an LED or laser diode! Generally, the light emitted by LEDs is not intense enough to cause eye damage, however, it is best to avoid looking at all collimated beams emitted from LEDs or lasers. Be familiar with the sources used. For more safety information, you can contact the Laser Society of America or OSHA.

15.6 Detectors

The detector performs the opposite function from the source: it converts optical energy to electrical energy. The detector can be called an optoelectronic transducer. The most common detectors in fiber optics are PIN photodiodes, avalanche photodiodes (APD), and integrated detectors-preamplifiers (IDP).

The PIN photodiode is the simplest type of detector, useful for most applications. It is a three-layer semiconductor device having a layer of undoped (or intrinsic) material sandwiched between a layer of positively doped material and negatively doped material. The acronym PIN comes from this ordering: positive, intrinsic, negative. Light falling on the intrinsic layer causes electron-hole pairs to flow as current. In a perfect photodiode, each photon will set an electron-hole pair flowing. In real PIN photodiodes, the conversion from light to electric current is not perfect; only 60% (or less) of the photons reaching the diode causes current flow.

This ratio is the detector’s responsivity. A photodiode has a responsivity of about 0.6 A/W; in practical terms, an electrical current of 60 \( \mu \)A results for every 100 \( \mu \)W of optical energy striking the diode. Responsivity (R) is the ratio of the diode’s output current to input optical power and is given in amperes/watt (A/W). The responsivity also depends on the wavelength of light. Being the simplest device, the PIN photodiode offers no amplification of the signal. Even so, it has several virtues: it is inexpensive, easy to use, and has a fast response time.

The avalanche photodiode (APD) provides some gain and is more sensitive to low-power signals than the PIN photodiode. A photon striking the APD will set a number of electron-hole pairs in motion, which in turn sets other pairs in motion, a phenomenon known as the avalanche effect. A photon initiates an avalanche of current. A typical APD has a responsivity of 15 \( \mu \)A/\( \mu \)W. An additional advantage of the APD is that it is very fast, turning on and off much faster than a photodiode. The drawback to the APD is its complexity and expense. It requires high voltages for operation and is sensitive to variations in temperature. Like the laser as a source, the APD is only used where speeds and distance require it.

The integrated detector-preamplifier (IDP) is a photodetector and transimpedance amplifier in the same integrated circuit. The advantage is that the signal can be amplified or strengthened immediately, before it meets the noise associated with the load resistor. This is important since any following amplifier stages will boost not only the signal but the noise as well. The IDP amplifies the light induced current and provides a usable voltage output. The responsivity of an IDP is in volts/watt (V/W). The responsivity of a typical IDP is about 15 mV/\( \mu \)W. Again, the device has provided gain to overcome noise and provide a suitable SNR.
The characteristics of typical detectors are shown in Table 15-4.

**15.6.1 Quantum Efficiency (η)**

Quantum efficiency, another way of expressing a photodiode’s sensitivity, is the ratio of photons to the number of electrons set flowing in the external circuit and is expressed either as a dimensionless number or as a percentage. The responsivity can be calculated from the quantum efficiency as follows:

\[ R = \frac{nq\lambda}{hc} \]  

(15-19)

where,

- \( q \) is the charge of an electron,
- \( h \) is Planck’s constant,
- \( c \) is the velocity of light.

Since \( q, c, \) and \( h \) are constants, responsivity is simply a function of quantum efficiency and wavelength.

**15.6.2 Noise**

Several types of noise are associated with the photodetector and with the receiver. Shot noise and thermal noise are particularly important to our understanding of photodiodes in fiber optics.

The noise current produced by a photodiode is called shot noise. Shot noise arises from the discrete nature of electrons flowing across the p-n junction of the photodiode. The shot noise can be calculated by using the following equation

\[ i_{sn} = \sqrt{2qI_a(BW)} \]  

(15-20)

where,

- \( q \) is the charge of an electron \( (1.6 \times 10^{-19} \text{ coulomb}) \),
- \( I_a \) is the average current (including dark current and signal current),
- \( BW \) is the receiver bandwidth.

Dark current in a photodiode is the thermally generated current. The term dark relates to the absence of light when in an operational circuit.

Thermal noise \( (i_{tn}) \), sometimes called Johnson or Nyquist noise, is generated from fluctuations in the load resistance of the photodiode. The following equation can be used to calculate the thermal noise

\[ i_{tn} = \frac{4KT(BW)}{\sqrt{2qI_a}} \]  

(15-21)

where,

- \( K \) is Boltzmann’s constant \( (1.38 \times 10^{-23} \text{ joules/K}) \),
- \( T \) is the absolute temperature in Kelvins,
- \( BW \) is the receiver’s bandwidth,
- \( R_{eq} \) is equivalent resistance, which can be approximated by a load resistor.

Noise in a PIN photodiode is

\[ i_n = \sqrt{i_{sn}^2 + i_{TN}^2} \]  

(15-22)

where, \( i_{TN} \) is the thermal noise.

For an APD, the noise associated with multiplication must also be added.

As a general rule, the optical signal should be twice the noise current to be adequately detected. More optical power may be necessary, however, to obtain the desired SNR.

**15.6.3 Bandwidth**

The bandwidth, or operating range, of a photodiode can be limited by either its rise time or its RC time constant, whichever results in the slower speed or bandwidth. The bandwidth of a circuit limited by the RC time constant is

\[ BW = \frac{1}{2\pi R_{eq}C_d} \]  

(15-23)

where,

- \( R_{eq} \) is the equivalent resistance offered by the sum of the load resistance and diode series resistance,
- \( C_d \) is the diode capacitance including any contribution from the mounting.

A photodiode's response does not completely follow the exponential response of an RC circuit because changes of light frequency or intensity change the parameters. Nevertheless, considering the device
equivalent to a low-pass RC filter yields an approximation of its bandwidth. Fig. 15-25 shows the equivalent circuit model of a PIN photodetector.

![Figure 15-25. Equivalent circuit model of a PIN diode.](image)

### 15.7 Transmitter/Receiver Modules

In most cases, fiber optic engineers will not design their own transmitters and receivers. They will use completed transmitter-receiver modules. A transmitter module may consist of the following elements:

1. Electronic interface analog/digital input.
3. Drive circuits (preamplifiers, etc.).
4. Optical monitoring circuit.
5. Temperature sensing and control for laser diodes.
6. LED or laser diode as light source.
7. FO connector or pigtail at output.

A receiver module may consist of the following elements:

1. PIN or APD photodiode at the input.
2. Amplification circuits.
3. Signal processor A/D.
4. Analog/digital electrical signal at the output.

Usually, the FO engineer will use a matched pair of transmitter and receiver modules as shown in Fig. 15-26. When considering transmitter/receiver modules one must consider the following requirements:

1. Type of modulation.
2. Bandwidth.
4. Dynamic range.
5. Electrical and optical interface.
6. Space and cost.

### 15.8 Transceivers and Repeaters

Transceivers and repeaters are two important components in fiber optics. A transceiver is a transmitter and receiver both in one package to allow transmission and reception from either station. A repeater is receiver driving a transmitter. The repeater is used to boost signals when the transmission distance is so great that the signal will be too highly attenuated before it reaches the receiver. The repeater accepts the signal, amplifies and reshapes it, and sends it on its way by retransmitting the rebuilt signal.

One advantage of digital transmission is that it uses regenerative repeaters that not only amplify a signal but reshape it to its original form as well. Any pulse distortions from dispersion or other causes are removed. Analog signals use nonregenerative repeaters that amplify the signal, including any noise or distortion. Analog signals cannot be easily reshaped because the repeater does not know what the original signal looked like. For a digital signal, it does know.

#### 15.8.1 Demand on Gigabit Optical Transceivers

The industry is now experiencing that the world needs more bandwidth for today’s high-definition technologies. Ethernet has become a standard using both copper and fiber. Manufacturers must keep up with the demand for higher bit rates. The audio/video industry is now employing 1/2/4/10 Gigabit optical transceivers for these high bandwidth applications. Also the need to carry these audio/video signals at distances of 10 km or greater has become a reality. Fiber optics can carry a signal with higher bandwidth and greater distance than their copper counterpart.

The price of copper has gone up tenfold due to the world market consumption of copper, especially in the China market. This has bought the price of fiber and fiber optic transceivers down considerably from 2 years ago. An example is the company 3Com, who manufactures fiber optic transceivers. Most of these fiber optic transceivers employ a SFP (small form factor plug-in) duplex type LC connector. Table 15-5 gives 3Com optical transceiver specification data. Fig. 15-27 is a photo of the 3Com Optical Transceiver.
15.9 The Fiber Optic Link

A basic fiber optic link, as shown in Fig. 15-28, consists of an optical transmitter and receiver connected by a length of fiber optic cable in a point-to-point link. The optical transmitter converts an electrical signal voltage into optical power, which is launched into the fiber by either a LED or laser diode.

At the receiving point, either a PIN or APD photodiode captures the lightwave pulses for conversion back into electrical current.

It is the fiber optic system designer’s job to determine the most cost- and signal-efficient means to convey this optical power, knowing the trade-offs and limits of various components. He or she must also design the physical layout of the system.

15.9.1 Fiber Optic Link Design Considerations

Fiber optic link design involves power budget analysis and rise time analysis. The power budget calculates total system losses to ensure that the detector receives sufficient power from the source to maintain the required system SNR or bit-error-rate (BER). Rise time analysis ensures that the link meets the bandwidth requirements of the application.

BER is the ratio of correctly transmitted bits to incorrectly transmitted bits. A typical ratio for digital systems is $10^{-9}$, which means that one wrong bit is received for every one billion bits transmitted. The BER in a digital system often replaces the SNR in an analog system and is a measure of system quality.

15.9.2 Passive Optical Interconnections

In addition to the fiber, the interconnection system includes the means for connecting the fiber to active devices or to other fibers and hardware for efficiently packaging the system to a particular application. The three most important interconnects are FO connectors, splices, and couplers.

Interconnect losses fall into two categories— intrinsic and extrinsic.

- Intrinsic or fiber-related factors are those caused by variations in the fiber itself, such as NA (numerical aperture) mismatch, cladding mismatches, concentricity, and ellipticity, see Fig. 15-29.
- Extrinsic or connector-related factors are those contributed by the connector itself, Fig. 15-30.
four main causes of loss that a connector or splice
must control are:

1. Lateral displacement.
2. End separation.
3. Angular misalignment.
4. Surface roughness.

Figure 15-29. Intrinsic fiber optic losses.

Figure 15-30. Extrinsic fiber optic losses.

15.9.3 Fiber Optic Connectors

A fiber optic connector (FOC) is a device designed to
simply and easily permit coupling, decoupling, and
recoupling of optical signals or power from each optical
fiber in a cable to corresponding fibers in another cable,
usually without the use of tools. The connector usually
consists of two mateable and demateable parts, one

attached to each end of a cable or to a piece of equip-
ment, for the purpose of providing connection and dis-
connection of fiber optic cables. When selecting FOCs
one should look for:

1. Minimum insertion loss.
2. Consistent loss characteristics with little change
after many connect/disconnect cycles.
3. Easy installation without expensive tools and
special training.
4. Reliability of connection (ruggedness).
5. Low cost.

There are many different types of FOCs being used
and newer types are emerging rapidly. We cannot even
attempt to cover them all, but will discuss the following
popular types in wide use in the communications
industry, see Fig. 15-31:

1. Biconic.
2. SMA.
3. FC/PC.
4. ST (preferred for audio applications).
5. SC.
7. FDDI (used in audio for duplex operations).
8. Small form factor connectors:
   - LC.
   - MT-RJ.

15.9.3.1 Biconic Connector

The biconic connector was invented by AT&T Bell Lab-
atories. The latest in precision molding techniques are
incorporated to yield fractional dB losses. It employs a
conic ferrule and has a precision taper on one end that
mates to a free-floating precision molded alignment
sleeve within the coupling adaptor. While the biconic is
still around, it has lost its popularity for the most part.

15.9.3.2 SMA Connector

The SMA was developed by Amphenol Corporation
and is the oldest of all FOCs. It is similar to the SMA
connector used for microwave applications. The SMA
employs a ceramic ferrule and requires preparation of
the fiber end for mounting. There are different versions
of the SMA by other manufacturers called FSMA.

15.9.3.3 FC/PC Connector

The FC was developed by NTT Nippon Telegraph and
Telephone Corp. It has a flat endface on the ferrule that
provides face contact between joining connectors. A modified version of the FC called FC/PC was the first to use physical contact between fiber ends to reduce insertion loss and to increase return loss by minimizing reflections at the interfaces of the joining fibers.

15.9.3.4 ST Connector

The ST (straight through) connector was introduced in early 1985 by AT&T Bell Laboratories. The ST connector design utilizes a spring-loaded twist and lock coupling, similar to the BNC connectors used with coax cable. The ST prevents the fiber from rotating during multiple connections. This insures more consistent insertion loss during multiple connections. The ST is becoming the most popular FOC at the present time because of performance and compatibility. There are many versions of this ST-type connector being offered by other FOC manufacturers, even some that require no epoxy, just a simple crimp.

15.9.3.5 SC Connector

Most recent on the market is the SC-type connector developed by NTT of Japan. It is a molded plastic connector which employs a rectangular cross section and push-pull instead of threaded coupling. The SC achieves a much lower insertion loss than other types of FOCs and has a greater packing density which is useful in multicable installations. Recently Hirose Electric Co. and Seiko of Japan are manufacturing an SC type that has push-pull locking and employs a zirconia ferrule.

15.9.3.6 D4 Connector

The D4 connector was designed by NEC Nippon Electric Corp., Tokyo, Japan. It is similar to the D3, which was a forerunner of the FC.

15.9.3.7 FDDI Connector

The FDDI (Fiber Data Distributed Interface) connector is another recently developed connector. This connector is described and endorsed by the FDDI standard. The IEEE 802.8 (Institute of Electrical and Electronic Engineers) committee now recommends the FDDI connector for all networks involving duplex fiber operation. However, the increasing gain of the duplex SC connector is making it more popular.

15.9.3.8 SFF (Small Form Factor) Connectors

The SFF connectors are fiber optic connectors newly designed to allow for fast, lower cost and increased density of the patch panel/cross-connect field. They are approximately half the size of the traditional ST and SC connectors.

15.9.3.9 LC Connector

The LC SFF connector by Lucent Technologies was introduced to the market in late 1996. The LC connector employs a 1.25 mm ceramic ferrule with a push-pull insertion release mechanism similar to the familiar RJ-45 telephone modular plug. The LC incorporates an antsnaug latch that improves durability and reduces cross-connect rearrangement effort. The LC is available in both simplex and duplex types.
15.9.3.10 MT-RJ Connector

The MT-RJ SSF connector was designed by AMP, Inc. (now TYCO) and uses the familiar RJ latching mechanism found in copper systems, but the MT-RJ latch is inherently snag-proof. The single ferrule design of the MT-RJ connector reduces the time and complication of assembly by enabling two-fiber terminations simultaneously.

15.9.3.11 OpticalCon®

Most recent on the market is the OpticalCon® connector developed and introduced in 2006 by Neutrik AG. The OpticalCon® fiber optic connection system consists of a ruggedized all-metal, dust- and dirt-protected chassis and cable connector to increase the reliability. The system is based on a standard optical LC-Duplex connection; however, the OpticalCon® improves this original design to ensure a safe and rugged connection. Due to the compatibility with conventional LC connectors, it offers the choice of utilizing a cost-effective LC connector as a permanent connection, or Neutrik’s rugged OpticalCon® cable connector for mobile applications, Fig. 15-32.

15.9.3.12 Toslink

The Toslink connector was developed by Toshiba of Japan in 1983 and is a registered trademark. This connector was originally designed for a plastic optical fiber of 1 mm diameter. The actual connector/adapter is of a square construction with newer types having a protective flip cap to close the connector adapter when no plug is mated. Also this connector is referred to as JIS FO5 (JIS C5974-1993 FO5) in a simplex type and JIS FO7 for the duplex version, Fig. 15-33.

15.9.4 Connector Installation

The procedure to install a fiber optic connector is similar to that of an electrical connector. However, FOCs require more care, special tools, and a little more time. But as one gains more experience, the time is significantly reduced. The following are steps in making a fiber optic connection:

1. Open the cable.
2. Remove jacketing and buffer layers to expose the fiber.
3. Cut or break the fiber.
4. Insert the fiber into the connector.
5. Attach connector to fiber with epoxy or crimp.
6. Polish or smooth the fiber end.
7. Inspect the fiber ends with a microscope.
8. Seal the connector and fiber cable.

There are presently some FOCs that do not require epoxy or polishing. Things are constantly improving for the better.

15.9.4.1 Current Fiber Optic Connectors for Glass Optical Fibers (GOF)

The LC connector is becoming a de facto standard for pro-audio and video applications. Audio equipment manufacturers are now seeing the benefits of this connector along with its harsh environment type by Neutrik called OpticalCon®. Ongoing work is still in progress for fiber optic cables and connectors by the AES standard group on fiber optic connectors and cables.
15.9.4.2 LC Versus Other Types of Fiber Optic Connectors (ST, SC, etc.)

The LC-type connector over other types of connectors is made for more consistent performance and reliability. The benefits of using the LC type connector are:

1. It is square in shape and keyed, allowing for anti-rotation, which in turn increases the life expectancy of the connector when mated frequently.
2. It provides for quicker access to patch panel applications where the ST connector (for example) has to be turned to lock.
3. It uses a push-pull insertion release mechanism similar to the familiar RJ-45 telephone plug.
4. It allows tightly spaced patch panels, because it need not be turned to be engaged or disengaged.
5. The LC is called a small form factor (SFF) connector, which is about half the size of the SC connector and provides for high-density patch panels.
6. It offers better axial load and side pull features than the ST connector, thus eliminating disturbances caused by the user touching the cable or boot.
7. Users feel comfortable with LC because of its operational resemblance to an RJ-45 electrical connector.
8. The LC type is universally available throughout the world.
9. It eliminates optical discontinuities resulting from pulling on the cable.
10. It is cost effective.

NOTE: For manufacturers with a large base of existing ST or SC type connectors installed, there are hybrid adapters to mate ST or SC connectors to an LC connector, or vice versa, if needed.

15.9.4.3 Fiber Optic Connector Termination Advancements

Fiber connector manufacturers have now improved the termination process in putting a connector together in a few easy steps. One such device is made by Corning, Inc., called the UniCam® connector system. The UniCam® can be best described as a mini pigtail. It incorporates a factory-installed fiber stub that is fully bonded into the connector’s ferrule. The other end is precisely cleaved and placed into the patented alignment mechanism of Corning’s mechanical splice. Both the field fiber and fiber stub are fully protected from environmental factors. Unlike other no-epoxy, field-installable connectors, the UniCam® connector requires no polish-

Figure 15-34. UniCam connector system. Courtesy of Corning, Inc.

15.9.4.4 Fiber Optic Splices

A splice is two fibers joined in a permanent fashion by fusion, welding, chemical bonding, or mechanical joining. The three main concerns in a splice are:

1. Splicing loss.
2. Physical durability of the splice.
3. Simplicity of making the splice.

The losses in a fiber optic splice are the same as for FOCs, intrinsic and extrinsic. However the tolerances for a splice are much tighter; therefore, lower attenuation figures are produced.

There are far too many splicing types available to mention; therefore, the following discussion is on splices useful for audio applications. One type by Lucent is called the CSL LightSplice System. It provides a fast, easy cleave/mechanical splice for permanent and restoration splicing of single mode and multimode fibers. The CSL LightSplice System features low loss
and reflection and unlimited shelf life, and it does not
require polishing or the use of adhesives. The splice,
Fig. 15-35, also enables the user to visually verify the
splicing process.

Another splice type is Fibrolk™ optical fiber splice
by 3M TelComm Products Division. After cable prepa-
ration, the two fibers are inserted into a Fibrolk splice.
The assembly tool is then used to close the cap, which
forces the three locating surfaces against the fibers. This
aligns the fibers precisely and permanently clamps them
inside the splice. Fibrolk is for both single- or multi-
mode fibers. The splice, Fig. 15-36, can be performed in
about 30 seconds after preparing the fiber ends.

There are two types of passive couplers called the T
and the Star couplers, Fig. 15-37. The T coupler has
three ports connected to resemble the letter T. The star
coupler can employ multiple input and output ports and
the number of inputs can be different from the number
of outputs.

Couplers are quite simple to use. The following
calculation must be made:

**Excess loss:** The losses that are internal to the coupler
from scattering, absorption, reflections, misalignment,
and poor isolation. Excess loss is the ratio of the sum of
all the output power at the output ports to the input
power at the input ports. Usually it is expressed in dB.

**Insertion loss:** This loss is the ratio of the power
appearing at a given output port to that of an input port.
Thus, insertion loss varies inversely with the number of
terminals.

### 15.10 Couplers

A fiber optic coupler is used to connect three or more
fibers together. The coupler is different from a connec-
tor or splice which joins only two entities. The fiber
optic coupler is more important in fiber optics than for
electrical signal transmission because the way optical
fibers transmit light makes it difficult to connect more
than two points. Fiber optic couplers or splitters were
designed to solve that problem.

There are five main concerns when selecting a
coupler:

1. Type of fiber used (single- or multimode).
2. Number of input or output ports.
4. Wavelength selectivity.
5. Cost.

**15.11 Fiber Optic System Design**

#### 15.11.1 System Specifications

When designing an FO system, it is often best to order
all the component parts from one manufacturer; this
way you can be sure of the parts being compatible.
Many manufacturers have developed complete systems
and have components available for the asking. The fol-
lowing are important things to consider when selecting
parts and designing a system:

1. If system is analog:
   A. Bandwidth in hertz (Hz) or megahertz (MHz).
B. Distortion in decibels (dB).
C. Operating temperature range in degrees Celsius (°C).

2. If system is digital:
   A. Required BER. Upper BER is usually in megabits per second (Mbps). Lower BER is usually in bits per second (bps).
   B. Operating temperature range in degrees Celsius (°C).

3. If system is audio/video:
   A. Bandwidth in hertz (Hz) or megahertz (MHz).
   B. Distortion in decibels (dB).
   C. Crosstalk in decibels (dB) (for multiple channels).
   D. Operating temperature in degrees Celsius (°C).

15.11.1.1 Transmitter Specifications

1. Input impedance in ohms (Ω).
2. Maximum input signal in dc volts (Vdc), rms or effective volts (Vrms), peak-to-peak volts (Vp-p).
3. Optical wavelength in micrometers (μm) or nanometers (nm).
4. Optical power output in microwatts (μW) or (dBm).
5. Optical output rise time in nanoseconds (ns).
6. Required power supply dc voltage, usually 5 ±0.25 Vdc or 15 ±1 Vdc.

15.11.1.2 Light Source Specifications

1. Continuous forward current in milliamps (mA).
2. Pulsed forward current in milliamps (mA).
3. Peak emission wavelength in nanometers (nm).
4. Spectral width in nanometers (nm).
5. Peak forward voltage in dc volts (Vdc).
6. Reverse voltage in dc volts (Vdc).
7. Operating temperature range in degrees Celsius (°C).
8. Total optical power output in microwatts (μW).
9. Rise/fall times in nanoseconds (ns).

15.11.1.3 Fiber Specifications

1. Mode—single or multimode.
2. Index—step or graded.
3. Attenuation in decibels per kilometer (dB/km).
4. Numerical aperture (NA) (a sine value).
5. Intermodal dispersion in nanoseconds per kilometer (ns/km).
6. Core and cladding diameters in micrometers (μm).
7. Core and cladding index of refraction (a ratio).
8. Bend radius of fiber in centimeters (cm).
9. Tensile strength in pounds per square inch (psi).

15.11.1.4 Cable Specifications

1. Number of fibers (a unit).
2. Core and cladding diameters in micrometers (μm).
3. Cable diameter in millimeters (mm).
4. Minimum bend radius in centimeters (cm).
5. Weight in kilograms per kilometer (kg/km).

15.11.1.5 Detector Specifications

1. Continuous forward current in milliamps (mA).
2. Pulsed forward current in milliamps (mA).
3. Peak reverse voltage in dc volts (Vdc).
5. Wavelength in micrometers (μm) or nanometers (nm).
6. Quantum efficiency (η) in percent (%).
7. Responsivity in amps per watt (A/W).
8. Rise/fall time in nanoseconds (ns).
10. Active area diameter in micrometers (μm).
11. Gain coefficient in volts (V) (for APD).
12. Operating temperature in degrees Celsius (°C).

15.11.1.6 Receiver Specifications

1. Output impedance in ohms (Ω).
2. Output signal in dc volts dc (Vdc), rms or effective volts (Vrms), peak-to-peak volts (Vp-p).
3. Optical sensitivity in microwatts (μW), nanowatts (nW), decibels referenced to 1 mW (dBm), or megabits per second (Mbps).
4. Optical wavelength for rated sensitivity in nanometers (nm).
5. Maximum optical input power (peak) in microwatts (μW) or (dBm).
6. Analog/digital rise and fall time in nanoseconds (ns).
7. Propagation delay in nanoseconds (ns).
8. Required power supply in dc volts (Vdc).
9. TTL compatibility.
10. Optical dynamic range in decibels (dB).
11. Operating temperature in degrees Celsius (°C).

15.11.2 Design Considerations

Before designing a fiber optic system, certain factors must be realized.

1. What type of signal information is it?
2. Is signal analog or digital?
3. What is the information bandwidth?
4. What power is required?
5. What is the total length of the fiber optic cable?
6. What is the distance between transmitter and receiver?
7. Are there any physical obstacles that the cable must go through?
8. What are the tolerable signal parameters?
9. What is the acceptable SNR if system is analog?
10. What is the acceptable BER and rise/fall time if system is digital?

Once these parameters are established, the fiber optic system can be designed.

15.11.3 Design Procedures

The procedures for designing a fiber optic system are as follows:

1. Determine the signal bandwidth.
2. If the system is analog, determine the SNR. This is the ratio of output signal voltage to noise voltage, the larger the ratio the better. The SNR is expressed in decibels (dB). SNR curves are provided on detector data sheets.
3. If the system is digital, determine the BER. A typical good BER is $10^{-9}$, BER curves are provided on detector data sheets.
4. Determine the link distance between the transmitter and the receiver.
5. Select a fiber based on attenuation.
6. Calculate the fiber bandwidth for the system. This is done by dividing the bandwidth factor in megahertz per kilometer by the link distance. The bandwidth factor is found on fiber data sheets.
7. Determine the power margin. This is the difference between the light source power output and the receiver sensitivity.
8. Determine the total fiber loss by multiplying the fiber loss in dB/km by the length of the link in kilometers (km).
9. Count the number of FO connectors. Multiply the connector loss (provided by manufacturer data) by the number of connectors.
10. Count the number of splices. Multiply the splice loss (provided by manufacturer data) by the number of splices.
11. Allow 1 dB for source/detector coupling loss.
13. Allow 3 dB for time degradation.
14. Sum the fiber loss, connector loss, splice loss, source/detector coupling loss, temperature degradation loss, time degradation loss (add values of Steps 8 through 13) to find the total system attenuation.
15. Subtract the total system attenuation from the power margin. If the difference is negative, the light source power receiver sensitivity must be changed to create a larger power margin. A fiber with a lower loss may be chosen or the use of fewer connectors and splices may be an alternative if it is possible to do so without degrading the system.
16. Determine the rise time. To find the total rise time, add the rise time of all critical components, such as the light source, intermodal dispersion, intramodal dispersion, and detector. Square the rise times. Then take the square root of the sum of the total squares and multiply it by a factor of 110%, or 1.1, as in the following equation:

$$\text{System rise time} = 1.1 \sqrt{T_1^2 + T_2^2 + T_3^2 + \ldots + T_N^2} \quad (15-24)$$

15.11.3.1 Fiber Optic System Attenuation

The total attenuation of a fiber optic system is the difference between the power leaving the light source/transmitter and the power entering the detector/receiver. In Fig. 15-38, power entering the fiber is designated as $P_S$ or source power, $L_{C1}$ is the power loss at the source to fiber coupling, usually 1 dB per coupling. The power is of that signal launched into the fiber from the light source at the fiber coupling. $L_{F1}$ represents the loss in the fiber between the source and the splice. Fiber optic cable losses are listed in manufacturer’s spec sheets and are in dB/km. $L_{SP}$ represents the power loss at the splice. A typical power loss of a splice is 0.3 to 0.5 dB. $L_{F2}$ represents the power loss in the second length of fiber. $L_{C2}$ is the power loss at the fiber to detector coupling. Finally, $P_D$ is the power transmitted into the detector. Other power losses due to temperature and time degradation are generally around 3 dB loss each. Power at the detector is then generalized as

$$P_D = P_S - (L_{C1} + L_{F1} + L_{SP} + L_{F2} + L_{C2}) \quad (15-25)$$

Note: All power and losses are expressed in decibels (dB).

15.11.3.2 Additional Losses

If the core of the receiving fiber is smaller than that of the transmitting fiber, loss is introduced. The following equation can be used to determine the coupling loss from fiber to fiber:

$$L_{dia} = -10 \log \left( \frac{\text{dia}_t}{\text{dia}_r} \right)^2 \quad (15-26)$$
where,
\[ L_{\text{dia}} = \text{the loss level of the core’s diameter,} \]
\[ d_{\text{ia}} \text{ is the diameter of the receiving fiber core in } \mu\text{m,} \]
\[ d_{\text{iat}} \text{ is the diameter of the transmitting fiber core in } \mu\text{m.} \]

No diameter mismatch loss occurs when light passes from a smaller core to a larger core.

Differences in NA also contribute loss when the input NA of the receiving fiber is less than that of the output NA of the transmitting fiber:

\[ L_{\text{NA}} = -10\log \left( \frac{N_{\text{A}_{\text{r}}}}{N_{\text{A}_{\text{t}}}} \right)^2 \]  
(15-27)

where,
\[ L_{\text{NA}} \text{ is the loss level of the numerical aperture,} \]
\[ N_{\text{A}_{\text{r}}} \text{ is the receiving numerical aperture,} \]
\[ N_{\text{A}_{\text{t}}} \text{ is the transmitting numerical aperture.} \]

Calculation of the NA loss requires that the output NA of the transmitting fiber be known. Since the actual output NA varies with source, fiber length, and modal patterns, using the material NA yields misleading results. No NA mismatch loss occurs when the receiving fiber has an NA greater than that of the transmitting fiber.

The loss of optical power from mismatches in NA and diameter between the source and the core of multimode fiber is as follows:

- When the diameter of the source is greater than the core diameter of the fiber, the mismatch loss is

\[ L_{\text{dia}} = -10\log \left( \frac{d_{\text{ia}}}{d_{\text{ifs}}_{\text{h}}} \right)^2 \text{ in dB} \]  
(15-28)

where,
\[ L_{\text{dia}} \text{ is the level of core diameter mismatch loss.} \]

- No loss occurs when the core diameter of the fiber is larger. When the NA of the source is larger than the NA of the fiber, the mismatch loss is

\[ L_{\text{NA}} = -10\log \left( \frac{N_{\text{A}_{\text{s}}}}{N_{\text{A}_{\text{f}}}} \right)^2 \text{ in dB} \]  
(15-29)

where,
\[ L_{\text{NA}} \text{ is the numerical aperture mismatch loss.} \]

- No loss occurs when the fiber NA is the larger. Area or diameter loss occurs when a source’s area or diameter of emitted light is larger than the core of the fiber. (Area is often used instead of diameter because of the elliptical beam pattern of edge emitters and lasers.) Area or diameter loss is equal to

\[ L_{\text{area}} = -10\log \left( \frac{\text{area}_{\text{fiber}}}{\text{area}_{\text{source}}} \right) \text{ in dB} \]  
(15-30)

where,
\[ L_{\text{area}} \text{ is the loss level of the area.} \]

Data sheets for sources often give the area and NA of the output. Although some may not, they may be calculated from information such as polar graphs that are often provided. Calculation of the NA loss and area loss yields an estimate of loss resulting from optical differences between source and fiber. Additional interconnection loss comes from connector related loss, which includes Fresnel reflections and misalignment contributed by a connector.

As with sources, two main causes of loss in coupling light from a fiber into the detector results from mismatches in diameter and NA. When \( d_{\text{det}} < d_{\text{fiber}} \), then

\[ L_{\text{dia}} = -10\log \left( \frac{d_{\text{det}}}{d_{\text{fiber}}} \right)^2 \text{ in dB} \]  
(15-31)

When \( N_{\text{A}_{\text{det}}} < N_{\text{A}_{\text{fiber}}} \), then

\[ L_{\text{NA}} = -10\log \left( \frac{N_{\text{A}_{\text{det}}}}{N_{\text{A}_{\text{fiber}}}^2} \right) \text{ in dB} \]  
(15-33)

where,
\[ L_{\text{dia}} \text{ is the loss level of the diameter,} \]
\[ L_{\text{NA}} \text{ is the loss level of the numerical aperture.} \]

Since detectors can be easily manufactured with large active diameters and wide angles of view, such mismatches are less common than with sources. Other losses occur from Fresnel reflections and mechanical
misalignment between the connector and the diode package.

15.12 Fiber Optic Considerations

The professional audio engineer, technician or personnel is now facing many new challenges of distributing audio signals. The use of fiber optics is becoming easier, more efficient and cost effective over its copper counterpart. The many breakthroughs in fiber optic technology are leading the way into the future. Glass optical fiber cables are more robust and cost effective enough to use for longer runs exceeding 2 km. Plastic fibers (POFs) are very good at shorter distances (25 ft or less), but they do not meet the fire codes for most building structures. Jitter still seems to be problematic with POFs even at 15 feet in some cases. However, plastic fiber is improving by mixing combinations of glass and plastic which is referred to as plastic-clad silica (PCS) (plastic cladding and glass core). These PCS are being used in industrial applications as well as some telecommunication areas. There are many types of fiber optic system link designs. Usually, the designer is far better off designing and buying components from one or two vendors, which took the guess work out of system compatibility. The advancements of tools for connecting and splicing optical fibers has now become simple and time efficient enough to easily integrate in any audio system. As bandwidths keep increasing, the only thing that will keep up with it is fiber optics. The integrity of the audio signals will not be altered, while keeping the quality at high levels. We are now experiencing fiber to the home FTTH and, to coin a phrase, fiber to the studio FTTS. The audio community is seeing many technological breakthroughs and these fiber optic cables, connectors, and opto-chips are becoming an integral part of pro-audio systems.

15.13 Glossary of Fiber Optic Terms

Absorption: Together with scattering, absorption forms the principal cause of the attenuation of an optical waveguide. It results from unwanted impurities in the waveguide material and has an effect only at certain wavelengths.

Angle of Incidence: The angle between an incident ray and the normal to a reflecting surface.

Attenuation: The reduction of average optical power in an optical waveguide, expressed in dB. The main causes are scattering and absorption, as well as optical losses in connectors and splices. Attenuation or loss is expressed by

\[
\mu = -10\log\left(\frac{P_o}{P_i}\right) \text{ dB}
\]

Attenuator: An optical element that reduces intensity of a optical signal passing through it (i.e., attenuates it). Example: AT&T makes attenuators built into connectors that incorporate a biconic sleeve consisting of a carbon-coated mylar filter. They come in steps of 6 dB, 12 dB, 16 dB, and 22 dB values.

Avalanche Photodiode (APD): A photodiode designed to take advantage of avalanche multiplication of photocurrent. As the reverse-bias voltage approaches the breakdown voltage, hole-electron pairs created by absorbed photons acquire sufficient energy to create additional hole-electron pairs when they collide with ions; thus, a multiplication or signal gain is achieved.

Axial Ray: A light ray that travels along the axis of an optical fiber.

Backscattering: A small fraction of light that is deflected out of the original direction of propagation by scattering suffers a reversal of direction. In other words, it propagates in the optical waveguide towards the transmitter.

Bandwidth: The lowest frequency at which the magnitude of the waveguide transfer function decreases to 3 dB (optical power) below its zero frequency value. The bandwidth is a function of the length of the waveguide, but may not be directly proportional to the length.

Bandwidth Distance Product (BDP): The bandwidth distance product is a figure of merit that is normalized for a distance of 1 km and is equal to the product of the fiber’s length and the 3 dB bandwidth of the optical signal. The bandwidth distance product is usually expressed in megahertz*kilometer (MHz*km) or gigahertz*kilometer (GHz*km). For example, a common multimode fiber with bandwidth-distance product of 500 MHz*km could carry a 500 MHz signal for 1 km. Therefore, a 1000 MHz or 1 GHz signal for 0.5 km. Thus, as the distance increases, for 2 km, the BDP would be 250 MHz etc.

Beamsplitter: A device used to divide or split an optical beam into two or more separate beams.

Beamwidth: The distance between two diametrically opposed points at which the irradiance is a specified fraction of the beam’s peak irradiance; Beamwidth is most often applied to beams that are circular in cross section.
BER (Bit Error Rate): In digital applications, the ratio of bits received in error to bits sent. BERs of one errored bit per billion \((1 \times 10^{-9})\) sent are typical.

Buffer: Material used to protect optical fiber from physical damage, providing mechanical isolation and/or protection. Fabrication techniques include tight or loose tube buffering, as well as multiple buffer layers.

Burrus LED: A surface-emitting LED with a hole etched to accommodate a light-collecting fiber. Named after its inventor, Charles A. Burrus of Bell Labs.

Chromatic Dispersion: Spreading of a light pulse caused by the difference in refractive indices at different wavelengths.

Cladding: The dielectric material surrounding the core of an optical fiber.

Coarse Wavelength Division Multiplexing (CWDM): CWDM is a cost-effective solution to dense wavelength division modulation (DWDM) that was developed to have channel spacing by the International Telecommunication Union (ITU) in 2002. This standard allows for a 20 nm spacing of channels using wavelengths between 1270 nm and 1610 nm.

Coherent: Light source (laser) in which the amplitude of all waves is exactly equivalent and rise and fall together.

Core: The central region of an optical fiber through which light is transmitted.

Coupler: An optical component used to split or combine optical signals. Also known as a “Splitter,” “T-coupler,” “2 × 2,” or “1 × 2” coupler.

Coupling Loss: The power loss suffered when coupling light from one optical device to another.

Critical Angle: The smallest angle from the fiber axis at which a ray may be totally reflected at the core-cladding interface.

Cutoff Wavelength: The shortest wavelength at which only the fundamental mode of an optical waveguide is capable of propagation.

Dark Current: The external current that, under specified biasing conditions, flows in a photodetector when there is no incident radiation.

Data Rate: The maximum number of bits of information that can be transmitted per second, as in a data transmission link. Typically expressed as megabits per second (Mb/s).

Decibel (dB): The standard unit of level used to express gain or loss of optical or electrical power.

Dense Wavelength Division Multiplexing (DWDM): An enhancement of WDM (see Wavelength Division Multiplexing) that uses many wavelengths in the 1550 nm window (ranges 1530 nm to 1560 nm) for transmitting multiple signals, and often uses fiber optic amplification. Many narrowband transmitters send signals to a DWDM Optical Multiplexer (Mux), which combines all of the signals onto a single fiber. At the other end a DWDM Optical Demultiplexer (Demux) separates the signals out to the many receivers.

Detector: A transducer that provides an electrical output signal in response to an incident optical signal. The current is dependent on the amount of light received and the type of device.

Dispersion: Spread of the signal delay in an optical waveguide. It consists of various components: modal dispersion, material dispersion, and waveguide dispersion. As a result of its dispersion, an optical waveguide acts as a low-pass filter for the transmitted signals.

Ferrule: A component of a fiber optic connection that holds a fiber in place and aids in its alignment.

Fiber Data Distributed Interface (FDDI): An emerging standard developed by AT&T, Hewlett-Packard Co, and Siemens Corp., using a 100 Mbps token ring network that employs dual optical fibers.

Fiber Optic: Any filament or fiber made of dielectric materials, that guides light.

Fiber Optic Link: A fiber optic cable with connectors attached to a transmitter (source) and receiver (detector).

Fresnel Reflection: The reflection of a portion of the light incident on a planar surface between two homogeneous media having different refractive indices. Fresnel reflection occurs at the air–glass interfaces at entrance and exit ends of an optical fiber.

Fundamental Mode: The lowest order mode of a waveguide.

Graded Index Fiber: An optical fiber with a variable refractive index that is a function of the radial distance from the fiber axis.

Incoherent: An LED light source that emits incoherent light as opposed to the laser which emits coherent light. (See Coherent.)
Index Matching Material: A material, often a liquid or cement, whose refractive index is nearly equal to the core index, used to reduce Fresnel reflections from a fiber end face.

Index of Refraction: See Refractive Index.

Injection Laser Diode (ILD): Laser diode.

Insertion Loss: The attenuation caused by the insertion of an optical component. In other words, a connector or coupler in an optical transmission system.

Intensity: Irradiance.

Integrated Optical Components (IOCs): Optical devices (singly or in combination) that use light transmission in waveguides. The waveguides structure and confine the propagating light to a region with one or two very small dimensions of the order of the wavelength of light. A common material used in the fabrication process of an IOC is Lithium Niobate (LiNbO).

Intermodal Distortion: Multimode distortion.

Irradiance: Power density at a surface through which radiation passes at the radiating surface of a light source or at the cross section of an optical waveguide. The normal unit is watts per centimeters squared, or W/cm².

Laser Diode (LD): Semiconductor diode that emits coherent light above a threshold current.

Launch Angle: Angle between the propagation direction of the incident light and the optical axis of an optical waveguide.

Launching Fiber: A fiber used in conjunction with a source to excite the modes of another fiber in a particular way. Launching fibers are most often used in test systems to improve the precision of measurements.

Light: In the laser and optical communication fields, the portion of the electromagnetic spectrum that can be handled by the basic optical techniques used for the visible spectrum extending from the near ultraviolet region of approximately 0.3 micron, through the visible region and into the mid infrared region of about 30 microns.

Light Emitting Diode (LED): A semiconductor device that emits incoherent light from a p-n junction when biased with an electrical current in the forward direction. Light may exit from the junction strip edge or from its surface, depending on the device’s structure.

Lightwaves: Electromagnetic waves in the region of optical frequencies. The term light was originally restricted to radiation visible to the human eye, with wavelengths between 400 nm and 700 nm. However, it has become customary to refer to radiation in the spectral regions adjacent to visible light (in the near infrared from 700 nm to about 2000 nm) as light to emphasize the physical and technical characteristics they have in common with visible light.

Macro bending: Macroscopic axial deviations of a fiber from a straight line, in contrast to microbending.

Microbending: Curvatures of the fiber that involve axial displacements of a few micrometers and spatial wavelengths of a few millimeters. Microbends cause loss of light and consequently increase the attenuation of the fiber.

Micron: Micrometer (μm). One millionth of a meter (1 × 10⁻⁶ m).

Modal Dispersion: Pulse spreading due to multiple light rays traveling different distances and speeds through an optical fiber.

Modal Noise: Disturbance in multimode fibers fed by laser diodes. It occurs when the fibers contain elements with mode-dependent attenuation, such as imperfect splices, and is more severe the better the coherence of the laser light.

Modes: Discrete optical waves that can propagate in optical waveguides. They are eigenvalue solutions to the differential equations that characterize the waveguide. In a single-mode fiber, only one mode, the fundamental mode, can propagate. There are several hundred modes in a multimode fiber that differ in field pattern and propagation velocity. The upper limit to the number of modes is determined by the core diameter and the numerical aperture of the waveguide.

Modified Chemical Vapor Deposition (MCVD) Technique: A process in which deposits are produced by heterogeneous gas/solid and gas/liquid chemical reactions at the surface of a substrate. The MCVD method is often used in fabricating optical waveguide preforms by causing gaseous material to react and deposit glass oxides. Typical starting chemicals include volatile compounds of silicon, germanium, phosphorus, and boron, which form corresponding oxides after heating with oxygen or other gases. Depending on its type, the preform may be processed further in preparation for pulling into an optical fiber.

Monochromatic: Consisting of a single wavelength. In practice, radiation is never perfectly monochromatic but, at best, displays a narrow band of wavelengths.
**Multimode Distortion**: The signal distortion in an optical waveguide resulting from the superposition of modes with differing delays.

**Multimode Fiber**: Optical waveguide whose core diameter is large compared with the optical wavelength and in which, consequently, a large number of modes are capable of propagation.

**Nanometer (nm)**: One billionth of a meter ($1 \times 10^{-9}$ m).

**Noise Equivalent Power (NEP)**: The rms value of optical power that is required to produce an rms SNR of 1; an indication of noise level that defines the minimum detectable signal level.

**Numerical Aperture**: A measure of the range of angles of incident light transmitted through a fiber. Depends on the differences in index of refraction between the core and the cladding.

**Optical Fiber Class (OM1, OM2, OM3, and OS1 designations in accordance with ISO11801)**: Bandwidth and the maximum transmission distance of different optical fiber classes for 10G Ethernet application, Table 15-6.

**Optical Time Domain Reflectometer (OTDR)**: A method for characterizing a fiber wherein an optical pulse is transmitted through the fiber and the resulting backscatter and reflections to the input are measured as a function of time. Useful in estimating the attenuation coefficient as a function of distance and identifying defects and other localized losses.

**Optoelectronic**: Any device that functions as an electrical-to-optical or optical-to-electrical transducer.

**Optoelectronic Integrated Circuits (OEICs)**: Combination of electronic and optical functions in a single chip.

**Peak Wavelength**: The wavelength at which the optical power of a source is at a maximum.

**Photocurrent**: The current that flows through a photosensitive device, such as a photodiode, as the result of exposure to radiant power.

**Photodiode**: A diode designed to produce photocurrent by absorbing light. Photodiodes are used for the detection of optical power and for the conversion of optical power into electrical power.

**Photon**: A quantum of electromagnetic energy.

**Pigtail**: A short length of optical fiber for coupling optical components. It is usually permanently fixed to the components.

**PIN-FET Receiver**: An optical receiver with a PIN photodiode and low noise amplifier with a high impedance input, whose first stage incorporates a field-effect transistor (FET).

**PIN Photodiode**: A diode with a large intrinsic region sandwiched between $p$-doped and $n$-doped semiconducting regions. Photons in this region create electron hole pairs that are separated by an electric field thus generating an electric current in the load circuit.

**Plastic Optical Fiber (POF)**: An optical fiber composed of plastic instead of glass. POFs are used for short distances of typically 25 ft or less.

**Preform:** A glass structure from which an optical fiber waveguide may be drawn.

**Primary Coating:** The plastic coating applied directly to the cladding surface of the fiber during manufacture to preserve the integrity of the surface.

**Ray:** A geometric representation of a light path through an optical medium; a line normal to the wavefront indicating the direction of radiant energy flow.

**Rayleigh Scattering:** Scattering by refractive index fluctuations (inhomogeneities in material density or composition) that are small with respect to wavelength.

**Receiver:** A detector and electronic circuitry to change optical signals into electrical signals.

**Receiver Sensitivity:** The optical power required by a receiver for low error signal transmission. In the case of digital signal transmission, the mean optical power is usually quoted in watts or dBm (decibels referenced to 1 mW).

**Reflection:** The abrupt change in direction of a light beam at an interface between two dissimilar media so that the light beam returns to the media from which it originated.

**Refraction:** The bending of a beam of light at an interface between two dissimilar media or in a medium whose refractive index is a continuous function of position (graded index medium).

**Refractive Index:** The ratio of the velocity of light in a vacuum to that in an optically dense medium.

**Repeater:** In a lightwave system, an optoelectronic device or module that receives an optical signal, converts it to electrical form, amplifies or reconstructs it, and retransmits it in optical form.

**Responsivity:** The ratio of detector output to input, usually measured in units of amperes per watt (or microamperes per microwatt).

**Single-Mode Fiber:** Optical fiber with a small core diameter in which only a single mode—the fundamental mode—is capable of propagation. This type of fiber is particularly suitable for wideband transmission over large distances, since its bandwidth is limited only by chromatic dispersion.

**Source:** The means (usually LED or laser) used to convert an electrical information carrying signal into a corresponding optical signal for transmission by an optical waveguide.

**Splice:** A permanent joint between two optical waveguides.

**Spontaneous Emission:** This occurs when there are too many electrons in the conduction band of a semiconductor. These electrons drop spontaneously into vacant locations in the valence band, a photon being emitted for each electron. The emitted light is incoherent.

**ST Connector:** A type of connector used on fiber optic cable utilizing a spring-loaded twist and lock coupling similar to the BNC connectors used with coax cable.

**Star Coupler:** An optical component used to distribute light signals to a multiplicity of output ports. Usually the number of input and output ports are identical.

**Step Index Fiber:** A fiber having a uniform refractive index within the core and a sharp decrease in refractive index at the core-cladding interface.

**Stimulated Emission:** A phenomenon that occurs when photons in a semiconductor stimulate available excess charge carriers to the emission of photons. The emitted light is identical in wavelength and phase with the incident coherent light.

**Superluminescent Diodes (SLDs):** Superluminescent diodes (SLDs) are distinguished from both laser diodes and LEDs in that the emitted light consists of amplified spontaneous emission having a spectrum much narrower than that of LEDs but wider than that of lasers.

**T (or Tee) Coupler:** A coupler with three ports.

**Threshold Current:** The driving current above which the amplification of the light-wave in a laser diode becomes greater than the optical losses, so that stimulated emission commences. The threshold current is strongly temperature dependent.

**Total Internal Reflection:** The total reflection that occurs when light strikes an interface at angles of incidence greater than the critical angle.

**Transmission Loss:** Total loss encountered in transmission through a system.

**Transmitter:** A driver and a source used to change electrical signals into optical signals.

**Tree Coupler:** An optical component used to distribute light signals to a multiplicity of output ports. Usually the number of output ports is greater than the number of input ports.
Vertical Cavity Surface Emitting Laser (VCSEL): A specialized laser diode that promises to revolutionize fiber optic communications by improving efficiency and increasing data speed. The acronym VCSEL is pronounced vixel. Typically used for the 850 nm and 1300 nm windows.

Y Coupler: A variation on the T coupler in which input light is split between two channels (typically planar waveguide) that branch out like a Y from the input.

Wavelength Division Multiplexing (WDM): Simultaneous transmission of several signals in an optical waveguide at differing wavelengths.

Window: Refers to ranges of wavelengths matched to the properties of the optical fiber. The window ranges for fiber optics are the following: First window, 820 nm to 850 nm; second window, 1300 nm to 1310 nm; and third window, 1550 nm.

16.1 Introduction

All sound sources have different characteristics; their waveform varies, their phase characteristics vary, their dynamic range and attack time vary and their frequency response varies, just to name a few. No one microphone will reproduce all of these characteristics equally well. In fact, each sound source will sound better or more natural with one type or brand of microphone than all others. For this reason we have and always will have many types and brands of microphones.

Microphones are electroacoustic devices that convert acoustical energy into electrical energy. All microphones have a diaphragm or moving surface that is excited by the acoustical wave. The corresponding output is an electrical signal that represents the acoustical input.

Microphones fall into two classes: pressure and velocity. In a pressure microphone the diaphragm has only one surface exposed to the sound source so the output corresponds to the instantaneous sound pressure of the impressed sound waves. A pressure microphone is a zero-order gradient microphone, and is associated with omni-directional characteristics.

The second class of microphone is the velocity microphone, also called a first-order gradient microphone, where the effect of the sound wave is the difference or gradient between the sound wave that hits the front and the rear of the diaphragm. The electrical output corresponds to the instantaneous particle velocity in the impressed sound wave. Ribbon microphones as well as pressure microphones that are altered to produce front-to-back discrimination are of the velocity type.

Microphones are also classified by their pickup pattern or how they discriminate between the various directions the sound source comes from, Fig. 16-1. These classifications are:

- Omnidirectional—pickup is equal in all directions.
- Bidirectional—pickup is equal from the two opposite directions (180°) apart and zero from the two directions that are 90° from the first.
- Unidirectional—pickup is from one direction only, the pickup appearing cardioid or heart-shaped.

The air particle relationships of the air particle displacement, velocity, and acceleration that a microphone sees as a plane wave in the far field, are shown in Fig. 16-2.

16.2 Pickup Patterns

Microphones are made with single- or multiple-pickup patterns and are named by the pickup pattern they employ. The pickup patterns and directional response characteristics of the various types of microphones are shown in Fig. 16-1.

Figure 16-1. Performance characteristics of various microphones.
The omnidirectional, or spherical, polar response of the pressure microphones, Fig. 16-3 is created because the diaphragm is only exposed to the acoustic wave on the front side. Therefore, no cancellations are produced by having sound waves hitting both the front and rear of the diaphragm at the same time.

Omnidirectional microphones become increasingly directional as the diameter of the microphone reaches the wavelength of the frequency in question, as shown in Fig. 16-4; therefore, the microphone should have the smallest diameter possible if omnidirectional characteristics are required at high frequencies. The characteristic that allows waves to bend around objects is known as diffraction and happens when the wavelength is long compared to the size of the object. As the wavelength approaches the size of the object, the wave cannot bend sharply enough and, therefore, passes by the object. The various responses start to diverge at the frequency at which the diameter of the diaphragm of the microphone, \( D \), is approximately one-tenth the wavelength, \( \lambda \), of the sound arriving as equation

\[
D = \frac{\lambda}{10} \tag{16-1}
\]

The frequency, \( f \), at which the variation begins is

\[
f = \frac{v}{10D} \tag{16-2}
\]

where,
\( v \) is the velocity of sound in feet per second, or meters per second,
\( D \) is the diameter of the diaphragm in feet or meters.

For example, a ½ inch (1.27 cm) microphone will begin to vary from omnidirectional, though only slightly, at

\[
f = \frac{1130}{\left(10 \times \frac{0.5}{12}\right)} = 2712 \text{ Hz}
\]

and will be down approximately 3 dB at 10,000 Hz.

Omnidirectional microphones are capable of having a very flat, smooth frequency response over the entire audio spectrum because only the front of the diaphragm is exposed to the source, eliminating phase cancellations found in unidirectional microphones.

For smoothness of response the smaller they are, the better. The problem usually revolves around the

Figure 16-2. Air particle motion in a sound field, showing relationship to velocity and acceleration.

16.2.1 Omnidirectional Microphones

The omnidirectional, or spherical, polar response of the pressure microphones, Fig. 16-3 is created because the diaphragm is only exposed to the acoustic wave on the front side. Therefore, no cancellations are produced by having sound waves hitting both the front and rear of the diaphragm at the same time.

Omnidirectional microphones become increasingly directional as the diameter of the microphone reaches

Figure 16-3. Omnidirectional pickup pattern. Courtesy Shure Incorporated.
smallest diaphragm possible versus the lowest
signal-to-noise ratio, SNR, or put another way, the
smaller the diaphragm, the lower the microphone sensi-
tivity, therefore, the poorer the SNR.

Omnidirectional microphones have very little prox-
imity effect. See Section 16.2.3.1 for a discussion on
proximity effect.

Because the pickup pattern is spherical, the random
energy efficiency is 100%, and the ratio of front
response to back or side is 1:1, therefore signals from
the sides or rear will have the same pickup sensitivity as
from the front, giving a directivity index of 0 dB. This
can be helpful in picking up wanted room characteris-
tics or conversations around a table as when recording a
symphony. However, it can be detrimental when in a
noisy environment.

Omnidirectional microphones are relatively free
from mechanical shock because the output at all
frequencies is high; therefore, the diaphragm can be
stiff. This allows the diaphragm to follow the magnet or
stationary system it operates against when subjected to
mechanical motion (see Section 16.3.3).

16.2.2 Bidirectional Microphones
A bidirectional microphone is one that picks up from
the front and back equally well with little or no pickup
from the sides. The field pattern, Fig. 16-5, is called a
figure eight.

Because the microphone discriminates between the
front, back, and sides, random energy efficiency is 33%.
In other words, background noise, if it is in a rever-
berant field, will be 67% lower than with an omnidirec-
tional microphone. The front-to-back response will still
remain one; however, the front-to-side response will
approach infinity, producing a directivity index of 4.8.
This can be extremely useful when picking up two
conversations on opposite sides of a table. Because of
the increased directional capabilities of the micro-
phone, pickup distance is 1.7 times greater before feed-
back in the direct field than for an omnidirectional
microphone. The included pickup cone angle shown in
Fig. 16-6 for 6 dB attenuation on a perfect bidirectional
microphone is 120° off the front of the microphone and
120° off the rear of the microphone. Because of diffrac-
tion, this angle varies with frequency, becoming
narrower as the frequency increases.

16.2.3 Unidirectional Microphones
Unidirectional microphones have a greater sensitivity to
sound pickup from the front than any other direction.

The average unidirectional microphone has a
front-to-back ratio of 20–30 dB; that is, it has 20–30 dB
greater sensitivity to sound waves approaching from the
front than from the rear.

Unidirectional microphones are usually listed as
cardioid or directional, Fig. 16-7, supercardioid, Fig.
16-8, or hypercardioid, Fig. 16-9. The pickup pattern is
called cardioid because it is heart shaped. Unidirec-
tional microphones are the most commonly used micro-

Figure 16-5. Bidirectional pickup pattern. Courtesy
Sennheiser Electronic Corporation.

Figure 16-6. Polar pattern of a typical bidirectional ribbon
velocity microphone showing the narrowing pattern at high
frequencies.
phones because they discriminate between signal and random unwanted noise. This has many advantages including:

- Less background noise,
- More gain before feedback especially when used in the direct field,
- Discrimination between sound sources.

The cardioid pattern can be produced by one of two methods:

1. The first method combines the output of a pressure diaphragm and a pressure-gradient diaphragm, as shown in Fig. 16-10. Since the pressure-gradient diaphragm has a bidirectional pickup pattern and the pressure diaphragm has an omnidirectional pickup pattern, the wave hitting the front of the diaphragms add, while the wave hitting the rear of the diaphragm cancels as it is 180° out-of-phase with the rear pickup pattern of the pressure diaphragm. This method is expensive and seldom used for sound reinforcement or general-purpose microphones.

2. The second and most widely used method of producing a cardioid pattern is to use a single diaphragm and acoustically delay the wave reaching the rear of the diaphragm. When a wave approaches from the front of the diaphragm, it first hits the front and then the rear of the diaphragm after traveling through an acoustical delay circuit, as shown in Fig. 16-11A. The pressure on the front of the diaphragm is at 0° while on the rear of the
Microphones

497

diaphragm it is some angle between 0° and 180°, as shown in Fig. 16-11B. If the rear pressure was at 0°, the output would be 0. It would be ideal if the rear pressure were at 180° so that it could add to the input, doubling the output.

![Diagram of microphone sensitivity and phase inversion](image)

**Figure 16-11.** Cardioid microphone employing acoustical delay.

The phase inversion is caused by the extra distance the wave has to travel to reach the back of the diaphragm. When the wave is coming from the rear of the microphone, it hits the front and back of the diaphragm at the same time and with the same polarity, therefore canceling the output.

The frequency response of cardioid microphones is usually rougher than an omnidirectional microphone due to the acoustical impedance path and its effects on the front wave response. The front and rear responses of a cardioid microphone are not the same. Although the front pattern may be essentially flat over the audio spectrum, the back response usually increases at low and high frequencies, as shown in Fig. 16-12.

![Graph of frequency response](image)

**Figure 16-12.** Frequency response of a typical cardioid microphone.

**16.2.3.1 Proximity Effects**

As the source is moved closer to the diaphragm, the low-frequency response increases due to the proximity effect, Fig. 16-13. The proximity effect is created because at close source-to-microphone distance, the magnitude of the sound pressure on the front is appreciably greater than the sound pressure on the rear. In the vector diagram shown in Fig. 16-14A, the sound source was a distance greater than 2 ft from the microphone. The angle $2KD$ is found from $D$, which is the acoustic distance from the front to the rear of the diaphragm and $K = 2\pi/\lambda$. Fig. 16-14B shows the vector diagram when used less than 4 inches to the sound source.

![Vector diagram of microphone response](image)

**Figure 16-14.** Vector diagram of a unidirectional microphone. Courtesy Telex Electro-Voice.
In both cases, force $F_1$, the sound pressure on the front of each diaphragm, is the same. Force $F_2$ is the force on the back of the diaphragm when the microphone is used at a distance from the sound source, and $F_0$ is the resultant force. The force $F_2'$ on the back of the diaphragm is created by a close sound source. Laterally, the vector sum $F_0'$ is considerably larger in magnitude than $F_0$ and therefore produces greater output from the microphone at low frequencies. This can be advantageous or disadvantageous. It is particularly useful when vocalists want to add low frequency to their voice or an instrumentalist to add low frequencies to the instrument. This is accomplished by varying the distance between the microphone and the sound source, increasing bass as the distance decreases.

16.2.3.1.1 Frequency Response

Frequency response is an important specification of unidirectional microphones and must be carefully analyzed and interpreted in terms of the way the microphone is to be used. If a judgment as to the sound quality of the microphone is made strictly from a single on-axis response, the influence of the proximity effect and off-axis response would probably be overlooked. A comparison of frequency response as a function of microphone-to-source distance will reveal that all unidirectional microphones experience a certain amount of proximity effect. In order to evaluate a microphone, this variation with distance is quite important.

When using a unidirectional microphone in a handheld or stand-mounted configuration, it is conceivable that the performer will not always remain exactly on axis. Variations of ±45° often occur, and so a knowledge of the uniformity of response over such a range is important. The nature of these response variations is shown in Fig. 16-15. Response curves such as these give a better indication of this type of off-axis performance than polar response curves. The polar response curves are limited in that they are usually given for only a few frequencies, therefore, the complete spectrum is difficult to visualize.

For applications involving feedback control or noise rejection, the polar response or particular off-axis response curves, such as at 135° or 180°, are important. These curves can often be misleading due to the acoustic conditions and excitation signals used. Such measurements are usually made under anechoic conditions at various distances with sine-wave excitation. Looking solely at a rear response curve as a function of frequency is misleading since such a curve does not indicate the polar characteristic at any particular frequency, but only the level at one angle. Such curves also tend to give the impression of a rapidly fluctuating high-frequency discrimination. This sort of performance is to be expected since it is virtually impossible to design a microphone of practical size with a constant angle of best discrimination at high frequencies, Fig. 16-16. The principal factor influencing this variation in rear response is diffraction, which is caused by the physical presence of the microphone in the sound field. This diffraction effect is frequency dependent and tends to disrupt the ideal performance of the unidirectional phase-shift elements.

To properly represent this high-frequency off-axis performance, a polar response curve is of value, but it, too, can be confusing at high frequencies. The reason for this confusion can be seen in Fig. 16-17, where two polar response curves only 20 Hz apart are shown. The question that arises then is how can such performance be properly analyzed? A possible solution is to run polar response curves with bands of random noise such as octave of pink noise. Random noise is useful because of its averaging ability and because its amplitude distribution closely resembles program material.

Anechoic measurements are only meaningful as long as no large objects are in close proximity to the microphone. The presence of the human head in front of a
microphone will seriously degrade the effective high-frequency discrimination. An example of such degradation can be seen in Fig. 16-18 where a head object was placed 2 in (5 cm) in front of the microphone. (The two curves have not been normalized.) This sort of performance results from the head as a reflector and is a common cause of feedback as one approaches a microphone. This should not be considered as a shortcoming of the microphone, but rather as an unavoidable result of the sound field in which it is being used. At 180°, for example, the microphone sees, in addition to the source it is trying to reject, a reflection of that source some 2 in (5 cm) in front of its diaphragm. This phenomenon is greatly reduced at low frequencies because the head is no longer an appreciable obstacle to the sound field. It is thus clear that the effective discrimination of any unidirectional microphone is greatly influenced by the sound field in which it is used.

16.2.3.1.3 Single-Entry Cardioid Microphones

All single-entrant cardioid microphones have the rear entrance port located at one distance from the rear of the diaphragm. The port location is usually within 1½ in (3.8 cm) of the diaphragm and can cause a large proximity effect. The Electro-Voice DS35 is an example of a single-entrant cardioid microphone, Fig. 16-20.

The low-frequency response of the DS35 varies as the distance from the sound source to the microphone decreases, Fig. 16-21. Maximum bass response is produced in close-up use with the microphone 1½ in (3.8 cm) from the sound source. Minimum bass response is experienced at distances greater than 2 ft (0.6 m). Useful effects can be created by imaginative application of the variable low-frequency response.

Another single-entrant microphone is the Shure SM-81. The acoustical system of the microphone operates as a first-order gradient microphone with two sound openings, as shown in Fig. 16-22. Fig. 16-23 shows a simplified cross-sectional view of the transducer, and Fig. 16-23 indicates the corresponding electrical analog circuit of the transducer and preamplifier.
One sound opening, which is exposed to the sound pressure $p_1$, is represented by the front surface of the diaphragm. The other sound opening, or rear entry, consists of a number of windows in the side of the transducer housing where the sound pressure $p_2$ prevails. The diaphragm has an acoustical impedance $Z_0$, which also includes the impedance of the thin air film between the diaphragm and backplate. The sound pressure $p_2$ exerts its influence on the rear surface of the diaphragm via a screen mounted in the side windows of the transducer housing, having a resistance $R_1$ and inerance $L_1$, through the cavity $V_1$ with compliance $C_1$. A second screen has a resistance $R_2$ and inerance $L_2$, through a second cavity $V_2$ with compliance $C_2$, and finally through the perforations in the backplate.

The combination of circuit elements $L_1, R_1, C_1, L_2, R_2, C_2$ forms a ladder network with lossy inerances, and is called a lossy ladder network. The transfer characteristic of this network enforces a time delay on the pressure $p_2$ imparting directional (cardioid) characteristics for low and medium frequencies. At high frequencies the attenuation caused by the network is large, and the resulting pressure arriving at the back of the diaphragm due to $p_2$ is small. The microphone then operates much like an omnidirectional system under the predominant influence of $p_1$. At these frequencies directional characteristics are attained by diffraction of the sound around a suitably shaped transducer housing.

A rotary low-frequency response shaping switch allows the user to select between a flat and a 6 dB/octave roll-off at 100 Hz or an 18 dB/octave cutoff at 80 Hz. The 100 Hz roll-off compensates for the proximity effect associated with a 6 in (15 cm) source to microphone distance, while the 80 Hz cutoff significantly reduces most low-frequency disturbances with minimal effect on voice material. In the flat position the microphone has a 6 dB/octave electronic infrasonic roll-off, with $-3$ dB at 10 Hz to reduce the effects of inaudible low-frequency disturbances on microphone preamplifier inputs. Attenuation is provided for operation at high sound pressure levels (to 145 dB SPL) by means of a rotary capacitive switch (see Section 16.3.4.1).

A final example of a single entry cardioid microphone is the Shure Beta 57 supercardioid dynamic microphone, Fig. 16-24. Both the Shure Beta 57 and the Beta 58 use neodymium magnets for hotter output and incorporate an improved shock mount.

### Three-Entry Cardioid Microphones

The Sennheiser MD441 is an example of a three-entry cardioid microphone, Fig. 16-25. The low-frequency rear entry has a $d$ (distance from center of diaphragm to the entry port) of about 2.8 inches (7 cm), the mid-frequency entry $d$ is about 2.2 inches (5.6 cm) and the high-frequency entry $d$ is about 1.5 inches (3.8 cm), with the transition in frequency occurring between 800 Hz and 1 kHz. Each entry consists of several holes around the microphone case rather than a single hole.
This configuration is used for three reasons. By using a multiple arrangement of entry holes around the circumference of the microphone case into the low-frequency system, optimum front response and polar performance can be maintained, even though most of the entries may be accidentally covered when the microphone is handheld or stand mounted. The microphone has good proximity performance because the low-frequency entry ports are far from the diaphragm (4.75 inches) as well as the high-frequency entry having very little proximity influence at low frequencies. The two-entry configuration has a cardioid polar response pattern that provides a wide front working angle as well as excellent noise rejection and feedback control.

16.2.3.1.5 Multiple-Entry Cardioid Microphones

The Electro-Voice RE20 Continuously Variable-D microphone, Fig. 16-26, is an example of multiple-entry microphones. Multiple-entry microphones have many rear entrance ports. They can be constructed as single ports, all at a different distance from the diaphragm, or as a single continuous opening port. Each entrance is tuned to a different band of frequencies, the port closest to the diaphragm being tuned to the high frequencies, and the port farthest from the diaphragm being tuned to the low-frequency band. The greatest advantage of this arrangement is reduced-proximity effect because of the large distance between the source and the rear entry low-frequency port and mechanical crossovers are not as sharp and can be more precise for the frequencies in question.

![Figure 16-24. Shure Beta 57 dynamic microphone. Courtesy Shure Incorporated.](image)

![Figure 16-25. Sennheiser MD441 three-entry cardioid microphone. Courtesy Sennheiser Electronic Corporation.](image)

![Figure 16-26. Electro-Voice RE20 multiple-entry (variable-D cardioid microphone). Courtesy Telex Electro-Voice.](image)

As in many cardioid microphones, the RE20 has a low-frequency roll-off switch to reduce the proximity effect when close micing. Fig. 16-27 shows the wiring
diagram of the RE20. By moving the red wire to either
the 250 $\Omega$ or 50 $\Omega$ tap, the microphone output imped-
ance can be changed. Note the “bass tilt” switch that,
when open, reduces the series inductance and, therefore,
the low-frequency response.

![Figure 16-27. Electro-Voice RE20 cardioid wiring diagram. Note “bass tilt” switch circuit and output impedance taps. Courtesy Telex Electro-Voice.](image)

16.2.3.1.6 Two-Way Cardioid Microphones

In a two-way microphone system, the total response
range is divided between a high-frequency and a
low-frequency transducer, each of which is optimally
adjusted to its specific range similar to a two-way loud-
speaker system. The two systems are connected by
means of a crossover network.

The AKG D-222EB schematically shown in
Fig. 16-28 employs two coaxially mounted dynamic
transducers. One is designed for high frequencies and is
placed closest to the front grille and facing forward. The
other is designed for low frequencies and is placed
behind the first and facing rearward. The low-frequency
transducer incorporates a hum-bucking winding to
cancel the effects of stray magnetic fields. Both trans-
ducers are coupled to a 500 Hz inductive-capaci-
tive-resistive crossover network that is electro-
acoustically phase corrected and factory preset for
linear off-axis response. (This is essentially the same
design technique used in a modern two-way loud-
speaker system.)

The two-way microphone has a predominantly
frequency-independent directional pattern, producing
more linear frequency response at the sides of the
microphone and far more constant discrimination at the
rear of the microphone. Proximity effect at working
distances down to 6 in (15 cm) is reduced because the
distance between the microphone windscreen and the
low frequency transducer is large.

The D-222EB incorporates a three-position
bass-roll-off switch that provides 6 dB or 12 dB attenu-
ation at 50 Hz. This feature is especially useful in
speech applications and in acoustically unfavorable
environments with excessive low-frequency ambient
noise, reverberation, or feedback.

16.3 Types of Transducers

16.3.1 Carbon Microphones

One of the earliest types of microphones, the carbon
microphone, is still found in old telephone handsets. It
has very limited frequency response, is very noisy, has
high distortion, and requires a hefty dc power supply. A
carbon microphone[^1] is shown in Fig. 16-29 and operates
in the following manner.

![Figure 16-28. Schematic of an AKG D222EB two-way
cardioid microphone. Courtesy AKG Acoustics, Inc.](image)

Several hundred small carbon granules are held in
close contact in a brass cup called a button that is
attached to the center of a metallic diaphragm. Sound
waves striking the surface of the diaphragm disturb the
carbon granules, changing the contact resistance
between their surfaces. A battery or dc power source is
connected in series with the carbon button and the
primary of an audio impedance-matching transformer.
The change in contact resistance causes the current from the power supply to vary in amplitude, resulting in a current waveform similar to the acoustic waveform striking the diaphragm.

The impedance of the carbon button is low so a step-up transformer is used to increase the impedance and voltage output of the microphone and to eliminate dc from the output circuit.

16.3.2 Crystal and Ceramic Microphones

Crystal and ceramic microphones were once popular because they were inexpensive and their high-impedance high-level output allowed them to be connected directly to the input grid of a tube amplifier. They were most popular in use with home tape recorders where microphone cables were short and input impedances high.

Crystal and ceramic microphones operate as follows: piezoelectricity is “pressure electricity” and is a property of certain crystals such as Rochelle salt, tourmaline, barium titanate, and quartz. When pressure is applied to these crystals, electricity is generated. Present-day commercial materials such as ammonium dihydrogen phosphate (ADP), lithium sulfate (LN), dipotassium tartrate (DKT), potassium dihydrogen phosphate (KDP), lead zirconate, and lead titanate (PZT) have been developed for their piezoelectric qualities. Ceramics do not have piezoelectric characteristics in their original state, but the characteristics are introduced in the materials by a polarizing process. In piezoelectric ceramic materials the direction of the electrical and mechanical axes depends on the direction of the original dc polarizing potential. During polarization a ceramic element experiences a permanent increase in dimensions between the poling electrodes and a permanent decrease in dimension parallel to the electrodes.

The crystal element can be cut as a bender element that is only affected by a bending motion or as a twister element that is only affected by a twisting motion, Fig. 16-30.

The internal capacitance of a crystal microphone is about 0.03 μF for the diaphragm-actuated type and 0.0005–0.015 μF for the sound-cell type.

The ceramic microphone operates like a crystal microphone except it employs a barium titanate slab in the form of a ceramic, giving it better temperature and humidity characteristics.

Crystal and ceramic microphones normally have a frequency response from 80 to 6500 Hz but can be made to have a flat response to 16 kHz. Their output impedance is about 100 kΩ, and they require a minimum load of 1–5 MΩ to produce a level of about −30 dB re 1 V/Pa.

16.3.3 Dynamic Microphones

The dynamic microphone is also referred to as a pressure or moving-coil microphone. It employs a small diaphragm and a voice coil, moving in a permanent magnetic field. Sound waves striking the surface of the diaphragm cause the coil to move in the magnetic field, generating a voltage proportional to the sound pressure at the surface of the diaphragm.

In a dynamic pressure unit, Fig. 16-31, the magnet and its associated parts (magnetic return, pole piece, and pole plate) produce a concentrated magnetic flux of approximately 10,000 G in the small gap.

The diaphragm, a key item in the performance of a microphone, supports the voice coil centrally in the magnetic gap, with only 0.006 inch clearance.

An omnidirectional diaphragm and voice-coil assembly is shown in Fig. 16-32. The compliance section has two hinge points with the section between them made up of tangential corrugated triangular sections that stiffen this portion and allow the diaphragm to move in and out with a slight rotating motion. The hinge points are designed to permit high-compliance action. A spacer supports the moving part of the diaphragm away from the top pole plate to...
provide room for its movement. The cementing flat is bonded to the face plate. A stiff hemispherical dome is designed to provide adequate acoustical capacitance. The coil seat is a small step where the voice coil is mounted, centered, and bonded on the diaphragm.

Early microphones had aluminum diaphragms that were less than 1 mil (0.001 in) thick. Aluminum is light-weight, easy to form, maintains its dimensional stability, and is unaffected by extremes in temperature or humidity. Unfortunately, being only 1 mil thick makes the diaphragms fragile. When it is touched or otherwise deformed by excessive pressure, an aluminum diaphragm is dead.

Mylar™, a polyester film manufactured by the DuPont Company, is commonly used for diaphragms. Mylar is a unique plastic. Extremely tough, it has high tensile strength, high resistance to wear, and outstanding flex life. Mylar™ diaphragms have been cycle tested with temperature variations from -40°F to +170°F (-40°C to +77°C) over long periods without any impairment to the diaphragm. Since Mylar™ is extremely stable, its properties do not change within the temperature and humidity range in which microphones are used.

The specific gravity of Mylar™ is approximately 1.3 as compared to 2.7 for aluminum so a Mylar™ diaphragm may be made considerably thicker without upsetting the relationship of the diaphragm mass to the voice-coil mass.

Mylar™ diaphragms are formed under high temperature and high pressure, a process in which the molecular structure is formed permanently to establish a dimensional memory that is highly retentive. Unlike aluminum, Mylar™ diaphragms will retain their shape and dimensional stability although they may be subjected to drastic momentary deformations.

The voice coil weighs more than the diaphragm so it is the controlling part of the mass in the diaphragm voice-coil assembly. The voice coil and diaphragm mass (analogous to inductance in an electrical circuit) and compliance (analogous to capacitance), make the assembly resonate at a given frequency as any tuned electrical circuit. The free-cone resonance of a typical undamped unit is in the region of 350 Hz.

If the voice coil were left undamped, the response of the assembly would peak at 350 Hz, Fig. 16-33. The resonant characteristic is damped out by the use of an acoustic resistor, a felt ring that covers the openings in the centering ring behind the diaphragm. This is analogous to electrical resistance in a tuned circuit. While

Figure 16-31. A simplified drawing of a dynamic microphone. Courtesy Shure Incorporated.

Figure 16-32. Omnidirectional diaphragm and voice coil assembly.

Figure 16-33. Diaphragm and voice-coil assembly response curve.
this reduces the peak at 350 Hz, it does not fix the droop below 200 Hz. Additional acoustical resonant devices are used inside the microphone case to correct the drooping. A cavity behind the unit (analogous to capacitance) helps resonate at the low frequencies with the mass (inductance) of the diaphragm and voice-coil assembly.

Another tuned resonant circuit is added to extend the response down to 35 Hz. This circuit, tuned to about 50 Hz, is often a tube that couples the inside cavity of the microphone housing to the outside, Fig. 16-34.

Fig. 16-35 illustrates the effect of a varying sound pressure on a moving-coil microphone. For this simplified explanation, assume that a massless diaphragm voice-coil assembly is used. The acoustic waveform, Fig. 16-35A, is one cycle of an acoustic waveform, where \( a \) indicates atmospheric pressure \( AT \); and \( b \) represents atmospheric pressure plus a slight overpressure increment \( \Delta \) or \( AT + \Delta \).

The electrical waveform output from the moving-coil microphone, Fig. 16-35B, does not follow the phase of the acoustic waveform because at maximum pressure, \( AT + \Delta \) or \( b \), the diaphragm is at rest (no velocity). Further, the diaphragm and its attached coil reach maximum velocity, hence maximum electrical amplitude—at point \( c \) on the acoustic waveform. This is of no consequence unless another microphone is being used along with the moving-coil microphone where the other microphone does not see the same 90° displacement. Due to this phase displacement, condenser microphones should not be mixed with moving-coil or ribbon microphones when micing the same source at the same distance. (Sound pressure can be proportional to velocity in many practical cases.)

A steady overpressure which can be considered an acoustic square wave, Fig. 16-35C, would result in the output shown in Fig. 16-35D. As the acoustic pressure rises from \( a \) to \( b \), it has velocity, Fig. 16-35, creating a voltage output from the microphone. Once the diaphragm reaches its maximum displacement at \( b \), and stays there during the time interval represented by the distance between \( b \) and \( c \), voice-coil velocity is zero so electrical output voltage ceases and the output returns to zero. The same situation repeats itself from \( c \) to \( e \) and from \( e \) to \( f \) on the acoustic waveform. As can be seen, a moving-coil microphone cannot reproduce a square wave.

Another interesting theoretical consideration of the moving-coil microphone mechanism is shown in Fig. 16-36. Assume a sudden transient condition. Starting at \( a \) on the acoustic waveform, the normal atmospheric pressure is suddenly increased by the first wavefront of a new signal and proceeds to the first overpressure peak, \( AT + \Delta \) or \( b \). The diaphragm will reach a maximum velocity halfway to \( b \) and then return to zero velocity at \( b \). This will result in a peak, \( a' \), in the electrical waveform. From \( b \) on, the acoustic waveform and the electrical waveform will proceed as before, cycle for cycle, but 90° apart.

In this special case, peak \( a' \) does not follow the input precisely so it is something extra. It will probably be swamped out by other problems (especially mass) encountered in a practical moving-coil microphone. It
Chapter 16

does illustrate that even with a “perfect,” massless, moving-coil microphone, “perfect” electrical waveforms will not be produced.

When sound waves vibrate the diaphragm, the voice coil has a voltage induced in it proportional to the magnitude and at the frequency of the vibrations. The voice coil and diaphragm have some finite mass and any mass has inertia that causes it to want to stay in the condition it is in—namely, in motion or at rest. If the stationary part of the diaphragm-magnet structure is moved in space, the inertia of the diaphragm and coil causes them to try to remain fixed in space. Therefore, there will be relative motion between the two parts with a resultant electrical output. An electrical output can be obtained in two ways, by motion of the diaphragm from airborne acoustical energy or by motion of the magnet circuit by structure-borne vibration. The diaphragm motion is the desired output, while the structure-borne vibration is undesired.

Several things may be tried to eliminate the undesired output. The mass of the diaphragm and voice coil may be reduced, but there are practical limits, or the frequency response may be limited mechanically with stiffer diaphragms or electronically with filter circuits. However limited response makes the microphone unsuitable for broad-range applications.

16.3.3.1 Unidirectional Microphones

To reject unwanted acoustical noise such as signals emanating from the sides or rear of the microphone, unidirectional microphones are used, Fig. 16-7. Unidirectional microphones are much more sensitive to vibration relative to their acoustic sensitivity than omnidirectional types. Fig. 16-37 shows a plot of vibration sensitivity versus frequency for a typical omnidirectional and unidirectional microphone with the levels normalized with respect to acoustical sensitivity.

The vibration sensitivity of the unidirectional microphone is about 15 dB higher than the omnidirectional and has a peak at about 150 Hz. The peak gives a clue to help explain the difference.
Unidirectional microphones are usually differential microphones; that is, the diaphragm responds to a pressure differential between its front and back surfaces. The oncoming sound wave is not only allowed to reach the front of a diaphragm but, through one or more openings and appropriate acoustical phase-shift networks, reaches the rear of the diaphragm. At low frequencies, the net instantaneous pressure differential causing the diaphragm to move is small compared to the absolute sound pressure, Fig. 16-38. Curve A is the pressure wave that arrives at the front of the diaphragm. Curve B is the pressure wave that reaches the rear of the diaphragm after a slight delay due to the greater distance the sound had to travel to reach the rear entry and some additional phase shift it encounters after entering. The net pressure actuating the diaphragm is curve C, which is the instantaneous difference between the two upper curves. In a typical unidirectional microphone, the differential pressure at 100 Hz will be about one-tenth of the absolute pressure or 20 dB down from the pressure an omnidirectional microphone would experience.

To obtain good low-frequency response, a reasonable low-frequency electrical output is required from a unidirectional microphone. To accomplish this, the diaphragm must move more easily for a given sound pressure. Some of this is accomplished by reducing the damping resistance to less than one-tenth used in an omnidirectional microphone. This reduction in damping increases the motion of the mechanical resonant frequency of the diaphragm and voice coil, around 150 Hz in Fig. 16-37, making the microphone much more acceptable to structure-borne vibrations. Since the diaphragm of an omnidirectional microphone is much more heavily damped, it will respond less to inertial or mechanical vibration forces.

To eliminate unwanted external low-frequency noise from effecting a unidirectional microphone, some kind of isolation such as a microphone shock mount is required to prevent the microphone cartridge from experiencing mechanical shock and vibration.

**16.3.4 Capacitor Microphones**

In a capacitor or condenser microphone the sound pressure level varies the head capacitance of the microphone by deflecting one or two plates of the capacitor, causing an electrical signal that varies with the acoustical signal. The varying capacitance can be used to modulate an RF signal that is later demodulated or can be used as one leg of a voltage divider, Fig. 16-39, where $R$ and $C$ form the voltage divider of the power supply $++$ to $-.$

The head of most capacitor microphones consists of a small two-plate 40–50 pF capacitor. One of the two plates is a stretched diaphragm; the other is a heavy back plate or center terminal, Fig. 16-39. The back plate is insulated from the diaphragm and spaced approximately 1 mil (0.001 in) from, and parallel to, the rear surface of the diaphragm. Mathematically the output from the head may be calculated as

$$E_O = \frac{E_p a^2 P}{8 dt} \quad (16-3)$$

where,
$E_O$ is the output in volts,
$E_p$ is the dc polarizing voltage in volts,
$a$ is the radius of active area of the diaphragm in centimeters,
$P$ is the pressure in dynes per square centimeter,
$d$ is the spacing between the back plate and diaphragm in centimeters,
$t$ is the diaphragm tension in dynes per centimeter.

Many capacitor microphones operate with an equivalent noise level of 15–30 dB SPL. Although a 20–30 dB SPL is in the range of a well-constructed studio, a 20–30 dB microphone equivalent noise is not masked by room noise because room noise occurs primarily at low frequencies and microphone noise at high frequency as hiss.

In the past the quality of sound recordings was limited by the characteristics of the analog tape and record material, apart from losses induced by the copying and pressing procedures. Tape saturation, for instance, created additional harmonic and disharmonic distortion components, which affected the recording fidelity at high levels, whereas the linearity at low and medium levels was quite acceptable. The onset of these distortions was rather soft and extended to a wide level range that makes it difficult to determine the threshold of audibility.

The distortion characteristics of the standard studio condenser microphones is adequate for operation with analog recording equipment. Although exhibiting a high degree of technical sophistication, these microphones show individual variations in the resolution of complex tonal structures, due to their specific frequency responses and directivity patterns and nonlinear effects inherent to these microphones.

These properties were mostly concealed by the distortions superimposed by the analog recording and playback processing. But the situation has changed essentially since the introduction of digital audio. The conversion of analog signals into digital information and vice versa is carried out very precisely, especially at high signal levels. Due to the linear quantization process the inherent distortions of digital recordings virtually decrease at increasing recording levels, which turns former distortion behavior upside down. This new reality, which is in total contrast to former experience with analog recording technique, contributes mostly to the fact that the specific distortion characteristics of the microphone may become obvious, whereas they have been masked previously by the more significant distortions of analog recording technique.

Another feature of digital audio is the enlarged dynamic range and reduced noise floor. Unfortunately, due to this improvement, the inherent noise of the microphones may become audible, because it is no longer covered up by the noise of the recording medium.

The capacitor microphone has a much faster rise time than the dynamic microphone because of the significantly lower mass of the moving parts (diaphragm versus diaphragm/coil assembly). The capacitor rise time rises from 10% of its rise time to 90% in approximately 15 μs, while the rise time for the dynamic microphone is in the order of 40 μs.

Capacitor microphones generate an output electrical waveform in step or phase with the acoustical waveform and can be adapted to measure essentially dc overpressures, Fig. 16-40.

![Figure 16-40. Capacitor microphone acoustic wave and electrical signals. Note the in-phase condition.](image)

Some advantages of capacitor microphones are:
- Small, low-mass rigid diaphragms that reduce vibration pickup.
- Smooth, extended-range frequency response.
- Rugged—capable of measuring very high sound pressure levels (rocket launches).
- Low noise (which is partially cancelled by the need for electronics).
- Small head size, which provides low diffraction interference.

16.3.4.1 Voltage Divider Capacitor Microphone

Voltage divider-type capacitor microphones require a preamplifier as an integral part of the housing and a
source of polarizing voltage for the head, and a source of power.

A high-quality capacitor microphone, the Sennheiser K6 Modular Condenser Microphone Series is suitable for recording studios, television and radio broadcast, motion picture studios, and stage and concert hall applications, as well as high-quality commercial sound installations.

The K6/ME62 series is a capacitor microphone system, Fig. 16-41, that uses AF circuitry with field-effect transistors so it has a low noise level (15 dB per DIN IEC 651), high reliability, and lifelong stability. Low current consumption at low voltage and phantom circuit powering permit feeding the microphone supply voltage via a standard two-conductor shielded audio cable or an internal AA battery.

![Figure 16-41. Modular microphone system with an omnidirectional cartridge utilizing a voltage divider circuit. Courtesy Sennheiser Electronic Corporation.](image)

The K6 offers interchangeable capsules, allowing the selection of different response characteristics from omnidirectional to cardioid to shotgun to adapt the microphone to various types of environments and recording applications.

Because of the new PCM recorders, signal-to-noise ratio (SNR) has reached a level of 90 dB, requiring capacitor microphones to increase their SNR level to match the recorder. The shotgun K6 series microphone, Fig. 16-42, has an equivalent noise level of 16 dB (DIN

![Figure 16-42. The same microphone shown in Fig. 16-41 but with a shotgun cartridge. Courtesy Sennheiser Electronic Corporation.](image)

As in most circuitry, the input stage of a voltage divider-type capacitor microphone has the most effect on noise, Fig. 16-43. It is important that the voltage on the transducer does not change. This is normally accomplished by controlling the input current. In the circuit of Fig. 16-43, the voltages $V_{in}$, $V_o$, and $V_D$ are within 0.1% of each other. Noise, which might come into the circuit as $V_{in}$ through the operational amplifier, is only $\frac{1}{10}$ of the voltage $V_o$.

![Figure 16-43. Simplified schematic of an AKG C-460B microphone input circuit. Courtesy AKG Acoustics.](image)

Preattenuation, that is, attenuation between the capacitor and the amplifier, can be achieved by connecting parallel capacitors to the input, by reducing the input stage gain by means of capacitors in the nega-
tive feedback circuit, or by reducing the polarizing voltage to one-third its normal value and by using a resistive voltage divider in the audio line. Fig. 16-44 is the schematic for the AKG C-460B microphone.

16.3.4.2 Phantom Power for Capacitor Microphones

A common way to supply power for capacitor microphones is with a phantom circuit. Phantom or simplex powering is supplying power to the microphone from the input of the following device such as a preamplifier, mixer, or console.

Most capacitor microphone preamplifiers can operate on any voltage between 9 Vdc and 52 Vdc because they incorporate an internal voltage regulator. The preamplifier supplies the proper polarizing voltage for the capacitor capsule plus impedance matches the capsule to the balanced low-impedance output.

Standard low-impedance, balanced microphone input receptacles are easily modified to simplex both operating voltage and audio output signal, offering the following advantages in reduced cost and ease of capacitor microphone operation:

- Special external power supplies and separate multi-conductor cables formerly required with capacitor microphones can be eliminated.
- The B+ supply in associated recorders, audio consoles, and commercial sound amplifiers can be used to power the microphone directly.
- Dynamic, ribbon, and capacitor microphones can be used interchangeably on standard, low-impedance, balanced microphone circuits.
- Dynamic, ribbon, and self-powered capacitor microphones may be connected to the modified amplifier input without defeating the microphone operating voltage.
- Any recording, broadcast, and commercial installation can be inexpensively upgraded to capacitor microphone operation using existing, two-conductor microphone cables and electronics.

Phantom circuit use requires only that the microphone operating voltage be applied equally to pins 2 and 3 of the amplifier low-impedance (normally an XLR input) receptacle. Pin 1 remains ground and circuit voltage minus. The polarity of standard microphone cable wiring is not important except for the usual audio polarity requirement (see Section 16.5.3). Two equally effective methods of amplifier powering can be used:

1. Connect an amplifier B+ supply of 9–12 V directly to the ungrounded center tap of the microphone input transformer, as shown in Fig. 16-45. A series-dropping resistor is required for voltages between 12 and 52 V. Fig. 16-46 is a typical resistor value chart. A chart can be made for any microphone if the current is known for a particular voltage.

2. A two-resistor, artificial center powering circuit is required when the microphone input transformer is not center-tapped, or when input attenuation

Figure 16-44. Schematic of an AKG C-460B microphone. Courtesy AKG Acoustics.
networks are used across the input transformer primary. Connect a B+ supply of 9–12 V directly to the artificial center of two 332 Ω, 1% tolerance precision resistors, as shown in Fig. 16-47. Any transformer center tap should not be grounded. For voltages between 12 and 52 V, double the chart resistor value of Fig. 16-46.

Any number of capacitor microphones may be powered by either method from a single B+ source according to the current available. Use the largest resistor value shown \( (R_v \text{ max}) \) for various voltages in Fig. 16-46 for minimum current consumption.

### 16.3.4.3 Capacitor Radio-Frequency, Frequency-Modulated Microphones

A frequency-modulated microphone is a capacitor microphone that is connected to a radio-frequency (RF) oscillator. Pressure waves striking the diaphragm cause variations in the capacity of the microphone head that frequency modulates the oscillator. The output of the modulated oscillator is passed to a discriminator and amplified in the usual manner.

Capacitor microphones using an RF oscillator are not entirely new to the recording profession, but since the advent of solid-state devices, considerable improvement has been achieved in design and characteristics. An interesting microphone of this design is the Schoeps Model CMT26U manufactured in West Germany by Schall-Technik, and named after Dr. Carl Schoeps, the designer.

The basic circuitry is shown in Fig. 16-48. By means of a single transistor, two oscillatory circuits are excited and tuned to the exact same frequency of 3.7 MHz. The output voltage from the circuits is rectified by a phase-bridge detector circuit, which operates over a large linear modulation range with very small RF voltages from the oscillator. The amplitude and polarity of the output voltage from the bridge depend on the phase angle between the two high-frequency voltages. The microphone capsule (head) acts as a variable capacitance in one of the oscillator circuits. When a sound wave impinges on the surface of the diaphragm of the microphone head, the vibrations of the diaphragm are detected by the phase curve of the oscillator circuit, and an audio frequency voltage is developed at the output of the bridge circuit. The microphone-head diaphragm is metal to guarantee a large constant capacitance. An automatic frequency control (afc) with a large range of operation is provided by means of capacitance diodes to preclude any influence caused by aging or temperature changes on the frequency-determining elements, that might throw the circuitry out of balance.

Internal output resistance is about 200 Ω. The signal, fed directly from the bridge circuit through two capacitors, delivers an output level of −51 dB to −49 dB (depending on the polar pattern used) into a 200 Ω load for a sound pressure level of 10 dynes/cm². The SNR and the distortion are independent of the load because of the bridge circuit; therefore, the microphone may be operated into load impedances ranging from 30 to 200 Ω.
16.3.4.3.1 Capacitor Radio-Frequency Microphones

A capacitor microphone of somewhat different design, manufactured by Sennheiser and also employing a crystal-controlled oscillator, is shown in Fig. 16-49. In the conventional capacitor microphone (without an oscillator) the input impedance of the preamplifier is in the order of 100 MΩ so it is necessary to place the capacitor head and preamplifier in close proximity. In the Sennheiser microphone, the capacitive element (head) used with the RF circuitry is a much lower impedance since the effect of a small change in capacitance at radio frequencies is considerably greater than at audio frequencies. Instead of the capacitor head being subjected to a high dc polarizing potential, the head is subjected to an RF voltage of only a few volts. An external power supply of 12 Vdc is required.

Referring to Fig. 16-49, the output voltage of the 8 MHz oscillator is periodically switched by diodes $D_1$ and $D_2$ to capacitor $C$. The switching phase is shifted 90° from that of the oscillator by means of loose coupling and individually aligning the resonance of the microphone circuit $M$ under a no-sound condition. As a result, the voltage across capacitor $C$ is zero. When a sound impinges on the diaphragm, the switching phase changes proportionally to the sound pressure, and a corresponding audio voltage appears across capacitor $C$. The output of the switching diodes is directly connected to the transistor amplifier stage, whose gain is limited to 12 dB by the use of negative feedback.

A high Q oscillator circuit is used to eliminate the effects of RF oscillator noise as noise in an oscillatory circuit is inversely proportional to the Q of the circuit. Because of the high Q of the crystal and its stability, compensating circuits are not required, resulting in low internal noise.

The output stage is actually an impedance-matching transformer adjusted for 100 Ω, for a load impedance of 2000 Ω or greater. RF chokes are connected in the output circuit to prevent RF interference and also to prevent external RF fields from being induced into the microphone circuitry.

16.3.4.3.2 Symmetrical Push-Pull Transducer Microphone

Investigations on the linearity of condenser microphones customarily used in the recording studios was carried out by Sennheiser using the difference frequency method incorporating a twin tone signal, Fig. 16-50. This is a very reliable test method as the harmonic distortions of both loudspeakers that generate the test sounds separately do not disturb the test result. Thus, difference frequency signals arising at the microphone output are arising from nonlinearities of the microphone itself.

Fig. 16-51 shows the distortion characteristics of eight unidirectional studio condenser microphones which were stimulated by two sounds of 104 dB SPL (3 Pa). The frequency difference was fixed to 70 Hz while the twin tone signal was swept through the upper audio range. The curves show that unwanted difference frequency signals of considerable levels were generated by all examined microphones. Although the curves are shaped rather individually, there is a general tendency...
for increased distortion levels (up to 1% and more) at high frequencies.

The measurement results can be extended to higher signal levels simply by linear extrapolation. This means, for instance, that 10 times higher sound pressures will yield 10 times higher distortions, as long as clipping of the microphone circuit is prevented. Thus, two sounds of 124 dB SPL will cause more than 10% distortion in the microphones. Sound pressure levels of this order are beyond the threshold of pain of human hearing but may arise at close-up micing. Despite the fact that the audibility of distortions depends significantly on the tonal structure of the sound signals, distortion figures of this order will considerably affect the fidelity of the sound pick-up.

The Cause of Nonlinearity. Fig. 16-52 shows a simplified sketch of a capacitive transducer. The diaphragm and backplate form a capacitor, the capacity of which depends on the width of the air gap. From the acoustical point of view the air gap acts as a complex impedance. This impedance is not constant but depends on the actual position of the diaphragm. Its value is increased if the diaphragm is moved toward the backplate and it is decreased at the opposite movement, so the air gap impedance is varied by the motion of the diaphragm. This implies a parasitic rectifying effect superimposed to the flow of volume velocity through the transducer, resulting in nonlinearity-created distortion.

Solving the Linearity Problem. A push-pull design of the transducer helps to improve the linearity of condenser microphones, Fig. 16-53. An additional plate equal to the backplate is positioned symmetrically in front of the diaphragm, so two air gaps are formed with equal acoustical impedances as long as the diaphragm is in its rest position. If the diaphragm is deflected by the sound signal, then both gap impedances are deviated opposite to each other. The impedance of one side increases while the other impedance decreases. The variation effects compensate each other regardless of the direction of the diaphragm motion, and the total air gap impedance is kept constant, reducing the distortion of a capacitive transducer.

Fig. 16-54 shows the distortion characteristics of the Sennheiser MKH series push-pull element transformer-less RF condenser microphones. The improvement on linearity due to the push-pull design can be seen by comparing Fig. 16-51 to Fig. 16-54.
statistics imply that sound pressure signals at the
diaphragm can be evaluated by a precision that
improves linearly with the diameter of the diaphragm.
Thus, larger diaphragms yield better noise performance
than smaller ones.

Another contribution of noise is the frictional effects
in the resistive damping elements of the transducer. The
noise generation from acoustical resistors is based on
the same principles as the noise caused by electrical
resistors so high acoustical damping implies more noise
than low damping.

Noise is also added by the electrical circuit of the
microphone. This noise contribution depends on the
sensitivity of the transducer. High transducer sensitivity
reduces the influence of the circuit noise. The inherent
noise of the circuit itself depends on the operation prin-
ciple and on the technical quality of the electrical
devices.

**Noise Reduction.** Large-diameter diaphragms improve
noise performance. Unfortunately, a large diameter
increases the directivity at high frequencies. A 1 inch
(25 mm) transducer diameter is usually a good choice.

A further method to improve the noise characteristics
is the reduction of the resistive damping of the
transducer. In most directional condenser microphones,
a high amount of resistive damping is used in order to
realize a flat frequency response of the transducer itself.
With this design the electrical circuit of the microphone
is rather simple. However, it creates reduced sensitivity
and increased noise.

Keeping the resistive damping of the transducer
moderate will be a more appropriate method to improve
noise performance, however it leads to the transducer
frequency response that is not flat so equalization has to
be applied by electrical means to produce a flat
frequency response of the complete microphone. This
design technique requires a more sophisticated elec-
trical circuit but produces good noise performance.

The electrical output of a transducer acts as a pure
capacitance. Its impedance decreases as the frequency
increases so the transducer impedance is low in an RF
circuit but high in an AF circuit. Moreover, in an RF
circuit the electrical impedance of the transducer does
not depend on the actual audio frequency but is rather
constant due to the fixed frequency of the RF oscillator.
Contrary to this, in an AF design, the transducer imped-
ance depends on the actual audio frequency, yielding
very high values especially at low frequencies. Resistors
of extremely high values are needed at the circuit input
to prevent loading of the transducer output. These resis-
tors are responsible for additional noise contribution.

The RF circuit features a very low output impedance
which is comparable to that of dynamic-type micro-
phones. The output signal can be applied directly to
bipolar transistors, yielding low noise performance by
impedance matching.

The Sennheiser MKH 20, Fig. 16-55, is a pressure
microphone with omnidirectional characteristics. The
MKH 30 is a pure pressure-gradient microphone with a
highly symmetrical bidirectional pattern due to the
symmetry of the push-pull transducer. The MKH 40,
Fig. 16-56, operates as a combined pressure and pres-
sure-gradient microphone yielding a unidirectional
cardioid pattern.

![Figure 16-55. Omnidirectional pressure capacitor microphone. Note the lack of rear entry holes in the case. Courtesy Sennheiser Electronic Corporation.](image)

![Figure 16-56. Unidirectional pressure/pressure-gradient capacitor microphone. Courtesy Sennheiser Electronic Corporation.](image)

- The microphones are phantom powered by 48 Vdc
  and 2 mA. The outputs are transformerless floated,
  Fig. 16-57.
- The SPL_{max} is 134 dB at nominal sensitivity and
  142 dB at reduced sensitivity.
- The equivalent SPL of the microphones range from
  10–12 dBA corresponding to CCIR-weighted figures
  of 20–22 dB.
- The directional microphones incorporate a switchable
  bass roll-off to cancel the proximity effect at close-up
  mic ing. The compensation is adjusted to about 5 cm
  (2 in) distance.
A special feature of the omnidirectional microphone is a switchable diffuse field correction that corrects for both direct and diffuse sound field conditions. The normal switch position is recommended for a neutral pickup when closeup micing and the diffuse field position is used if larger recording distances are used where reverberations become significant.

The distinction between both recording situations arises because omnidirectional microphones tend to attenuate lateral and reverse impinging sound signals at high frequencies. Diffuse sound signals with random incidence cause a lack of treble response, which can be compensated by treble emphasis at the microphone. Unfortunately, frontally impinging sounds are emphasized also, but this effect is negligible if the reverberant sound is dominant.

**16.3.5 Electret Microphones**

An **electret microphone** is a capacitor microphone in which the head capacitor is permanently charged, eliminating the need for a high-voltage bias supply.

From a design viewpoint a microphone intended to be used for critical recording, broadcast, or sound reinforcement represents a challenge involving minimal performance compromise. Early electrets offered the microphone designer a means of reducing the complexity of a condenser microphone by eliminating the high-voltage bias supply, but serious environmental stability problems negated this advantage. Well-designed electret microphones can be stored at 50°C (122°F) and 95% relative humidity for years with a sensitivity loss of only 1 dB. Under normal conditions of temperature and humidity, electret transducers will demonstrate a much lower charge reduction versus time than under the severe conditions indicated. Even if a proper electret material is used, there are many steps in the fabricating, cleaning, and charging processes that greatly influence charge stability.

The Shure SM81 cardioid condenser microphone uses an electret material as a means of establishing a bias voltage on the transducer. The backplate carries the electret material based upon the physical properties of halocarbon materials such as Teflon™ and Aclar, which are excellent electrets, and materials such as polypropylene and polyester terephthalate (Mylar™), which are more suitable for diaphragms.
The operation of the Shure SM-81 microphone is explained in Section 16.2.3.4.

16.4 Microphone Sensitivity

*Microphone sensitivity* is the measure of the electrical output of a microphone with respect to the acoustic sound pressure level input.

Sensitivity is measured in one of three methods:

- **Open-circuit voltage**: $0 \text{ dB} = 1 \text{ V/μbar}$
- **Maximum power output**: $0 \text{ dB} = 1 \text{ mW/10 μbar} = 1 \text{ mW/Pa}$
- **Electronic Industries Association (EIA) sensitivity**: $0 \text{ dB} = \text{EIA standard SE-105}$

The common sound pressure levels used for measuring microphone sensitivity are:

- 94 dB SPL, 10 dyn/cm$^2$ SPL, 10 μbar or 1 Pa
- 74 dB SPL, 1 dyn/cm$^2$ SPL, 1 μbar or 0.1 Pa
- 0 dB SPL, 0.0002 dyn/cm$^2$ SPL, 0.0002 Pa or 20 μPa—threshold of hearing

94 dB SPL is recommended since 74 dB SPL is too close to typical noise levels.

### 16.4.1 Open-Circuit Voltage Sensitivity

There are several good reasons for measuring the open-circuit voltage:

- If the open-circuit voltage and the microphone impedance are known, the microphone performance can be calculated for any condition of loading.
- It corresponds to an effective condition of use. A microphone should be connected to a high impedance to yield maximum SNR. A 150–250 Ω microphone should be connected to 2 kΩ or greater.
- When the microphone is connected to a high impedance compared to its own, variations in microphone impedance do not cause variations in response.

The open-circuit voltage sensitivity ($S_v$) can be calculated by exposing the microphone to a known SPL, measuring the voltage output, and using the following equation:

$$S_v = 20 \log(E_o - dB_{SPL} + 94) \quad (16-4)$$

where,

- $S_v$ is the open-circuit voltage sensitivity in decibels re $1 \text{ V}$ for a 10 dyn/cm$^2$ SPL (94 dB SPL) acoustic input to the microphone,
- $E_o$ is the output of the microphone in volts,
- $dB_{SPL}$ is the level of the actual acoustic input.

The microphone measurement system can be set up as shown in Fig. 16-59. The setup requires a random-noise generator, a microvoltmeter, a high-pass and a low-pass filter set, a power amplifier, a test-loudspeaker, and a sound level meter (SLM). The SLM is placed at a specific measuring distance (about 5–6 ft or 1.5–2 m) in front of the loudspeaker. The system is adjusted until the SLM reads 94 dB SPL (a band of pink noise from 250 to 5000 Hz is excellent for this purpose). The microphone to be tested is now substituted for the SLM.

It is often necessary to know the voltage output of the microphone for various SPLs to determine whether the microphone will overload the preamplifier circuit or the SNR will be inadequate. To determine this, use

$$E_o = 10\left(\frac{S_v + dB_{SPL} - 94}{20}\right) \quad (16-5)$$

where,

- $E_o$ is the voltage output of microphone,
- $S_v$ is the open-circuit voltage sensitivity,
- $dB_{SPL}$ is the sound pressure level at the microphone.

### 16.4.2 Maximum Power Output Sensitivity

The *maximum power output sensitivity* form of specification gives the maximum power output in decibels available from the microphone for a given sound pressure and power reference. Such a specification can be
calculated from the internal impedance and the open-circuit voltage of the microphone. This specification also indicates the ability of a microphone to convert sound energy into electrical power. The equation is

\[ S_p = 10 \log \frac{V_o^2}{R_o} + 44 \text{ dB} \]  

where,

- \( S_p \) is the power level microphone sensitivity in decibels,
- \( V_o \) is the open-circuit voltage produced by a 1 μbar (0.1 Pa) sound pressure,
- \( R_o \) is the internal impedance of the microphone.

The output level can also be determined directly from the open-circuit voltage

\[ S_p = S_v - 10 \log Z + 44 \text{ dB} \]  

where,

- \( S_v \) is the decibel rating for an acoustical input of 94 dB SPL (10 dyn/cm²) or 1 Pa,
- \( Z \) is the measured impedance of the microphone (the specifications of most manufacturers use the rated impedance).

The form of this specification is similar to the voltage specification except that a power as opposed to a voltage reference is given with the sound pressure reference. A 1 mW power reference and a 10 μbar (1 Pa) pressure reference are commonly used (as for the previous case). This form of microphone specification is quite meaningful because it takes into account both the voltage output and the internal impedance of the microphone.

\[ S_p \] can also be calculated easily from the open-circuit voltage sensitivity

\[ S_p = S_v - 10 \log Z + 44 \text{ dB} \]  

where,

- \( S_v \) is the decibel rating for an acoustical input of 94 dB SPL (10 dyn/cm²) or 1 Pa,
- \( Z \) is the measured impedance of the microphone (the specifications of most manufacturers use the rated impedance).

The output level can also be determined directly from the open-circuit voltage

\[ S_p = 10 \log \frac{E_o^2}{0.001 Z} - 6 \text{ dB} \]  

where,

- \( E_o \) is the open-circuit voltage,
- \( Z \) is the microphone impedance.

Because the quantity \( 10 \log (E_o^2/0.001 Z) \) treats the open-circuit voltage as if it appears across a load, it is necessary to subtract 6 dB. (The reading is 6 dB higher than it would have been had a load been present.)

### 16.4.3 Electronic Industries Association (EIA) Output Sensitivity

The Electronic Industries Association (EIA) Standard SE-105, August 1949, defines the system rating \( G_M \) as the ratio of the maximum electrical output from the microphone to the square of the undisturbed sound field pressure in a plane progressive wave at the microphone in decibels relative to 1 mW/0.0002 dyn/cm². Expressed mathematically,

\[ G_M = 20 \log \frac{E_o}{P} - 10 \log Z_o - 50 \text{ dB} \]  

where,

- \( E_o \) is the open-circuit voltage of the microphone,
- \( P \) is the undisturbed sound field pressure in dyn/cm²,
- \( Z_o \) is the microphone-rated output impedance in ohms.

For all practical purposes, the output level of the microphone can be obtained by adding the sound pressure level relative to 0.0002 dyn/cm² to \( G_M \).

Because \( G_M \), \( S_p \), and \( S_v \) are compatible, \( G_M \) can also be calculated

\[ G_M = S_v - 10 \log R_{MR} - 50 \text{ dB} \]  

where,

- \( G_M \) is the EIA rating,
- \( R_{MR} \) is the EIA center value of the nominal impedance range shown below.

<table>
<thead>
<tr>
<th>Ranges (ohms)</th>
<th>Values Used (ohms)</th>
</tr>
</thead>
<tbody>
<tr>

<td>= 9600</td>
</tr>
<tr>
<td>20,000–70,000</td>
<td>= 40,000</td>
</tr>
</tbody>
</table>

The EIA rating can also be determined from the chart in Fig. 16-60.
16.4.4 Various Microphone Sensitivities

Microphones are subjected to sound pressure levels anywhere from 40 dB SPL when distant micing to 150 dB SPL when extremely close micing (i.e., ¼ inch from the rock singer’s mouth or inside a drum or horn).

Various types of microphones have different sensitivities, which is important to know if different types of microphones are intermixed since gain settings, SNR, and preamplifier overload will vary. Table 16-1 gives the sensitivities of a variety of different types of microphones.

16.4.5 Microphone Thermal Noise

Since a microphone has an impedance, it generates thermal noise. Even without an acoustic signal, the microphone will still produce a minute output voltage. The thermal noise voltage, \( E_n \), produced by the electrical resistance of a sound source is dependent on the frequency bandwidth under consideration, the magnitude of the resistance, and the temperature existing at the time of the measurement. This voltage is

\[
E_n = 4ktRbw
\]  

(16-11)

where,

- \( k \) is the Boltzmann’s constant, \( 1.38 \times 10^{-23} \) J/K,
- \( t \) is the absolute temperature, \( 273° + \) room temperature, both in °C,
- \( R \) is the resistance in ohms,
- \( bw \) is the bandwidth in hertz.

To change this to \( dBv \) use

\[
EIN_{dBv} = 20\log \frac{E_n}{0.775}
\]  

(16-12)

The thermal noise relative to 1 V is \(-198 \) dB for a 1 Hz bandwidth and 1 Ω impedance. Therefore,

\[
\frac{TN}{1V} = -198 + 10\log(bw) + 10\log Z
\]  

(16-13)

where,
Microphones 519

$TN$ is the thermal noise relative to 1 V, $bw$ is the bandwidth in hertz, $Z$ is the microphone impedance in ohms.

Thermal noise relative to 1 V can be converted to equivalent input noise (EIN) by

$$EIN_{dBm} = -198 \text{ dB} + 10 \log (bw) + 10 \log Z - 6 - 20 \log 0.775 \text{ V}.$$  \hspace{1cm} (16-14)

Since the $EIN$ is in dBm and dBm is referenced to 600 Ω, the impedance $Z$ is 600 Ω.

16.5 Microphone Practices

16.5.1 Placement

Microphones are placed in various relationships to the sound source to obtain various sounds. Whatever position gives the desired effect that is wanted is the correct position. There are no exact rules that must be followed, however, certain recommendations should be followed to assure a good sound.

16.5.1.1 Microphone-to-Source Distance

Microphones are normally used in the direct field. Under this condition, inverse square law attenuation prevails, meaning that each time the distance is doubled, the microphone output is reduced 6 dB. For instance, moving from a microphone-to-source distance of 2.5 to 5 cm (1 to 2 in) has the same effect as moving from 15 to 30 cm (6 to 12 in), 1 to 2 ft (30 to 60 cm), or 5 to 10 ft (1.5 to 3 m).

Distance has many effects on the system. In a reinforcement system, doubling the distance reduces gain before feedback 6 dB; in all systems, it reduces the effect of microphone-to-source variations.

Using the inverse-square-law equation for attenuation,

$$\text{attenuation}_{dB} = 20 \log \frac{D_1}{D_2}$$  \hspace{1cm} (47-15)

it can be seen, at a microphone-to-source distance of 2.5 cm (1 in), moving the microphone only 1.25 cm (½ in) closer will increase the signal 6 dB and 1.25 cm (½ in) farther away will decrease the signal 3.5 dB for a total signal variation of 9.5 dB for only 2.5 cm (1 in) of total movement! At a source-to-microphone distance of 30 cm (12 in), a movement of 2.5 cm (1 in) will cause a signal variation of only 0.72 dB. Both conditions can be used advantageously; for instance, close micing is useful in feedback-prone areas, high noise level areas (rock groups), or where the talent wants to use the source to microphone variations to create an effect.

The farther distances are most useful where lecterns and table microphones are used or where the talker wants movement without level change.

The microphone-to-source distance also has an effect on the sound of a microphone, particularly one with a cardioid pattern. As the distance decreases, the proximity effect increases creating a bassy sound (see Section 16.2.3.1). Closing in on the microphone also increases breath noise and pop noise.

16.5.1.2 Distance from Large Surfaces

When a microphone is placed next to a large surface such as the floor, 6 dB of gain can be realized, which can be a help when far micing.

As the microphone is moved away from the large surface but still in proximity of it, cancellation of some specific frequencies will occur, creating a notch of up to 30 dB, Fig. 16-65. The notch is created by the cancellation of a frequency that, after reflecting off the surface, reaches the microphone diaphragm 180° out of polarity with the direct sound.

The frequency of cancellation, $f_c$, can be calculated from the equation

$$f_c = \frac{0.5c}{D_{r1} + D_{r2} - D_d}$$  \hspace{1cm} (16-16)

where,
- $c$ is the speed of sound, 1130 feet per second or 344 meters per second,
- 0.5 is the out-of-polarity frequency ratio,
- $D_{r1}$ is the reflected path from the source to the surface in feet or meters,
$D_r$ is the reflected path from the surface to the microphone in feet or meters,

$D_d$ is the direct path from the source to the microphone in feet or meters.

If the microphone is 10 ft from the source and both are 5 ft above the floor, the canceled frequency is

$$f_c = \frac{1130 \times 0.5}{7.07 + 7.07 - 10}$$

$$= 136.47 \text{ Hz} \quad (16-17)$$

If the microphone is moved to 2 ft above the floor, the canceled frequency is 319.20 Hz. If the microphone is 6 inches from the floor, the canceled frequency is 1266.6 Hz. If the microphone is 1 inch from the floor, the canceled frequency is 7239.7 Hz.

16.5.1.3 Behind Objects

Sound, like light, does not go through solid or acoustically opaque objects. It does, however, go through objects of various density. The transmission loss or ability of sound to go through this type of material is frequency dependent; therefore, if an object of this type is placed between the sound source and the microphone, the pickup will be attenuated according to the transmission characteristics of the object.

Low-frequency sound bends around objects smaller than their wavelength, which affects the frequency response of the signal. The normal effect of placing the microphone behind an object is an overall reduction of level, a low-frequency boost, and a high-frequency roll-off.

16.5.1.4 Above the Source

When the microphone is placed above or to the side of a directional sound source (i.e., horn or trumpet), the high-end frequency response will roll off because high frequencies are more directional than low frequencies, so less high-frequency SPL will reach the microphone than low-frequency SPL.

16.5.1.5 Direct versus Reverberant Field

Micing in the reverberant field picks up the characteristic of the room because the microphone is picking up as much or more of the room, as it is the direct sound from the source. When micing in the reverberant field, only two microphones are required for stereo since isolation of the individual sound sources is impossible. When in the reverberant field, a directional microphone will lose much of its directivity. Therefore, it is often advantageous to use an omnidirectional microphone that has smoother frequency response. To mic sources individually, you must be in the direct field and usually very close to the source to eliminate cross-feed.

16.5.2 Grounding

The grounding of microphones and their interconnecting cables is of extreme importance since any hum or noise picked up by the cables will be amplified along with the audio signal. Professional systems generally use the method shown in Fig. 16-61. Here the signal is passed through a two-conductor shielded cable to the balanced input of a preamplifier. The cable shield is connected to pin number 1, and the audio signal is carried by the two conductors and pins 2 and 3 of the XLR-type connector. The actual physical ground is connected at the preamplifier chassis only and carried to the microphone case. In no instance is a second ground ever connected to the far end of the cable, because this will cause the flow of ground currents between two points of grounding.

![Figure 16-61. Typical low-impedance microphone to preamplifier wiring.](image)
16.5.3 Polarity

Microphone polarity, or phase as it is often called, is important especially when multiple microphones are used. When they are in polarity they add to each other rather than have canceling effects. If multiple microphones are used and one is out of polarity, it will cause comb filters, reducing quality and stereo enhancement. The EIA standard RS-221.A, October 1979, states “Polarity of a microphone or a microphone transducer element refers to in-phase or out-of-phase condition of voltage developed at its terminals with respect to the sound pressure of a sound wave causing the voltage.”

Note: Exact in-phase relationship can be taken to mean that the voltage is coincident with the phase of the sound pressure wave causing the voltage. In practical microphones, this perfect relationship may not always be obtainable.

The positive or in-phase terminal is that terminal that has a positive potential and a phase angle less than 90° with respect to a positive sound pressure at the front of the diaphragm.

When connected to a three-pin XLR connector as per EIA standard RS-297, the polarity shall be as follows:

- Out-of-phase—terminal 3 (black).
- In-phase—terminal 2 (red or any color other than black).
- Ground—terminal 1 (shield).

Fig. 16-63 shows the proper polarity for three-pin and five-pin XLR connectors and for three-pin and five-pin DIN connectors.

A simple method of determining microphone polarity is as follows:

If two microphones have the same frequency response and sensitivity and are placed next to each other and connected to the same mixer, the output will double if both are used. However, if they are out of polarity with each other, the total output will be down 40–50 dB from the output of only one microphone.

The microphones to be tested for proper polarity are placed alongside each other and connected to their respective mixer inputs. With a single acoustic source into the microphones (pink noise is a good source), one mixer volume control is adjusted for a normal output level as indicated on a VU meter. Note the volume control setting and turn it off. Make the same adjustment for the second microphone, and note the setting of this volume control. Now open both controls to these settings. If the microphones are out of polarity, the quality of reproduction will be distorted, and there will be a distinct drop in level. Reversing the electrical connections to one microphone will bring them into polarity, making the quality about the same as one microphone operating and the output level higher.

If the microphones are of the bidirectional type, one may be turned 180° to bring it into polarity and later corrected electrically. If the microphones are of the directional type, only the output or cable connections can be reversed. After polarizing a bidirectional microphone, the rear should be marked with a white stripe for future reference.

16.5.4 Balanced or Unbalanced

Microphones can be connected either balanced or unbalanced. All professional installations use a balanced system for the following reasons:

- Reduced pickup of hum.
• Reduced pickup of electrical noise and transients.
• Reduced pickup of electrical signals from adjacent wires.

These reductions are realized because the two signal conductors shown in Fig. 16-63 pick up the same stray signal with equal intensity and polarity, so the noise is impressed evenly on each end of the transformer primary, eliminating a potential across the transformer and canceling any input noise. Because the balanced wires are in a shielded cable, the signal to each conductor is also greatly reduced.

When installing microphones into an unbalanced system, any noise that gets to the inner unbalanced conductor is not canceled by the noise in the shield, so the noise is transmitted into the preamplifier. In fact, noise impressed on the microphone end of the shield adds to the signal because of the resistance of the shield between the noise and the amplifier.

Balanced low-impedance microphone lines can be as long as 500 ft (150 m) but unbalanced microphone lines should never exceed 15 ft (4.5 m).

16.5.5 Impedance

Most professional microphones are low impedance, 200 Ω, and are designed to work into a load of 2000 Ω. High-impedance microphones are 50,000 Ω and are designed to work into an impedance of 1–10 MΩ. The low-impedance microphone has the following advantages:

• Less susceptible to noise. A noise source of relatively high impedance cannot “drive” into a source of relatively low impedance (i.e., the microphone cable).
• Capable of being connected to long microphone lines without noise pickup and high-frequency loss.

All microphone cable has inductance and capacitance. The capacitance is about 40 pF (40 × 10⁻¹²)/ft (30 cm). If a cable is 100 ft long (30 m), the capacitance would be (40 × 10⁻¹²) × 100 ft or 4 × 10⁻⁹ F or 0.004 μF. This is equivalent to a 3978.9 Ω impedance at 10,000 Hz and is found with the equation

\[ X_c = \frac{1}{2\pi fC} \]  

(16-18)

This has little effect on a microphone with an impedance of 200 Ω as it does not reduce the impedance appreciably as determined by

\[ Z_T = \frac{X_c Z_m}{X_c + Z_m} \]  

(16-19)

For a microphone impedance of 200 Ω, the total impedance \( Z_T = 190 \) Ω or less than 0.5 dB.

If this same cable were used with a high-impedance microphone of 50,000 Ω, 10,000 Hz would be down more than 20 dB.

Making the load impedance equal to the microphone impedance will reduce the microphone sensitivity 6 dB, which reduces the overall SNR by 6 dB. For the best SNR, the input impedance of low-impedance microphone preamplifiers is always 2000 Ω or greater.

If the load impedance is reduced to less than the microphone impedance, or the load impedance is not resistive, the microphone frequency response and output voltage will be affected.

Changing the load of a high-impedance or ceramic microphone from 10 MΩ to 100 kΩ reduces the output at 100 Hz by 27 dB.

16.6 Miscellaneous Microphones

16.6.1 Pressure Zone Microphones (PZM)

The pressure zone microphone, referred to as a PZM microphone or PZM, is a miniature condenser microphone mounted face-down next to a sound-reflecting plate or boundary. The microphone diaphragm is placed in the pressure zone just above the boundary where direct and reflected sounds combine effectively in-phase over the audible range.

In many recording and reinforcement applications, the sound engineer is forced to place microphones near hard reflective surfaces such as when recording an instrument surrounded by reflective baffles, reinforcing drama or opera with the microphones near the stage floor, or recording a piano with the microphone close to the open lid.

In these situations, sound travels from the source to the microphone via two paths: directly from the source
to the microphone, and reflected off the surface to the microphone. The delayed sound reflections combine with the direct sound at the microphone, resulting in phase cancellations of various frequencies, Fig. 16-65. This creates a series of peaks and dips in the net frequency response called the *comb-filter effect*, affecting the recorded tone quality and giving an unnatural sound.

![Diagram of sound reflections](image)

**Figure 16-65.** Effects of cancellation caused by near reflections (comb filters).

The PZM was developed to avoid the tonal coloration caused by microphone placement near a surface. The microphone diaphragm is arranged parallel with and very close to the reflecting surface and facing it, so that the direct and reflected waves combine at the diaphragm in-phase over the audible range, Fig. 16-66.

This arrangement can provide several benefits:

- Wide, smooth frequency response (natural reproduction) because of the lack of phase interference between direct and reflected sound.
- A 6 dB increase in sensitivity because of the coherent addition of direct and reflected sound.
- High SNR created by the PZM’s high sensitivity and low internal noise.
- A 3 dB reduction in pickup of the reverberant field compared to a conventional omnidirectional microphone.
- Lack of off-axis coloration as a result of the sound entry’s small size and radial symmetry.
- Good-sounding pickup of off-mic instruments due to the lack of off-axis coloration.
- Identical frequency response for random-incidence sound (ambience) and direct sound due to the lack of off-axis coloration.
- Consistent tone quality regardless of sound-source movement or microphone-to-source distance.
- Excellent reach (clear pickup of quiet distant sounds).
- Hemispherical polar pattern, equal sensitivity to sounds coming from any direction above the surface plane.
- Inconspicuous low-profile mounting.

![Diagram of PZM arrangement](image)

**Figure 16-66.** Effects of receiving direct and reflected sound simultaneously.

The Crown PZM-30 series microphones, Fig. 16-67, one of the original PZMs, are designed for professional use and built to take the normal abuse associated with professional applications. Miniaturized electronics built into the microphone cantilever allow the PZM-30 series to be powered directly by simplex phantom powering.

![PZM 30D pressure zone microphone](image)

**Figure 16-67.** PZM 30D pressure zone microphone. Courtesy Crown International, Inc.
16.6.1.1 Phase Coherent Cardioid (PCC)

The phase coherent cardioid microphone (PCC) is a surface-mounted supercardioid microphone with many of the same benefits as the PZM. Unlike the PZM, however, the PCC uses a subminiature supercardioid microphone capsule.

Technically, the PCC is not a pressure zone microphone. The diaphragm of a PZM is parallel to the boundary; the diaphragm of the PCC is perpendicular to the boundary. Unlike a PZM, the PCC aims along the plane on which it is mounted. In other words, the main pickup axis is parallel with the plane.

The Crown PCC-160 microphone, a Phase Coherent Cardioid surface-mounted boundary microphone, Fig. 16-68, is intended for use on stage floors, lecterns, and conference tables wherever gain-before-feedback and articulation are important. Fig. 16-69 shows the horizontal polar response for this microphone.

Figure 16-68. Crown PCC®-200 Phase Coherent Cardioid microphone. Courtesy Crown International, Inc.

The PCC-160 can be directly phantom powered. A bass-tilt switch is provided for tailoring low end response.

16.6.1.2 Directivity

The PZM picks up sounds arriving from any direction above the surface it is mounted on (hemispherical). It is often necessary to discriminate against sounds arriving from certain directions. To make the microphone directional or hemicardioid (reject sounds from the rear) the capsule can be mounted with the cantilever in a corner boundary made of ¼ inch (6 mm) thick Plexiglas. The larger the boundary, the better it discriminates against low-frequency sounds from the rear.

For best results, a corner boundary 12 in × 24 in wide (0.3 m × 0.6 m) is recommended and is nearly invisible to the audience, Fig. 16-70.

Figure 16-70. Corner boundary used to control directivity of pressure zone microphones.

A boom-mounted or suspended PZM can be taped to the center of a ¼ inch (6 mm) thick 2 ft × 2 ft (0.6 m × 0.6 m) or 4 ft × 4 ft (1.2 m × 1.2 m) panel. The microphone should be placed 4 inches (10 cm) off-center for a smoother frequency response. Using clear acrylic plastic (Plexiglas) makes the panel nearly invisible from a distance. If the edges of the Plexiglas pick up light, they can be taped or painted black.

16.6.1.2.1 Sensitivity Effects

If a PZM capsule is placed very near a single large boundary (within 0.020 inch or 0.50 mm), such as a large plate, floor, or wall, incoming sound reflects off the surface. The reflected sound wave adds to the incoming sound wave in the Pressure Zone next to the boundary. This coherent addition of sound waves doubles the sound pressure at the microphone, effectively increasing the microphone sensitivity or output by 6 dB over a standard microphone.

If the PZM capsule is placed at the junction of two boundaries at right angles to each other, such as the
floor and a wall, the wall increases sensitivity 6 dB, and the floor increases sensitivity another 6 dB. Adding two boundaries at right angles increases sensitivity 12 dB.

With the PZM element at the junction of three boundaries at right angles, such as in the corner of the floor and two walls, microphone sensitivity will be 18 dB higher than what it was in open space.

Note that the acoustic sensitivity of the microphone rises as boundaries are added, but the electronic noise of the microphone stays constant, so the effective SNR of the microphone improves 6 dB every time a boundary is added at right angles to previous boundaries.

16.6.1.2.2 Direct-to-Reverberant Ratio Effects

Direct sound sensitivity increases 6 dB per boundary added, while reverberant or random-incidence sound increases only 3 dB per boundary added. Consequently, the direct-to-reverberant ratio increases 3 dB (6 dB_{dir} − 3 dB_{rev}) whenever a boundary is added at right angles to previous boundaries.

16.6.1.2.3 Frequency-Response Effects

The low-frequency response of the PZM or PCC depends on the size of the surface it is mounted on. The larger the surface, the more the low-frequency response is extended. The low-frequency response shelves down to a level 6 dB below the mid-frequency level at the frequency where the wavelength is about 6 times the boundary dimension. For example, the frequency response of a PZM on a 2 ft × 2 ft (0.6 m × 0.6 m) panel shelves down 6 dB below 94 Hz. On a 5 inch × 5 inch (12 cm × 12 cm) plate, the response shelves down 6 dB below 376 Hz.

For best bass and flattest frequency response, the PZM or PCC must be placed on a large hard boundary such as a floor, wall, table, or baffle at least 4 ft × 4 ft (1.2 m × 1.2 m).

To reduce bass response, the PZM or PCC can be mounted on a small plate well away from other reflecting surfaces. This plate can be made of thin plywood, Masonite, clear plastic, or any other hard, smooth material. When used on a carpeted floor the PZM or PCC should be placed on a hard-surfaced panel at least 1 ft × 1 ft (0.3 m × 0.3 m) for flattest high-frequency response.

To determine the frequency $f_{-6 \text{ dB}}$ where the response shelves down 6 dB, use

$$f_{-6 \text{ dB}} = \frac{188 \times D}{D_{\text{max}}} \quad \text{(16-20)}$$

*57.3 for SI units

where,

$D$ is the boundary dimension in feet or meters.

For example, if the boundary is 2 ft (0.6 m) square, the 6 dB down point is

$$f_{-6 \text{dB}} = \frac{188}{2} = 94 \text{ Hz}$$

Below 94 Hz, the response is a constant 6 dB below the upper mid-frequency level. Note that there is a response shelf, not a continuous roll-off.

When the PZM is on a rectangular boundary, two shelves appear. The long side of the boundary is $D_{\text{max}}$ and the short side $D_{\text{min}}$. The response is down 3 dB at

$$f_{-3 \text{dB}} = \frac{188 \times D_{\text{max}}}{D_{\text{max}}} \quad \text{(47-21)}$$

*57.3 for SI units

and is down another 3 dB at

$$f_{-3 \text{dB}} = \frac{188 \times D_{\text{min}}}{D_{\text{min}}} \quad \text{(47-22)}$$

*57.3 for SI units

The low-frequency shelf varies with the angle of the sound source around the boundary. At 90° incidence (sound wave motion parallel to the boundary), there is no low-frequency shelf.

The depth of the shelf also varies with the distance of the sound source to the panel. The shelf starts to disappear when the source is closer than a panel dimension away. If the source is very close to the PZM mounted on a panel, there is no low-frequency shelf; the frequency response is flat.

If the PZM is at the junction of two or more boundaries at right angles to each other, the response shelves down 6 dB per boundary at the above frequency. For example, a two-boundary unit made of 2 ft (0.6 m) square panels shelves down 12 dB below 94 Hz.

There are other frequency-response effects in addition to the low-frequency shelf. For sound sources on-axis to the boundary, the response rises about 10 dB
above the shelf at the frequency where the wavelength equals the boundary dimension.

For a square panel,

\[ F_{peak} = \frac{0.88c}{D} \]  \hspace{1cm} \text{(16-23)}

where,

- \( c \) is the speed of sound (1130 ft/s or 344 m/s)
- \( D \) is the boundary dimension in feet or meters

For a circular panel

\[ F_{peak} = \frac{c}{D} \]  \hspace{1cm} \text{(16-24)}

As an example, a 2 ft (0.6 m) square panel has a 10 dB rise above the shelf at

\[ F_{peak} = \frac{0.88c}{D} \]
\[ = \frac{0.88 \times 1130}{2} \]
\[ = 497 \text{ Hz} \]

Note that this response peak is only for the direct sound of an on-axis source. The effect is much less if the sound field at the panel is partly reverberant, or if the sound waves strike the panel at an angle. The peak is also reduced if the microphone capsule is placed off-center on the boundary.

Fig. 16-71 shows the frequency response at various angles of sound incidence of a PZM mounted on a 2 ft square panel. Note the several phenomena shown in the figure:

- The low-frequency shelf (most visible at 30° and 60°).
- The lack of low-frequency shelving at 90° (grazing incidence).
- The 10 dB rise in response at 497 Hz.
- The edge-interference peaks and dips above 497 Hz (most visible at 0° or normal incidence).
- The lessening of interference at increasing angles.
- The greater rear rejection of high frequencies than low frequencies.

16.6.1.2.4 Frequency-Response Anomalies Caused by Boundaries

Frequency response is affected by:

- When sound waves strike a boundary, pressure doubling occurs at the boundary surface, but does not occur outside the boundary, so there is a pressure difference at the edge of the boundary. This pressure difference creates sound waves.

These sound waves generated at the edge of the boundary travel to the microphone in the center of the boundary. At low frequencies, these edge waves are opposite in polarity to the incoming sound waves. Consequently, the edge waves cancel the pressure-doubling effect.

- At low frequencies, pressure doubling does not occur, but at mid- to high-frequencies, pressure doubling does occur. The net effect is a mid- to high-frequency boost, which could be considered a low-frequency loss or shelf.

- Incoming waves having wavelengths about six times the boundary dimensions are canceled by edge effects while waves much smaller than the boundary dimensions are not canceled by edge effects.

- Waves having wavelengths on the order of the boundary dimensions are subject to varying interference versus frequency; i.e., peaks and dips in the frequency response.

- At the frequency where the wavelength equals the boundary dimension, the edge wave is in phase with the incoming wave. Consequently, there is a response rise (about 10 dB above the low frequency shelf) at that frequency. Above that frequency, there is a series
of peaks and dips that decrease in amplitude with frequency.
- The edge-wave interference decreases if the incoming sound waves approach the boundary at an angle.
- Interference also is reduced by placing the microphone capsule off-center. This randomizes the distances from the edges to the microphone capsule, resulting in a smoother response.

16.6.2 Lavalier Microphones

Lavalier microphones are made either to wear on a lavalier around the neck or to clip onto a tie, shirt, or other piece of clothing. The older heavy style lavalier microphone, Fig. 16-72, which actually laid on the chest, had a frequency response that was shaped to reduce the boomingness of the chest cavity, and the loss of high-frequency response caused by being 90° off axis to the signal, Fig. 16-73. These microphones should not be used for anything except as a lavalier microphone.

Most lavalier microphones are omnidirectional, however, more manufacturers are producing directional lavalier microphones. The Sennheiser MKE 104 clip-on lavalier microphone, Fig. 16-74, has a cardioid pickup pattern, Fig. 16-76. This reduces feedback, background noise, and comb filtering caused by the canceling between the direct sound waves and sound waves that hit the microphone on a reflective path from the floor, lectern, and so forth.

Figure 16-72. Shure SM11 dynamic omnidirectional lavalier microphone. Courtesy Shure Incorporated.

Figure 16-73. Typical frequency response of a heavy-style dynamic lavalier microphone.

Lavalier microphones may be dynamic, condenser (capacitor), pressure-zone, electret, or high-impedance ceramic.

The newer loss mass clip-on lavalier microphones, Figs. 16-74 and 16-75, do not require frequency response correction because there is no coupling to the chest cavity and the small diameter of the diaphragm does not create pressure build-up at high frequencies, creating directionality.

One of the smallest microphones is the Countryman B6, Fig. 16-77. The B6 microphone has a diameter of 0.1 inches and has replaceable protective caps. Because of its small size, it can be hidden even when it’s in plain sight. By choosing a color cap to match the environment, the microphone can be pushed through a button hole or placed in the hair.

Lavalier microphones are normally used to give the talker freedom of movement. This causes problems associated with motion—for instance, noise being transmitted through the microphone cable. To reduce this noise, soft, flexible microphone cable with good fill to reduce wire movement should be used (see Chapter 14). The cable, or power supply for electret/condenser microphones, should be clipped to the user’s belt or pants to reduce cable noise to only that created between the clip and the microphone, about 2 ft (0.6 m). Clip-
ping to the waist also has the advantage of acting as a strain relief when the cord is accidentally pulled or stepped on.

A second important characteristic of the microphone cable is size. The cable should be as small as possible to make it unobtrusive and light enough so it will not pull on the microphone and clothing.

Because the microphone is normally 10 inches (25 cm) from the mouth of the talker and out of the signal path, the microphone output is less than a microphone on a stand in front of the talker. Unless the torso is between the microphone and loudspeaker, the lavalier microphone is often a prime candidate for feedback. For this reason, the microphone response should be as smooth as possible.

As in any microphone situation, the farther the microphone is away from the source, the more freedom of movement between microphone and source without adverse effects. If the microphone is worn close to the neck for increased gain, the output level will be greatly affected by the raising and lowering and turning of the talker’s head. It is important that the microphone be worn chest high and free from clothing, etc. that might cover the capsule, reducing high-frequency response.

16.6.3 Head-Worn Microphones

Head-worn microphones such as the Shure Model SM10A, Fig. 16-78, and Shure Beta 53, Fig. 16-79, are low-impedance, unidirectional, dynamic microphones, designed for sports and news announcing, for interviewing and intercommunications systems, and for special-event remote broadcasting. The Shure SM10A is a unidirectional microphone while the Beta 53 is an omnidirectional microphone.

![Figure 16-76. Polar response of the microphone in Fig. 16-75. Courtesy Sennheiser Electronic Corporation.](image)

![Figure 16-77. Countryman B6 miniature lavalier microphone. Courtesy of Countryman Associates, Inc.](image)

![Figure 16-78. Shure SM10A dynamic unidirectional head-worn microphone. Courtesy Shure Incorporated.](image)

Head-worn microphones offer convenient, hands-free operation without user fatigue. As close-talking units, they may be used under noisy conditions without losing or masking voice signals. They are small, lightweight, rugged, and reliable units that
normally mount to a cushioned headband. A pivot permits the microphone boom to be moved 20° in any direction and the distance between the microphone and pivot to be changed 9 cm (3½ in).

Another head-worn microphone, the Countryman Isomax E6 Directional EarSet microphone, is extremely small. The microphone clips around the ear rather than around the head. The units come in different colors to blend in with the background. The ultra-miniature condenser element is held close to the mouth by a thin boom and comfortable ear clip. The entire assembly weighs less than one-tenth of an ounce and almost disappears against the skin, so performers can forget it’s there and audiences barely see it, Fig. 16-80.

The microphone requires changeable end caps that create a cardioid pickup pattern for ease of placement, or a hypercardioid pattern when more isolation is needed. The C (cardioid) and H (hypercardioid) end caps modify the EarSet’s directionality, Fig. 16-81.

The EarSet series should always have a protective cap in place to keep sweat, makeup and other foreign material out of the microphone.

The hypercardioid cap provides the best isolation from all directions, with a null toward the floor where wedge monitors are often placed. The hypercardioid is slightly more sensitive to air movement and handling noise and should always be used with a windscreen.

The cardioid cap is slightly less directional, with a null roughly toward the performer’s back. It’s useful for trade show presenters or others who have a monitor loudspeaker over their shoulders or behind them.

The microphone can be connected to a sound board or wireless microphone transmitter with the standard 2 mm cable or an extra small 1 mm cable, Fig. 16-80.
16.6.4 Base Station Microphones

Base station power microphones are designed specifically for citizens band transceivers, amateur radio, and two-way radio applications. For clearer transmission and improved reliability, transistorized microphones can be used to replace ceramic or dynamic, high- or low-impedance microphones supplied as original equipment.

The Shure Model 450 Series II, Fig. 16-82, is a high output dynamic microphone designed for paging and dispatching applications. The microphone has an omnidirectional pickup pattern and a frequency response tailored for optimum speech intelligibility, Fig. 16-83. It includes an output impedance selection switch for high, 30,000 Ω, and low, 225 Ω, and a locking press-to-talk switch.

The press-to-talk switch can be converted to a monitor/transmit switch with the Shure RK199S Split-Bar Conversion Kit. When the optional split-bar Transmit/Monitor Switch Conversion Kit is installed, the monitor bar must be depressed before the transmit switch can be depressed, requiring the operator to verify that the channel is open before transmitting. The monitor bar can be locked in the on position. The transmit bar is momentary and cannot be locked.

16.6.5 Differential Noise-Canceling Microphones

Differential noise-canceling microphones, Fig. 16-84, are essentially designed for use in automobiles, aircraft, boats, tanks, public-address systems, industrial plants, or any service where the ambient noise level is 80 dB or greater and the microphone is handheld. Discrimination is afforded against all sounds originating more than ¼ in (6.4 mm) from the front of the microphone. The noise-canceling characteristic is achieved through the use of a balanced port opening, which directs the unwanted sound to the rear of the dynamic unit diaphragm out of phase with the sound arriving at the front of the microphone. The noise canceling is most effective for frequencies above 2000 Hz. Only speech originating within ¼ in (6.4 mm) of the aperture is fully reproduced. The average discrimination between speech and noise is 20 dB with a frequency response of 200–5000 Hz.

16.6.6 Controlled-Reluctance Microphones

The controlled-reluctance microphone operates on the principle that an electrical current is induced in a coil, located in a changing magnetic field. A magnetic armature is attached to a diaphragm suspended inside a coil. The diaphragm, when disturbed by a sound wave, moves the armature and induces a corresponding varying voltage in the coil. High output with fairly good frequency response is typical of this type of microphone.

16.6.7 Handheld Entertainer Microphones

The handheld entertainer microphone is most often used by a performer on stage and, therefore, requires a special frequency response that will increase articulation and presence. The microphones are often subjected to rough handling, extreme shock, and vibration. For live performances, the proximity effect can be useful to produce a low bass sound.
Probably the most famous entertainer’s microphone is the Shure SM58, Fig. 16-85. The microphone has a highly effective spherical wind screen that also reduces breath pop noise. The cardioid pickup pattern helps reduce feedback. The frequency response, Fig. 16-86, is tailored for vocals with brightened midrange and bass roll-off. Table 16-2 gives the suggested microphone placement for best tone quality.

To overcome rough handling and handling noise, special construction techniques are used to reduce wind, pop noise, and mechanical noise and to ensure that the microphone will withstand sudden collisions with the floor. The Sennheiser MD431, Fig. 16-87, is an example of a high-quality, rugged, and low-mechanical-noise microphone. To eliminate feedback, the MD431 incorporates a supercardioid directional characteristic, reducing side pickup to 12% or less than half that of conventional cardioids.

Another problem, particularly with powerful sound reinforcement systems, is mechanical (handling) noise. Aside from disturbing the audience, it can actually damage equipment. As can be seen in the cutaway, the MD 431 is actually a microphone within a microphone. The dynamic transducer element is mounted within an inner capsule, isolated from the outer housing by means of a shock absorber. This protects it from handling noise as well as other mechanical vibrations normally encountered in live performances.

### Table 16-2. Suggested Placement for the SM58 Microphone

<table>
<thead>
<tr>
<th>Application</th>
<th>Suggested Microphone Placement</th>
<th>Tone Quality</th>
</tr>

<td>1 m (3 ft) to 2 m (6 ft) away</td>
<td>Thinner; distant sound; ambience</td>
</tr>
</tbody>
</table>

To screen out noise still further, an internal electrical high pass filter network is incorporated to ensure that low-frequency disturbances will not affect the audio signal. A built-in mesh filter in front of the diaphragm reduces the popping and excessive sibilance often produced by close micing.

The microphone case is a heavy-duty cast outer housing with a stainless steel front grille and reed-type on-off switch. A hum bucking coil is mounted behind the transducer to cancel out any stray magnetic fields.

### 16.6.8 Pressure-Gradient Condenser Microphones

One of the most popular studio microphones is the Neumann U-87 multidirectional condenser microphone, Fig. 16-88, and its cousin, the Neumann U-89,
Fig. 16-89. This microphone is used for close micing where high SPLs are commonly encountered. The response below 30 Hz is rolled off to prevent low-frequency blocking and can be switched to 200 Hz to allow compensation for the bass rise common to all directional microphones at close range.

The figure-eight characteristic is produced by means of two closely spaced or assembled cardioid characteristic capsules, whose principal axes are pointed in opposite directions and are electrically connected in antiphase.

These microphones are usually made with backplates equipped with holes, slots, and chambers forming delay elements whose perforations act as part friction resistances and part energy storage (acoustic inductances and capacitances), giving the backplate the character of an acoustic low-pass network. In the cutoff range of this low-pass network, above the transition frequency $f_t$, the membrane is impinged upon only from the front, and the microphone capsule changes to a pressure or interference transducer.

The output voltage $e(t)$ of a condenser microphone using dc polarization is proportional to the applied dc voltage $E_o$ and, for small displacement amplitudes of the diaphragm, to the relative variation in capacity $c(t)/C_o$ caused by the sound pressure

$$e(t) = E_o \frac{c(t)}{C_o} \quad (16-25)$$

where,

- $E_o$ is the applied dc voltage,
- $c(t)$ is the variable component of capsule capacity,
- $C_o$ is the capsule capacity in the absence of sound pressure,
- $t$ is the time.

The dependence of output voltage $e(t)$ on $E_o$ is utilized in some types of microphones to control the directional characteristic. Two capsules with cardioid characteristics as shown in Fig. 16-90 are placed back to back. They can also be assembled as a unit with a common backplate. The audio (ac) signals provided by the two diaphragms are connected in parallel through a capacitor $C$. The intensity and phase relationship of the outputs from the two capsule halves can be affected by varying the dc voltage applied to one of them (the left cartridge in Fig. 16-90). This can be accomplished through a switch, or a potentiometer. The directional characteristic of the microphone may be changed by remote control via long extension cables.

If the switch is in its center position C, then the left capsule-half does not contribute any voltage, and the microphone has the cardioid characteristic of the right capsule-half. In switch position A, the two ac voltages are in parallel, resulting in an omnidirectional pattern. In position E the two halves are connected in antiphase, and the result is a figure-8 directional response pattern.

The letters A to E given for the switch positions in Fig. 16-90 produce the patterns given the same letters in Fig. 16-91.

### 16.6.9 Interference Tube Microphone

The interference tube microphone as described by Olson in 1938 is often called a shotgun microphone because of its physical shape and directional characteristics.

Important characteristics of any microphone are its sensitivity and directional qualities. Assuming a constant sound pressure source, increasing the micro-
phone to the source distance requires an increase in the gain of the amplifying system to produce the same output level. This is accompanied by a decrease in SNR and an increase in environmental noises including reverberation and background noise to where the indirect sound may equal the direct sound. The wanted signal then deteriorates to where it is unusable. Distance limitations can be overcome by increasing the sensitivity of the microphone, and the effect of reverberation and noise pickup can be lessened by increasing the directivity of the pattern. The interference tube microphone has these two desirable qualities.

The DPA 4017 is a supercardioid shotgun microphone. It is 8.3 in (210 mm) long and weighs 2.5 oz (71 g), making it useful on booms, Fig. 16-92. The polar pattern is shown in Fig. 16-93.

The difference between interference tube microphones and standard microphones lies in the method of pickup.

An interference tube is mounted over the diaphragm and is schematically drawn in Fig. 16-94.

The microphone consists of four parts as shown in the schematic:

1. Interference tube with one frontal and several lateral inlets covered with fabric or other damping material.
Capsule with the diaphragm and counter electrode(s).

Rear inlet.

Electronic circuit.

The directional characteristics are based on two different principles:

1. In the low-frequency range, tube microphones behave as first-order directional receivers. The tube in front of the capsule can be considered as an acoustic element with a compliance due to the enclosed air volume and a resistance determined by the lateral holes or slits of the tube. The rear inlet is designed as an acoustic low-pass filter to achieve the phase shift for the desired polar pattern (normally cardioid or supercardioid).

2. In the high-frequency range, the acoustical properties of the interference tube determine the polar patterns. The transition frequency between the two different directional characteristics depends on the length of the tube and is given by

\[ f_o = \frac{c}{2L} \]  \hspace{1cm} (16-26)

where,

- \( f_o \) is the transition frequency,
- \( c \) is the velocity of sound in air in feet per second or meters per second,
- \( L \) is the length of the interference tube in feet or meters.

Referring to Fig. 16-94, if the tube is exposed to a planar sound wave, every lateral inlet is the starting point of a new wave traveling inside the tube toward the capsule as well as towards the frontal inlet. Apart from the case of frontal sound incidence, every particular wave covers a different distance to the capsule and, therefore, arrives at a different time. Fig. 16-94 shows the delay...
times of waves $b$ and $c$ compared to wave $a$. Note that they increase with the angle of sound incidence.

The resulting pressure at the capsule can be calculated by the sum of all particular waves generated over the tube’s length, all with equal amplitudes but different phase shifts. The frequency and phase response curves can be described by

$$\frac{P(\theta)}{P(\theta = 0^\circ)} = \frac{\sin \left( \frac{\pi L}{\lambda} \times (1 - \cos \theta) \right)}{\frac{\pi L}{\lambda} \times (1 - \cos \theta)}$$

where,

- $P(\theta)$ is the microphone output at a given angle of sound incidence,
- $P(\theta = 0^\circ)$ is the microphone output along principal axis,
- $\lambda$ is the wavelength,
- $L$ is the length of the tube,
- $\theta$ is the angle of sound incidence.

The calculated curves and polar patterns are plotted in Figs. 16-95 and 16-96 for a tube length of 9.8 inches (25 cm) without regard to the low-frequency directivity caused by the rear inlet. The shape of the response curves looks similar to that of a comb filter with equidistant minima and maxima decreasing with 6 dB/octave. The phase response is frequency independent only for frontal sound incidence. For other incidence angles, the phase depends linearly on frequency, so that the resulting pressure at the capsule shows an increasing delay time with an increasing incidence angle.

In practice, interference tube microphones show deviations from this simplified theoretical model. Fig. 16-97 is the polar pattern of the Sennheiser MKH 60P48. The built-in tube delivers a high-frequency roll-off for lateral sound incidence with a sufficient attenuation especially for the first side lobes. The shape of the lateral inlets as well as the covering material influences the frequency and phase response curves. The transition frequency can be lowered with an acoustic mass in the frontal inlet of the tube to increase the delay times for low frequencies.

Another interference tube microphone is the Shure SM89, Fig. 16-98. In this microphone, a tapered acoustic resistance is placed over the elongated interference tube slit, varying the effective length of the tube with frequency so that $L/M$ (the ratio of tube length to wavelength) remains nearly constant over the desirable frequency range. This allows the polar response to be more consistent as frequency increases, Fig. 16-99, because the resistance in conjunction with the compliance of the air inside the tube forms an acoustical low-pass filter. High frequencies are attenuated at the end of the tube because it is the high-resistance end,
allowing the high frequencies to enter the tube only near
the diaphragm. This makes the tube look shorter at high
frequencies, Eq. 16-27.

While a cardioid microphone may be capable of
picking up satisfactorily at 3 ft (1 m), a cardioid in-line
may reach 6–9 ft (1.8–2.7 m), and a super in-line may
reach as far as 40 ft (12 m) and be used for picking up a
group of persons in a crowd from the roof of a nearby
building, following a horse around a race track, picking
up a band in a parade, and picking up other hard-to-get
sounds from a distance.

There are precautions that should be followed when
using interference tube microphones. Because they
obtain directivity by cancellation, frequency response
and phase are not as smooth as omnidirectional micro-
phones. Also, since low frequencies become omnidi-
rectional, the frequency response drops rapidly below
200 Hz, which helps control directivity.

It should not be assumed that no sound will be
picked up outside the pickup cone. As the microphone
is rotated from an on-axis position to a 180° off-axis
position, there will be a progressive drop in level.
Sounds originating at angles of 90° to 180° off-axis will
cancel by 20 dB or more; however, the amount of
cancellation depends on the level and distance of the
microphone from the sound source. As an example, if
an on-axis sound originated at a distance of 20 ft (6 m), a 90° to 180° off-axis sound occurring at the same distance and intensity will be reduced by 20 dB or more, providing none of the off-axis sound is reflected into the front of the microphone by walls, ceiling, and so on. On the other hand, should the off-axis sound originate at a distance of 2 ft (0.6 m) and at the same sound pressure level as the sound at 20 ft (6 m) on axis, it will be reproduced at the same level. The reason for this behavior is that the microphone is still canceling the unwanted sound as much as 20 dB, but due to the difference in the distances of the two sounds, the off-axis sound is 20 dB louder than the on-axis sound at the microphone. Therefore, they are reproduced at the same level. For a pickup in an area where random noise and reverberation are problems, the microphone should be located with the back end to the source of unwanted sound and as far from the disturbances as possible.

If the microphone is being used inside a truck or enclosed area, and pointing out a rear door, poor pickup may be experienced because all sounds, both wanted and unwanted, arrive at the microphone on-axis. Since the only entrance is through the truck door, no cancellation occurs because the truck walls inhibit the sound from entering the sides of the microphone. In this instance, the microphone will be operating as an omnidirectional microphone. Due to the reflected sound from the walls, the same condition will prevail in a room where the microphone is pointed through a window or when operating in a long hallway. For good pickup, the microphone should be operated in the open and not in closely confined quarters.

A shotgun interference tube microphone cannot be compared to a zoom lens since the focus does not vary nor does it reach out to gather in the sound. What the narrow polar pattern and high rate of cancellation do are to reduce pickup of the random sound energy and permit the raising of the amplifier gain following the microphone without seriously decreasing the SNR.

Difficulties may also be encountered using interference tube microphones on stage and picking out a talker in the audience, particularly where the voice is 75–100 ft (23–30 m) away and fed back through a reinforcement system for the audience to hear. Under these circumstances, only about 30–50 ft (9–15 m) is possible without acoustic feedback; even then, the system must be balanced very carefully.

### 16.6.10 Rifle Microphones

The **rifle microphone** consists of a series of tubes of varied length mounted in front of either a capacitor or dynamic transducer diaphragm, Fig. 16-100. The transducer may be either a capacitor or dynamic type. The tubes are cut in lengths from 2–60 inches (5–150 m) and bound together. The bundling of the tubes in front of the transducer diaphragm creates a distributed sound entrance, and the omnidirectional transducer becomes highly directional.

![RCA rifle microphone. Courtesy of Radio Corporation of America.](image)

Sound originating on the axis of the tubes first enters the longest tube and, as the wavefront advances, enters successively shorter tubes in normal progression until the diaphragm is reached. Sounds reaching the diaphragm from the source travel the same distance, regardless of the tube entered, so all sounds arriving on-axis are in phase when they reach the diaphragm. Sounds originating 90° off-axis enter all tubes simultaneously. A sound entering a longer tube may travel 18 inches (46 cm) to reach the diaphragm, while the same sound traveling through the shortest tube will travel only 3 inches (7.6 cm), with other differences for the varied length of tubing causing an out-of-phase signal at the diaphragm. Under these conditions, a large portion of the sound originating at 90° is canceled, and from 180° an even greater phase difference occurs, and cancellation is increased considerably.

The **RCA MI-100006A vari-directional microphone**, Fig. 16-100, consists of nineteen ⅛ inches (0.8 cm) plastic tubes, ranging from 3–18 inches (7.6–46 cm) in length. The tubes are bundled and mounted in front of an omnidirectional capacitor-microphone head. Rifle microphones are not used very much today.

### 16.6.11 Parabolic Microphones

**Parabolic microphones** use a parabolic reflector with a microphone to obtain a highly directional pickup response. The microphone diaphragm is mounted at the focal point of the reflector, Fig. 16-101. Any sound
arriving from an angle other than straight on will be scattered and therefore will not focus on the pickup. The microphone is focused by moving the diaphragm in or out from the reflector for maximum pickup. This type concentrator is often used to pick up a horse race or a group of people in a crowd.

The greatest gain in sound pressure is obtained when the reflector is large compared to the wavelength of the incident sound. With the microphone in focus, the gain is the greatest at the mid-frequency range. The loss of high frequencies may be improved somewhat by defocusing the microphone a slight amount, which also tends to broaden the sharp directional characteristics at the higher frequencies. A bowl 3 ft (0.91 m) in diameter is practically nondirectional below 200 Hz but is very sharp at 8000 Hz, Fig. 16-102. For a diameter of 3 ft, the gain over the microphone without the bowl is about 10 dB and, for a 6 ft (1.8 m) diameter bowl, approximately 16 dB.

16.6.12 Zoom Microphones

A zoom microphone, or variable-directivity microphone, is one that operates like and in conjunction with a zoom lens. This type of microphone is useful with television and motion-picture operations.

The optical perception of distance to the object is simply determined by the shot angle of the picture. On the other hand, a sound image is perceived by:

- **Loudness.**
- **Reverberation** (ratio of direct sound to reflected sound).
- **Acquired response to sound.**

If the sound is recorded in monophonic, the following factors can be skillfully combined to reproduce a natural sound image with respect to the perceived distance:

- **Loudness**: Perceived loudness can be controlled by varying microphone sensitivity.
- **Reverberation**: The representation of the distance is made by changing the microphone directivity or the ratio between direct and reverberant sound. In a normal environment, we hear a combination of direct sound and its reflections. The nearer a listening point is to the source, the larger the ratio of direct to reverberant sound. The farther the listening point is from the source, the smaller the ratio; therefore, use of a high-directivity microphone to keep direct sound greater than reflected sound permits the microphone to get apparently closer to the source by reducing reverberant sound pickup. For outdoor environments, use of directional microphones allows the ambient noise level to be changed for natural representation of distances.
- **Acquired human response to sound**: Normally we can tell approximately how far a familiar object as a car or a person is by the sound generated by the objects because we acquire the response to sound through our daily experiences.
16.6.12.1 Distance Factor

The fact that microphone directivity determines the perceived distance can be explained from the viewpoint of the distance factor. Fig. 16-103 shows the sound pressure level at the position of an omnidirectional microphone versus the distance between the microphone and a sound source \( S \), with ambient noise evenly distributed. Suppose the distance is 23 ft (7 m) and the ambient noise level is at 1. If the microphone is replaced by one that has a narrow directivity with the same on-axis sensitivity, less noise is picked up, so the observed noise level is lowered to 2. For an omnidirectional microphone, the same effect can be obtained at a distance of 7.5 ft (2.3 m). From a different standpoint, the same SNR as for an omnidirectional microphone at 20.6 ft (6.3 m) can be obtained at a distance of 65 ft (20 m). The ratio of actual-to-observed distance is called the distance factor.

![Figure 16-103. Relationship between sound pressure level and distance in an evenly distributed noise environment.](image)

16.6.12.2 Operation of Zoom Microphones

By changing the sensitivity and directivity of a microphone simultaneously, an acoustical zoom effect is realized, and more reality becomes possible in sound recording. Fig. 16-104 is the basic block diagram of a zoom microphone system. The system consists of three unidirectional microphone capsules (1 through 3) arranged on the same axis. The three capsules have the same characteristics, and capsule 3 faces the opposite direction. The directivity can be varied from omnidirectional to second-order gradient unidirectional by varying the mixing ratio of the output of each capsule and changing the equalization characteristic accordingly. An omnidirectional pattern is obtained by simply combining the outputs of capsule 2 and 3. In the process of directivity change from omnidirectional to unidirectional, the output of capsule 3 is gradually faded out, while the output of capsule 1 is kept off. Furthermore, the equalization characteristic is kept flat, because the on-axis frequency response does not change during this process. In the process of changing from unidirectional to second-order gradient unidirectional, the output of capsule 3 is kept off. The second-order gradient unidirectional pattern is obtained by subtracting the output of capsule 1 from the output of capsule 2. To obtain the second-order gradient unidirectional pattern with minimum error, the output level of capsule 1 needs to be trimmed. Since the on-axis response varies according to the mixing ratio, the equalization characteristics also have to be adjusted along with the level adjustment of the mixing ratio. The on-axis sensitivity increase of second-order gradient setup over the unidirectional setup allows the gain of the amplification to be unchanged.

![Figure 16-104. Configuration of the zoom microphone.](image)
16.6.12.3 Zoom Microphone Video Camera Linkage

In order to obtain a good matching of picture and sound, a mechanism that synchronizes the optical zooming and acoustical zooming becomes inevitable. Electrical synchronization would also be possible by using voltage-controlled amplifiers (VCA) or voltage-controlled resistors (VCR).

16.6.13 Automatic Microphone Systems

There have been many advances in automatic mixers where the microphone is normally off until gated on by a signal, hopefully, a wanted signal. Many operate on an increased level in one or more microphones with respect to the random background noise, see Chapter 21.

While the Shure Automatic Microphone System (AMS) is a discontinued microphone, it is still used in many venues. The system turns microphones on and off (with automatic gating), greatly reducing the reverberant sound quality and feedback problems often associated with the use of multiple microphones. The AMS microphones are gated on only by sounds arriving from the front within their acceptance angle of 120°. Other sounds outside the 120° angle, including background noise, will not gate the microphones on, regardless of level. In addition, the AMS adjusts gain automatically to prevent feedback as the number of on microphones increases.

The Shure Model AMS22 low-profile condenser microphone, Fig. 16-105, is designed for use only with the Shure AMS. Unlike conventional microphones, it contains electronic circuitry and a novel transducer configuration to make it compatible with the Shure AMS mixers. The microphone should not be connected to standard simplex- (phantom-) or non-simplex-powered microphone inputs because they will not function properly.

AMS microphones, in conjunction with the special circuitry in the AMS mixers, uniquely discriminate between desired sounds that originate within their 120° front acceptance angle and all other sounds. Sounds from the front of a microphone are detected and cause it to be gated on, transmitting its signal to the mixer output. Sounds outside the acceptance angle will not gate the microphone on. When an AMS22 is gated on, it operates like a hemi- or half-cardioid microphone because half the cardioid pattern disappears when the microphone is placed on a surface, Fig. 16-106. Each AMS microphone operates completely independently in analyzing its own sound field and deciding whether or not a sound source is within the front acceptance angle.

The microphone should be placed so that intended sources are within 60° of either side of the front of the microphone—that is, within 120° acceptance angle. Sources of undesired sound should be located outside the 120° acceptance angle. Each microphone should be at least 3 ft from the wall behind it, and items such as large ashtrays or briefcases should be at least 1 ft behind it. If the microphones are closer than that, reflections will reduce the front-to-back discrimination and, therefore, make the microphone act more like a conventional cardioid type.

16.6.14 PolarFlex™ Microphone System

The PolarFlex system by Schoeps models any microphone. The system features two output channels with two microphones per channel, Fig. 16-107. The standard system consists of an omnidirectional and a figure 8 microphone for each channel and an analog/digital processor.

Essential sonic differences between condenser microphones of the same nominal directional pattern are not only due to frequency response, but also to the fact that the polar pattern is not always uniformly maintained throughout the entire frequency range particularly at the lowest and highest frequencies. Though ostensibly a defect, this fact can also be used to advantage (e.g., adaptation to the acoustic of the recording room). While the frequency response at a given pickup angle can be controlled by equalizers, there was no way to alter the polar pattern correspondingly. The only way
to control this situation was through the choice of microphones having different variations of the polar pattern versus frequency. With the DSP-4P processor, nearly ideal directional characteristics can be selected, and nearly any frequency-dependent directional characteristic that may be desired—e.g., a cardioid becomes omnidirectional below the midrange, so that it has better response at the very lowest frequencies. Also modeling a large-diaphragm microphone is possible.

Furthermore, in excessively reverberant spaces one could record a drier sound (cardioid or supercardioid setting) or, in spaces that are dry, accept more room reflections (wide cardioid or omni setting) in the corresponding frequency range.

In such cases it is not the frequency response but rather the ratio of direct to reflected sound, that will be altered. That cannot be done with an equalizer nor can a reverb unit reduce the degree of reflected sound after the fact.

In the arrangement of Fig. 16-107, an omnidirectional microphone with a mild high-frequency emphasis in the direct sound field is used. Because of its angle of orientation, the capsule has ideal directional response in the horizontal plane; the high-frequency emphasis compensates for the high-frequency losses due to lateral sound incidence.

A figure 8 microphone is set directly above the omni. The direction to which it is aimed will determine the orientation of the resulting adjustable virtual microphone. The hemispherical device attached to the top of the figure 8 flattens the response of the omnidirectional microphone at the highest frequencies.

Figure 16-106. Hemicardioid polar pickup pattern for a Shure AMS surface microphone. Courtesy Shure Incorporated.

Figure 16-107. A Schoeps PolarFlex microphone with an omnidirectional and a figure 8 microphone. Courtesy Schoeps GmbH.
By using the DSP-4P processor, Fig. 16-108, the following settings can be made independently of one another in three adjustable frequency ranges. With the three knobs in the upper row, the directional patterns in each of the three frequency bands can be set. The settings are indicated by a circle of LEDs around each of the knobs. At the lower left of each knob is the omni-directional setting; at the lower right is the figure 8 setting. Eleven intermediate pattern settings are available. The knobs in the lower row are set between those in the upper row. They are used for setting the boundaries between the frequency ranges; 100 Hz–1 kHz and 1–10 kHz, respectively, in ½ octave steps.

The three buttons at the lower right are for storing and recalling presets. If the unprocessed microphone signals have been recorded, these adjustments can be made during postprocessing.

The processor operates at 24-bit resolution with either a 44.1 kHz or 48 kHz sampling rate. When a digital device is connected to the input, the PolarFlex™ processor adapts to its clock signal.

16.7 Stereo Microphones

Stereo microphones are microphones or systems used for coincident, XY, M/S, SASS, binaural in-the-head, and binaural in-the-ear (ITE) recording. These systems have the microphones close together (in proximity of a point source or ear-to-ear distance) and produce the stereophonic effect by intensity stereo, time-based stereo, or a combination of both.

16.7.1 Coincident Microphones

A highly versatile stereo pickup is the coincident microphone technique.¹¹,¹²,¹³ Coincident means that sound reaches both microphones at the same time, implying that they are at the same point in space. In practice, the two microphones cannot occupy the same point, but they are placed as closely together as possible. There are special-purpose stereo microphones available that combine the two microphones in one case. Since they are essentially at the same point, there can be no time differences between arrival of any sound from any direction; thus no cancellation can occur. It might first appear that there could be no stereophonic result from this configuration. The two microphones are usually unidirectional and oriented at 90° to one another. The combination is then aimed at the sound source, each microphone 45° to a line through the source. Stereo results from intensity differences—the left microphone (which is to the right of the pair) will receive sounds from the left-hand part of the stage with greater volume than it will receive from the right-hand side of the stage.

The stereo result, although often not as spectacular as that obtained from spaced microphones, is fully mono compatible, and it most accurately reproduces the sound of the acoustic environment. It is quite foolproof and quick to set up.

Variations of the coincident technique include changing the angle between the microphone (some stereo microphones are adjustable); using bidirectional microphones, which results in more reverberant sound; using combinations of unidirectional and bidirectional microphones; and using matrix systems, which electrically provide sum and difference signals from the left and right channels (these can be manipulated later for the desired effect).

The basic coincident technique was developed in the 1930s (along with the first stereo recordings) by English engineer Alan Blumlein.¹⁴ Blumlein used two figure 8 pattern ribbon microphones mounted so that their pattern lobes were at right angles (90°) to each other, as shown in Fig. 16-104. The stereo effect is produced

![Figure 16-109. Coincident microphone technique using two bidirectional microphones.](image-url)
primarily by the difference in amplitude generated in the two microphones by the sound source. A sound on the right generates a larger signal in microphone B than in microphone A. A sound directly in front produces an equal signal in both microphones, and a sound on the left produces a larger signal in microphone A than in microphone B. The same process takes place with spaced omnidirectional microphones, but because of the spacing, there is also a time delay between two signals (comb filter effect). It can also produce a loss in gain and unpleasant sound if the two channels are combined into a single monosignal. Since the coincident microphone has both its transducers mounted on the same vertical axis, the arrival time is identical in both channels, reducing this problem to a large degree.

Modern coincident microphones often use cardioid or hypercardioid patterns. These patterns work as well as the figure 8 pattern microphones in producing a stereo image, but they pick up less of the ambient hall sound.

Probably the strongest virtue of the coincident microphone technique is its simplicity under actual working conditions. Just place the microphone in a central location that gives a good balance between the musicians and the acoustics of the hall. It is this simplicity that makes coincident microphones a favorite of broadcast engineers recording (or transmitting) live symphonic concerts.

16.7.2 XY Stereo Technique

The XY technique uses two identical directional microphones that, in relation to the recording axis, are arranged at equal and opposed offset angles. The leftward pointing X microphone supplies the L signal directly, and the rightward pointing Y microphone supplies the R signal, Fig. 16-110. The stereophonic properties depend on the directional characteristics of the microphones and the offset angle.

One property specific to a microphone system is the recording angle, which defines the angle between the center axis (symmetry axis of the system) and the direction where the level differences between the L and R define the angular range of sound incidence where regular stereophonic reproduction is obtained. In most cases there is another opening for backward sound reception besides the recording angle for frontal sound pick-up.

Another important aspect concerns the relationship between the sound incidence angle and the stereophonic reproduction angle. As both XY and M/S recording techniques supply pure intensity cues, a relationship can be applied that relates the reproduction angle to the level difference of the L and R signals for the standard listening configuration based on an equilateral triangle, Fig. 16-111. This relationship is shown in Fig. 16-112 and is valid at frequencies between 330 and 7800 Hz within ±3°. The level difference is plotted on the horizontal axis and the reproduction angle can be read on the vertical scale. A 0° reproduction angle means localization at the center of the stereo base, and 30° means localization at one of the loudspeakers.

Fig. 16-113 shows the XY properties of wide-angle cardioids. The lower graph illustrates that the stereo image does not cover the full base width but is rather limited to some 20° at best. The recording angle can be altered between 90° and 120°. In-phase reproduction with correct side direction is maintained for all angles of sound incidence. The downward bend of the curves
indicates that the stereo image is affected by geometric compression effects.

Fig. 16-114 shows the XY properties of cardioids. The recording angle can be altered between 90° and 180°. Again, in-phase reproduction at the correct side is maintained for all directions of sound incidence. As all reproduction curves touch the upper edge of the graph, full stereo width is available at all offset angles. The individual curvatures indicate deviations from the ideal geometrical reproduction performance which would be represented by a straight line. Downward bends indicate image compression at the base edges, whereas upward bends indicate expansion. The lower graph shows that compression effects occur at frontal sound pick-up for offset angles above 30°, whereas expansion occurs at smaller offset angles. Best reproduction linearity is performed at offset angles around 30°. The reproduction of back sound is always affected by angular compression. Extreme compression effects occur where the curves touch the upper edge of the graph. The reproduction is then clustered at one of the loudspeakers.

16.7.3 The ORTF Technique

A variation on the basic XY coincident technique is the ORTF technique. The initials ORTF stand for Office de Radiodiffusion Television Francais, the French government radio network that developed this technique. The ORTF method uses two cardioid microphones spaced 7 inches (17 cm) apart and facing outward with an angle of 110° between them, Fig. 16-115. Because of the spacing between the transducers, the ORTF method does not have the time-coherence properties of M/S or XY micing.

16.7.4 The M/S Stereo Technique

The M/S technique employs a mid (M) cartridge that directly picks up the mono sum signal, and a side (S) cartridge that directly picks up the stereo difference signal (analogous to the broadcast stereo subcarrier
modulation signal). Although two individual microphones may be used, single-unit M/S microphones are more convenient and generally have closer cartridge placement. Fig. 16-116, a Shure VP88, and Fig. 16-117, an AKG C-422, are examples of M/S microphones.

Fig. 16-118 indicates the pickup patterns for a typical M/S microphone configuration. The mid cartridge is oriented with its front (the point of greatest sensitivity) aimed at the center of the incoming sound stage. A cardioid (unidirectional) pattern as shown is often chosen for the mid cartridge, although other patterns may also be used. For symmetrical stereo pickup, the side cartridge must have a side-to-side facing bidirectional pattern (by convention, the lobe with the same polarity as the front mid signal aims 90° to the left, and the opposite polarity lobe to the right).

In a stereo FM or television receiver, the mono sum baseband signal and the stereo difference subcarrier signal are demodulated and then decoded, using a sum-and-difference matrix, into left and right stereo audio signals. Similarly, the mid (mono) signal and the
side (stereo difference) signal of the MS microphone may be decoded into useful left and right stereo signals.

The mid cartridge signal’s relation to the mono sum signal, and the side cartridge signal’s relation to the stereo difference signal, can be expressed simply by

\[
M = \frac{1}{2(L + R)} \quad (16-28)
\]

\[
S = \frac{1}{2(L - R)} \quad (16-29)
\]

Solving for the left and right signals,

\[
L = M + S \quad (16-30)
\]

\[
R = M - S \quad (16-31)
\]

Therefore, the left and right stereo signals result from the sum and difference, respectively, of the mid and side signals. These stereo signals can be obtained by processing the mid and side signals through a sum and difference matrix, implemented with transformers, Fig. 16-119, or active circuitry. This matrix may be external to the M/S microphone or built-in.

In theory, any microphone pattern may be used for the mid signal pickup. Some studio M/S microphones provide a selectable mid pattern. In practice, however, the cardioid mid pattern is most often preferred in M/S microphone broadcast applications.

The AKG C422 shown in Fig. 16-120 is a studio condenser microphone that has been specially designed for sound studio and radio broadcasting. The microphone head holds two twin diaphragm condenser capsules elastically suspended to protect against handling noise.

The AKG C422 is connected to an S42E remote-control unit that allows any one of nine polar patterns to be selected for each channel. Because of noiseless selection, polar pattern changeover is possible even during recording.
Each channel of the microphone incorporates two cardioid diaphragms facing 180° of each other (back to back), Fig. 16-120. Note the 12 Vdc phantom power for the electronics and the 60 Vdc phantom power for the lower transducer (1), ensuring that transducer 1 is always biased on. This transducer has a positive output for a positive pressure. The second or upper transducer is connected to pin K, which through the S42E, has nine switchable voltages between 0 Vdc and 120 Vdc. When the voltage at K is 60 Vdc, the output of transducer 2 is 0 (60 Vdc on either side of it), so the microphone output is cardioid.

When the voltage at K is 120 Vdc, transducer 2 is biased with 60 Vdc of an opposite polarity from transducer 1 so the output is 180° out of polarity, the mixed output being a figure 8 pattern.

When the voltage at K is 0 Vdc, transducer 2 has a 60 Vdc bias on it with the same polarity as transducer 1. Because the transducers face in opposite directions, when these two outputs are combined, an omnidirectional pattern is produced.

By varying the voltage on K between 0 Vdc and 120 Vdc, various patterns between a figure 8 and an omnidirectional pattern can be produced.

The Shure VP88 stereo microphone, Fig. 16-116, also employs a switchable pattern. Fig. 16-121 shows the polar response of the mid capsule and the side capsule.

The left and right stereo signals exhibit their own equivalent pickup patterns corresponding to, respectively, left-forward-facing and right-forward-facing microphones. Fig. 16-122 shows the relative levels of the mid and side microphones and the stereo pickup pattern of the Shure VP88 microphone in the L position with the bidirectional side pattern maximum sensitivity 6 dB lower than the maximum mid sensitivity. The small rear lobes of each pattern are 180° out of polarity with the main front lobes. For sound sources arriving at 0° the left and right output signals are equal, and a center image is reproduced between the loudspeakers. As the sound source is moved off-axis, an amplitude difference between left and right is created, and the loudspeaker image is moved smoothly off-center in the direction of the higher amplitude signal.

When the mid (mono) pattern is fixed as cardioid, the stereo pickup pattern can be varied by changing the side level relative to the mid level. Fig. 16-123 shows an M/S pattern in the M position with the side level 1.9 dB lower than the mid level. Fig. 16-124, position H, increases the side level to 1.6 dB higher than the mid level. The three resultant stereo patterns exhibit pickup angles of 180°, 127°, and 90°, respectively. The incoming sound angles, which will create left,
left-center, center, right-center, and right images, are also shown. Note the changes in the direction of the stereo patterns and the size of their rear lobes.

Taking the directional properties of real microphones into consideration, it becomes clear that the M/S technique provides a higher recording fidelity than the XY technique. There are at least three reasons for this:

1. The microphones in an XY system are operated mainly at off-axis conditions, especially at larger offset angles. The influence of directivity imperfections is more serious than with MS systems, where the M microphone is aimed at the performance center. This is illustrated by Fig. 16-125.

2. The maximum sound incidence angle for the microphone is only half that of the X and Y microphones, although the covered performance area is the same for all microphones. This area is symmetrically picked up by the M microphone, but unsymmetrically by the X and Y microphones. The M/S system can supply the more accurate monophonic (M) signal in comparison with the XY system.

3. The M/S system picks up the S signal with a bidirectional microphone. The directivity performance of this type of microphone can be designed with a high degree of perfection, so errors in the S signal can be kept particularly small for all directions of sound incidence. The M/S system can supply a highly accurate side (S) signal.

4. In the M/S technique, the mono directivity does not depend on the amount of S signal applied to create the stereophonic effect. If recordings are made in the M/S format, a predictable mono signal is always captured. On the other hand, the stereophonic image can be simply influenced by modifying the S level without changing the mono signal. This can even be done during postproduction.

16.7.5 The Stereo Boom Microphone

Microphones for stereophonic television broadcasting have their own special problems. The optimal distance
from the TV screen is considered to be five times the screen diagonal, at which distance the line structure of the TV image can no longer be resolved by the human eye. The resulting minimum observer distance is therefore 11 ft (3.3 m) and the two loudspeakers should be at least 12.5 ft (3.8 m) apart. This is certainly not realistic for television viewing.

The sound engineer must take into account that the reproduction will be through loudspeakers right next to the TV screen as well as through hi-fi equipment. If, for instance, the full base width is used during the sound recording of a TV scene, an actor appearing at the right edge of the picture will be heard through the right loudspeaker of the hi-fi system and sound as if he is far to the right of the TV set. This will result in an unacceptable perception of location.

The viewer must be able to hear realistically the talker on the TV screen in the very place where the viewer sees the talker. To achieve this goal, German television proposed to combine a unidirectional microphone for the recording of the actors with a figure 8 microphone for the recording of the full stereophonic basic width.

This recording technique utilizes a figure-eight microphone suspended from the boom in such a way that it maintains its direction when the boom is rotated while a second microphone with unidirectional pattern is mounted on top and follows the movement of an actor or reporter, Fig. 16-126. To make sure that the directional characteristic of the moving microphone does not have too strong an influence and that a slight angular error will not lead to immediately perceptible directional changes, the lobe should be somewhat wider as with the customary shotgun microphones in use today.

It is now possible to produce a finished stereo soundtrack on location by positioning the microphones in the manner of an M/S combination. The level of the figure 8 microphone can be lowered and used only for the recording of voices outside of the picture, ambience and music. This microphone should always remain in a fixed position and its direction should not be changed. The S-signal generated in this way must be attenuated to such a degree that the M-signal microphone will
always remain dominant. This microphone is the one through which the actors pictured on the screen will be heard.

16.7.6 SASS Microphones

The Crown® SASS-P MK II or Stereo Ambient Sampling System™, Fig. 16-127, is a patented, mono-compatible, near-coincident array stereo condenser microphone using PZM technology.

The SASS uses two PZMs mounted on boundaries (with a foam barrier between them) to make each microphone directional. Another Crown model, SASS-B, is a similarly shaped stereo boundary mount for Brüel & Kjaer 4006 microphones and is used for applications requiring extremely low noise.

Controlled polar patterns and human-head-sized spacing between capsules create a focused, natural stereo image with no hole-in-the-middle for loudspeaker reproduction, summing comfortably to mono if required.

The broad acceptance angle (125°) of each capsule picks up ambient sidewall and ceiling reflections from the room, providing natural reproduction of acoustics in good halls and ambient environments. This pattern is consistent for almost ±90° vertical.

A foam barrier/baffle between the capsules shapes the pickup angle of each capsule toward the front, limiting overlap of the two sides at higher frequencies. Although the microphone capsules are spaced a few centimeters apart, there is little phase cancellation when both channels are combined to mono because of the shadowing effect of the baffle. While there are phase differences between channels, the extreme amplitude differences between the channels caused by the baffle, reduce phase cancellations in mono up to 20 kHz.

The SASS has relatively small boundaries. However, it has a flat response down to low frequencies because there is no 6 dB shelf as in standard PZM microphones (see Section 16.6.1.2.3). The flat response is attained because the capsules are omnidirectional below 500 Hz, and their outputs at low frequencies are equal in level, which, when summed in stereo listening, causes a 3 dB rise in perceived level. This effectively counteracts one half of the low frequency shelf normally experienced with small boundaries.

In addition, when the microphone is used in a reverberant sound field, the effective low-frequency level is boosted another 3 dB because the pattern is omnidirectional at low frequencies and unidirectional at high frequencies. All of the low-frequency shelf is compensated, so the effective frequency response is uniform from 20 Hz–20 kHz. Fig. 16-128 is the polar response of the left channel (the right channel is the reverse of the left channel).

16.7.7 Surround Sound Microphone System

16.7.7.1 Schoeps 5.1 Surround System

The Schoeps 5.1 surround system consists of the KFM 360 sphere microphone, two figure 8 microphones with
suspension and the DSP-4 KFM 360 processor, Fig. 16-129.

The central unit in this system is the sphere microphone KFM 360. It uses two pressure transducers and can, even without the other elements of the system, be used for stereophonic recording. Its recording angle is about 120°, permitting closer micing than a standard stereo microphone. The necessary high-frequency boost is built into the processor unit.

Surround capability is achieved through the use of two figure 8 microphones, which can be attached beneath the pressure transducers by an adjustable, detachable clamp system with bayonet-style connectors. The two microphones should be aimed forward.

The DSP-4 KFM 360 processor derives the four corner channels from the microphone signals. A center channel signal is obtained from the two front signals, using a special type of matrix. An additional channel carries only the low frequencies, up to 70 Hz. To avoid perceiving the presence of the rear loudspeakers, it is possible to lower the level of their channels, to delay them and/or to set an upper limit on their frequency response, Fig. 16-130.

The front stereo image width is adjustable and the directional patterns of the front-facing and rear-facing pairs of virtual microphones can be chosen independently of one another.

The processor unit offers both analog and digital inputs for the microphone signals. In addition to providing gain, it offers a high-frequency emphasis for the built-in pressure transducers as well as a low-frequency boost for the figure 8s.

As with M/S recording, matrixing can be performed during post-production in the digital domain.

The system operates as follows: the front and rear channels result from the sum (front) and difference (rear) of the omnidirectional and figure 8 microphones on each side, respectively, Fig. 16-131. The four resulting virtual microphones that this process creates will seem to be aimed forward and backward, as the figure 8s are. At higher frequencies they will seem to be aimed more toward the sides (i.e., apart). Their directional pattern can be varied, anywhere from omnidirectional to cardioid to figure 8. The pattern of the two rear-facing virtual microphones can be different from that of the two forward-facing ones. Altering the directional patterns alters the sound as well, in ways that are not possible with ordinary equalizers. This permits a flexible means of adapting to a recording situation—to the acoustic conditions in the recording space—and this can even be done during postproduction, if the unprocessed microphones signals are recorded.

This four-channel approach yields a form of surround reproduction without a center channel—something that is not what everybody requires.

16.7.7.2 Holophone® H2-PRO Surround Sound System

The elliptical shape of the Holophone® H2-PRO emulates the characteristics of a human head, Fig. 16-132. Sound waves bend around the H2-PRO as they do around the head providing an accurate spatiality, audio imaging, and natural directionality. Capturing the directionality of these soundwaves translates into a very realistic surround sound experience. The total surface area of the eight individual elements combines with the spherical embodiment of the H2-PRO to capture the acoustic textures required for surround reproduction, Fig. 16-133. The embodiment acts as an acoustic lens capturing lows and clean highs.

A complete soundfield can be accurately replicated without the use of additional microphones—a simple point-and-shoot operation. The Holophone H2-PRO is
capable of recording up to 7.1 channels of discrete surround sound. It terminates in eight XLR microphone cable ends (Left, Right, Center, Low Frequency, Left Surround, Right Surround, Top, and Center Rear). These co-relate to the standard 5.1 channels and add a top channel for formats such as IMAX and a center rear channel for extended surround formats such as Dolby EX, DTS, ES, and Circle Surround. Because each microphone has its own output, the engineer may choose to use as many or as few channels as the surround project requires as channel assignments are discrete all the way from the recording and mixing process to final delivery. It is well suited for television broadcasters (standard TV, DTV, and HDTV), radio broadcasters, music producers and engineers, film location recording crews, and independent project studios.
16.7.7.3 Holophone H4 SuperMINI Surround Sound System

The H4 SuperMINI head, Fig. 16-134 contains six microphone elements, that translate to the standard surround sound loudspeaker configuration; L, R, C, LFE, LS, RS. The LFE collects low-frequency signals for the subwoofer. The six discrete channels are fed into a Dolby® Pro-Logic II encoder which outputs the audio as a stereo signal from a stereo mini-plug to dual XLRs, dual RCAs, or dual mini-plugs. The left and right stereo signals can then be connected to the stereo audio inputs of a video camera or stereo recorder. The encoded signal is recorded onto the media in the camera or recorder and the captured audio can be played back in full 5.1-channel surround over any Dolby® Pro Logic II–equipped home theatre system. The material can be edited and the audio can be decoded via a Dolby® Pro Logic II Decoder and then brought into an NLE including Final Cut or iMovie, etc. The stereo recording can also be broadcast directly through the standard infrastructure. Once it is received by a home theatre system, containing a Dolby® Pro-Logic II or any compatible decoder, the six channels are completely unfolded to their original state. Where no home theatre receiver is detected, the signal will simply be heard in stereo. The SuperMINI has additional capabilities that include an input for an external, center-channel-placed shotgun or lavalier microphone to enhance sonic opportunity options and features an audio zoom button that increases the forward bias of the pickup pattern. It also includes virtual surround monitoring via headphones for real-time on-camera 3D audio monitoring of the surround field.

16.8 Microphones for Binaural Recording

16.8.1 Artificial Head Systems

Human hearing is capable of selecting single sounds from a mixture of sounds while suppressing the unwanted components (the cocktail party effect). This is done in the listener’s brain by exploiting the ear signals as two spatially separated sound receivers in a process frequently referred to as binaural signal processing. A simple test will verify this statement: when listening to a recording of several simultaneous sound events recorded by a single microphone, the individual sources cannot be differentiated.

Two spaced microphones or more elegant multielement spatially sensitive microphones, such as a stereo coincident microphone, have been used to capture the spatial characteristics of sounds, but they have frequently been deficient when compared to what a person perceives in the same environment. This lack of realism is attributed to absence of the spectrum modification inherent in sound propagation around a person’s head and torso and in the external ear—i.e., the transfer function of the human and the fact that the signals are kept separate until very late in the human analysis chain.

The acoustic transfer function of the human external ear is uniquely related to human body geometry. It is composed of four parts that can be modeled mathemati-
cally, as shown in Fig. 16-135, or recreated by an artificial head system.\textsuperscript{15,16,17} Reflections and diffraction of sound at the upper body, the shoulder, the head, and the outer ear (pinna), as well as resonances caused by the concha and ear canal, are mainly responsible for the transfer characteristic. The cavum concha is the antechamber to the ear. The spectral shape of the external ear transfer function varies from person to person due to the uniqueness of people and the dimensions of these anatomical features. Therefore, both artificial heads and their mathematical models are based on statistical composites of responses and dimensions of a number of persons.

All of these contributions to the external ear transfer function are direction sensitive. This means that sound from each direction has its own individual frequency response. In addition, the separation of the ears with the head in between affects the relative arrival time of sounds at the ears. As a result the complete outer-ear transfer function is very complicated, Fig. 16-136, and can only be partially applied as a correction to the response of a single or even a pair of microphones. In the figure, the base of each arrow indicates reference SPL. The solid curves represent the free-field (direct sound) external ear transfer function, while the dashed curves represent the difference, at each direction, relative to frontal free-field sound incidence.

Artificial heads have been used for recording for some time. However, the latest heads and associated signal processing electronics have brought the state of the art close to in the ear (ITE) recording, which places microphones in human ears.

The KU 100 measurement and recording system by Georg Neumann GmbH in Germany is an example of a high-quality artificial head system, Fig. 16-137. Originally developed by Dr. Klaus Genuit and his associates at the Technical University of Aachen, the artificial head, together with carefully designed signal processing equipment, provides binaural recording systems that allow very accurate production of spatial imaging of complex sound fields.

The head is a realistic replica of a human head and depends on a philosophy of sound recording and reproduction—namely, that the sound to be recreated for a listener should not undergo two transfer functions, one in the ears of the artificial head and one in the ears of the listener.

Fig. 16-138 is a block diagram of a head microphone and recording system. A high-quality microphone is mounted at the ear canal entrance position on each side of the head. Signals from each microphone pass through diffuse-field equalizers in the processor and are then available for further use in recording or reproduction. The diffuse-field equalizer is specifically tuned for the head to be the inverse of the frontal diffuse-field transfer function of the head. This signal is then recorded and can be used for loudspeaker playback and for measurement. The headphone diffuse-field equalizers in the Reproduce Unit yield a linear diffuse-field
heard and enjoyed with earphone playback as well as with high quality loudspeakers.

The heads are constructed of rugged fiberglass. The microphones can be calibrated by removal of the detachable outer ears and applying a pistonphone. Preamplifiers on the microphones provide polarization and have balanced transformerless line drivers. A record processor and modular unit construction provides dc power to the dummy head and act as the interface between the head and the recording medium or analysis equipment. The combination of low noise electronics and good overload range permits full use of the 135 dB dynamic range of the head microphones and 145 dB with the 10 dB attenuator switched in.

For headphone playback, a reproduce unit provides an equalized signal for the headphones that produces ear canal entrance sound signals that correspond to those at the corresponding location on the artificial head.

An important parameter to consider in any head microphone recording system is the dynamic range available at this head signal output. For example, the canal resonance can produce a sound pressure that may exceed the maximum allowed on some ear canal-mounted microphones.

### 16.8.2 In the Ear Recording Microphones

In-the-Ear (ITE™) recording and Pinna Acoustic Response (PAR™) playback represent a new-old approach to the recording of two channels of spatial images with full fidelity and their playback over two channels, Fig. 16-138. It is important that the loudspeakers are in signal synchronization and that they be placed at an angle so that the listener position is free of early reflections.

Low noise, wide frequency, and dynamic range probe microphones employing soft silicone probes are placed in the pressure zone of the eardrum of live listeners. This microphone system allows recording with or without equalization to compensate for the ear canal resonances while leaving the high-frequency comb filter spatial clues unaltered. The playback system consists of synchronized loudspeaker systems spaced approximately equal distances from the listener in the pattern shown in Fig. 16-139. Both left loudspeakers are in parallel, and both right loudspeakers are in parallel. However, the front and back loudspeakers are on individual volume controls. This is to allow balancing side-to-side and to adjust the front-to-back relative levels for each individual listener. The two front loud-
speakers are used to provide hearing signals forward of the listener.

Fig. 16-140A shows an ETC made in a listening room ($L_D - L_R = 0.24$). Fig. 16-140B is the identical position measured with the ITE technique ($L_D - L_R = 5.54$). Note particularly the difference in $L_D - L_R$ for the two techniques. ITE recording and PAR playback allow a given listener to hear a given speech intelligibility environment as perceived by another person’s head and outer ear configuration right up to the eardrum.

Recordings made using ITE microphones in two different people’s ears of the same performance in the same seating area sound different. Playback over loudspeakers where the system is properly balanced for perfect geometry for one person may require as much as 10 dB different front to back balance for another person to hear perfect geometry during playback.

Since ITE recordings are totally compatible with normal stereophonic reproduction systems and can provide superior fidelity in a many cases, the practical use of ITE microphony would appear to be unlimited.

16.9 USB Microphones

The computer has become an important part of sound systems. Many consoles are digital and microphones are connected directly to them. Microphones are also connected to computers through the USB input.

The audio-technica AT2020 USB cardioid condenser microphone, Fig. 16-141 is designed for computer-based recording. It includes a USB (Universal Serial Bus) digital output that is Windows and Mac compatible. The sample rate is 44.1 kHz with a bit depth of
16 bits. The microphone is powered directly from the 5 Vdc USB output.

The MXL.006 USB is a cardioid condenser microphone with a USB output that connects directly to a computer without the need for external mic preamps through USB 1.1 and 2.0, Fig. 16-142.

The analog section of the MXL.006 microphone features a 20 Hz–20 kHz frequency response, a large gold diaphragm, pressure-gradient condenser capsule, and a three-position, switchable attenuation pad with settings for Hi (0 dB), Medium (–5 dB), and Lo (–10 dB). The digital section features a 16-bit Delta Sigma A/D converter with a sampling rate of 44.1 kHz and 48 kHz. Protecting the instrument’s capsule is a heavy-duty wire mesh grill with an integrated pop filter.

The MXL.006 includes a red LED behind the protective grill to inform the user that the microphone is active and correctly oriented. The MXL.006 ships with a travel case, a desktop microphone stand, a 10 ft USB cable, windscreen, an applications guide, and free downloadable recording software for PCs and Mac.

16.10 Wireless Communication Systems

Wireless communication systems are wireless microphones (radio microphones), Fig. 16-143, and a related concept, wireless intercoms. Often the same end user buys both the microphones and intercoms for use in television and radio broadcast production, film production, and related entertainment-oriented applications.

Wireless microphone systems can be used with any of the preceding microphones discussed. Some wireless microphone systems include a fixed microphone cartridge while others allow the use of cartridges by various manufacturers.

A block diagram of a wireless microphone system is shown in Fig. 16-144. The sending end of a wireless microphone system has a dynamic, condenser, electret, or pressure zone microphone connected to a preamplifier, compressor, and a small transmitter/modulator and antenna.

The receiving end of the system is an antenna, receiver/discriminator, expander, and preamplifier, which is connected to external audio equipment.

In a standard intercom system, each person has a headset and belt pack (or equivalent), all interconnected by wires. Wireless intercoms are essentially identical in operation, only they use no cable between operators. Instead, each belt pack includes a radio transmitter and receiver. The wireless intercom user typically
wears a headset (a boom microphone with one or two earpieces) and can simultaneously transmit on one frequency and receive on another. The wireless intercom transmitter is virtually identical to a wireless microphone transmitter, but the receiver is miniaturized so that it, too, can be conveniently carried around and operated with minimum battery drain.

Wireless microphones are widely used in television production. Handheld models (integral microphone capsule and transmitter) are used by performers “on camera,” where they not only free the performer to walk around and gesture spontaneously, they also avoid the need for stage personnel to feed wires around cameras, props, etc. Lavalier models (small pocket-sized transmitters that work with lavalier or miniature “hidden” microphones) are used in game shows, soap operas, dance routines, etc., where they eliminate the need for boom microphones and further avoid visual clutter.

For location film production, as well as electronic news gathering (ENG) and electronic field production (EFP), wireless microphones make it possible to obtain usable “first take” sound tracks in situations where previously, postproduction dialogue looping was necessary.

In theatrical productions, wireless microphones free actors to speak and/or sing at normal levels through a properly designed sound-reinforcement system.

In concerts, handheld wireless microphones permit vocalists to move around without restriction, and without shock hazard even in the rain. Some lavalier models have high-impedance line inputs that accept electric guitar cords to create wireless guitars.

In all of the above applications where wireless microphones are used, in the studio or on location, a wireless intercom also is an invaluable communication aid between directors, stage managers, camera, lighting and sound crews, and security personnel. For cueing of talent and crews (or monitoring intercom conversations), economical receive-only units can be used. In sports production, wireless intercoms are used by coaches, spotters, players, production crews, and reporters. A major advantage is zero setup time. In critical stunt coordination, a wireless intercom can make the difference between a safe event or none at all. For more information on intercoms, refer to Chapter 43.

### 16.10.1 Criteria for Selecting a Wireless Microphone

There are a number of criteria that must be considered in obtaining a wireless microphone system suitable for professional use. Ideally, such a system must work perfectly and reliably in a variety of tough environments with good intelligibility and must be usable near strong RF fields, lighting dimmers, and sources of electromagnetic interference. This relates directly to the type of modulation (standard frequency modulation or narrow-band frequency modulation), the operating frequency, high frequency (HF), very high frequency (VHF), ultrahigh frequency (UHF), the receiver selectivity, and so forth. The system must be very reliable and capable of operating at least five hours on one set of disposable batteries (or on one recharge if Ni-Cads are used).

#### 16.10.1.1 Frequency Bands of Operation

Based on the FCC’s reallocation of frequencies and the uncertainty of current and future allocations, some wireless manufacturers are offering systems that avoid the VHF and UHF bands completely. The ISM (industrial, science, and medicine) bands provide a unique alternative to the TV bands. By international agreement,
all devices are low powered so there will never be any grossly high-powered RF interference potential. The 2.4 GHz band provides a viable alternative to traditional UHF bands, and as long as line of sight between transmitters and receivers is monitored users can easily get a 100 meter range. Another benefit of 2.4 GHz is that it can simplify wireless inventory for traveling shows. The same wireless frequencies are accepted worldwide, so there is no need to adhere to the country-specific frequency rules that severely complicate the situation for international tours. The same applies within the United States—the same frequencies work in all areas.

Currently wireless microphones are licensed on several frequencies, the most common being:

VHF low band (AM and FM) 25 to 50 MHz
  72 to 76 MHz
FM broadcast (FM) 88 to 108 MHz
VHF high band (FM) 150 to 216 MHz
UHF (FM) 470 to 746 MHz
  902 to 952 MHz

The VHF bands are seldom used anymore and can only be found on old equipment. The low band is in the noisiest radio spectrum and, because the wavelength is about 20 ft (6 m) it requires a long antenna (5 ft or 1.5 m). The VHF low band is susceptible to skip, which can be defined as external signals from a long distance away bouncing off the ionosphere back to earth, creating interference.

The VHF high band is more favorable than the low band. The ¼-wavelength antenna is only about 17 in (43 cm) long and requires little space. The VHF band has some penetration through buildings that can be advantageous and disadvantageous. It is advantageous in being able to communicate between rooms and around surfaces. It is disadvantageous in that transmission is not controlled (security), and outside noise sources can reach the receiver.

Most often the frequencies between 174 MHz and 216 MHz are used in the VHF band, corresponding to television channels 7 to 13. The VHF high band is free of citizens band and business radio interference, and any commercial broadcast stations that might cause interference are scheduled so you know where they are and can avoid them. Inherent immunity to noise is built in because it uses FM modulation. Better VHF high-band receivers have adequate selectivity to reject nearby commercial television or FM broadcast signals. If operating the microphone or intercom on an unused television channel—for instance Channel 7—protection might be required against a local television station on Channel 8. Another problem could be caused by an FM radio station. If a multi–thousand watt FM station is broadcasting near a 50 mW wireless microphone, even a well-suppressed second harmonic can have an RF field strength comparable to the microphone or intercom signal because the second harmonic of FM 88 MHz is 176 MHz, which is in the middle of television Channel 7. The second harmonic of FM 107 MHz is 214 MHz, which is in the middle of Channel 13. Thus, if a VHF wireless system is to be utilized fully, especially with several microphones or intercoms on adjacent frequencies, the wireless receiver must have a very selective front end.

One television channel occupies a 6 MHz wide segment of the VHF band. Channel 7, for example, covers from 174–180 MHz. A wireless intercom occupies about 0.2 MHz (200 kHz). By FCC Part 74 allocation, up to 24 discrete VHF high-band microphones and/or intercoms can be operated in the space of a single television channel. In order to use multiple systems on adjacent frequencies, the wireless microphone/intercom receivers must be very selective and have an excellent capture ratio (see Section 16.10.1.3). On a practical basis, this means using narrow-deviation FM (approximately 12 kHz modulation). Wide-deviation systems (75 kHz modulation or more) can easily cause interference on adjacent microphone/intercom frequencies; such systems also require wide bandwidth receivers that are more apt to be plagued by interference from adjacent frequencies. The trade-off between narrowband FM and wideband FM favor wideband for better overall frequency response, lower distortion, and inherently better SNR versus maximum possible channels within an unused TV channel for equal freedom from interference (max. 6). Poorly designed FM receivers, are also subject to desensing. Desensing means the wireless microphone/intercom receiver is muted because another microphone, intercom, television station, or FM station (second harmonic) is transmitting in close proximity; this limits the effective range of the microphone or intercom.

The UHF band equipment is the band of choice and is the only one used by manufacturers today. The wavelength is less than 3 ft (1 m) so the antennas are only 9 in (23 cm). The range is not as good as VHF, because it can sneak through small openings and can reflect off surfaces more readily.

All of the professional systems now are in the following UHF bands:

- A band 710–722 MHz.
• B band of 722–734 MHz
• 728.125–740.500 MHz band.

The FCC has assigned most of the DTV channels between channel 2 and 51, and only four channels between 64 and 69, which is where most of the professional wireless microphones operate.

16.10.1.2 Adjustment of the System's Operating Frequency

Many of the professional wireless microphones are capable of being tuned to many frequencies. In the past the systems were fixed frequency, often because that was the only way they could be made stable. With PLL-synthesized channels (Phase Lock Loop), it is not uncommon for systems to be switch tunable to 100 different frequencies in the UHF band and have a frequency stability of 0.005%. This is especially important with DTV coming into the scene.

16.10.1.3 Capture Ratio and Muting

Capture ratio and muting specifications of the receiver are important. The capture ratio is the ability of the receiver to discriminate between two transmitters transmitting on the same frequency. When the signal is frequency modulated (FM), the stronger signal controls what the receiver receives. The capture ratio is the difference in the signal strength between the capturing transmitter and the captured transmitter that is blanketed. The lower the number, the better the receiver is at capturing the signal. For instance, a receiver with a capture ratio of 2 dB will capture a signal that is only 2 dB stronger than the second signal.

Most systems have a muting circuit that squelches the system if no RF signal is present. To open the circuit, the transmitter sends a special signal on its carrier that breaks the squelch and passes the audio signal.

16.10.1.4 RF Power Output and Receiver Sensitivity

The maximum legal RF power output of a VHF high-band microphone or intercom transmitter is 50 mW; most deliver from 25–50 mW. Up to 120 mW is permissible in the business band (for wireless intercoms) under FCC part 90.217, but even this represents less than 4 dB more than 50 mW. The FCC does not permit the use of high-gain transmitter antennas, and even if they did, such antennas are large and directional so they would not be practical for someone who is moving around. Incidentally, high-gain receiving antennas are also a bad idea because the transmitter is constantly moving around with the performer so much of the received radio signal is actually caught on the bounce from walls, props, and so on (see Section 16.9.2).

Even if an offstage antenna is aimed at the performer, it probably would be aiming at the wrong target. Diversity receiving antenna systems, where two or more antennas pick up and combine signals to feed the receiver, will reduce dropouts or fades for fixed receiver installations.

The received signal level can’t be boosted, given the restrictions on antenna and transmitted power, so usable range relies heavily on receiver sensitivity and selectivity (i.e., capture ratio and SNR) as well as on the audio dynamic range. In the pre-1980 time frame, most wireless microphones and intercoms used a simple compressor to avoid transmitter overmodulation. Today, systems include compandor circuitry for 15–30 dB better audio SNR without changing the RF SNR (see Section 16.10.3). This is achieved by building a full-range compressor into the microphone or intercom transmitter, and then providing complementary expansion of the audio signal at the receiver—much like the encoder of a tape noise-reduction system. The compression keeps loud sounds from overmodulating the transmitter and keeps quiet sounds above the hiss and static. The expander restores the loud sounds after reception and further reduces any low-level hiss or static. Companding the audio signal can provide from 80–85 dB of dynamic range compared to the 50–60 dB of a straight noncompanded transmit/receive system using the same deviation.

16.10.1.5 Frequency Response, Dynamic Range, and Distortion

No wireless microphone will provide flat response from 20 Hz–20 kHz, nor is it really needed. Wireless or not, by the time the audience hears the broadcast, film, or concert, the frequency response has probably been reduced to a bandwidth from 40 Hz–15 kHz. Probably the best criteria for judging a handheld wireless microphone system is to compare it to the microphone capsule’s naked response. If the transmit/receive bandwidth basically includes the capsule’s bandwidth, it is enough. Generally speaking, a good wireless microphone should sound the same as a hard-wired microphone that uses the same capsule. Wireless intercom systems, because they are primarily for speech commu-
Microphones

| 16.10.2 Receiving Antenna Systems |

RF signal dropout or multipath cancellation is caused by the RF signal reflecting off a surface and reaching a single receiver antenna 180° out-of-phase with the direct signal, Fig. 16-145. The signal can be reflected off surfaces such as armored concrete walls, metal grids, vehicles, buildings, trees, and even people.

Although you can often eliminate the problem by experimenting with receiver antenna location, a more foolproof approach is to use a space diversity system where two or more antennas pick up the transmitted signal, as shown in Fig. 16-146. It is highly unlikely that the obstruction or multipath interference will affect two or more receiver antennas simultaneously.

There are three diversity schemes: switching diversity, true diversity, and antenna combination.

- **Switching Diversity.** In the switching diversity system, the RF signals from two antennas are compared, and only the stronger one is selected and fed to one receiver.
- **True Diversity.** This receiving technique uses two receivers and two antennas set up at different positions, Fig. 16-147. Both receivers operate on the same frequency. The AF signal is taken from the output of the receiver that at any given moment has the stronger signal at its antenna. The probability of no signal at both antennas at the same time is
extremely small. The advantages of diversity compared to conventional RF transmission are shown in Fig. 16-148. Only the receiving chain with the better input signal delivers audio output. Not only does this system provide redundancy of the receiving end, but it also combines signal strength, polarity and space diversity.

**Antenna Combination Diversity.** The antenna combination diversity system is a compromise of the other methods. This system uses two or more antennas, each connected to a wideband RF amplifier to boost the received signal. The signals from both receiving antennas are then actively combined and fed to one standard receiver per microphone. In this way, the receiver always gets the benefit of the signals present at all antennas. There is no switching noise, no change in background noise, and only requires one receiver for each channel. A drawback is the possibility of complete signal cancellation when phase and amplitude relationships due to multipath provide the proper unfavorable conditions.

### 16.10.2.1 Antenna Placement

It is often common to use a near antenna and a far antenna. The near antenna, which is the one nearest the transmitter, produces the majority of the signal most of the time; in fact, it may even be amplified with an in-line amplifier. The far-field antenna may be one or more antennas usually offset in elevation and position; therefore, the possibility of dropout is greatly reduced. Because the antennas are common to all receivers, many wireless microphones can be used at the same time on the same antenna system. This means that there are fewer antennas and a greater possibility of proper antenna placement.

The following will generally prevent dead spots:

- Do not set up antennas in niches or doorways.
- Keep the antennas away from metal objects including armored concrete walls. Minimum distance: 3 ft (1 m).
- Position the antennas as close as possible to the point where the action takes place.
- Keep antenna cables short to keep RF losses at a minimum. It is better to use longer AF leads instead.
Note: If long runs of antenna cable are used, be sure they are of the low-loss type.

- Make a walkaround test, i.e., operate the transmitter at all positions where it will be used later. Mark all points where field strength is weak. Try to improve reception from these points by changing the antenna position. Repeat this procedure until the optimum result is achieved.

Interference is mainly caused by spurious signals arriving at the receiver input on the working frequency. These spurious signals may have various causes:

- Two transmitters operating on the same frequency (not permissible).
- Intermodulation products of a multichannel system whose frequencies have not been selected carefully enough.
- Excessive spurious radiation from other radio installations—e.g., taxi, police, CB-radio, etc.
- Insufficient interference suppression on electric machinery, vehicle ignition noise, etc.
- Spurious radiation from electronic equipment—e.g., light control equipment, digital displays, synthesizers, digital delays, computers, etc.

### 16.10.3 Companding

Two of the biggest problems with using wireless microphones are SNR and dynamic range. To overcome these problems, the signal is compressed at the transmitter and expanded at the receiver. Figs. 16-144 and 16-149 graphically illustrate how and what this can accomplish with respect to improving the SNR and reducing the susceptibility to low-level incidental FM modulation, such as buzz zones.

As the typical input level changes by a factor of 80 dB, the audio output to the modulator undergoes a contoured compression, so a change in input audio level is translated into a pseudologarithmic output. This increases the average modulation level, which reduces all forms of interference encountered in the transmission medium.

By employing standard narrowband techniques at the receiver, the recovered audio is virtually free of adjacent channel and spurious response interference. In addition, up to ten times the number of systems can be operated simultaneously without cross-channel interference. The ability of the receiver to reject all forms of interference is imperative when utilizing expansion and compression techniques because the receiver must complimentarily expand the audio component to restore the original signal integrity.

![Figure 16-149. Compression and expansion of the audio signal. Notice the −80 dB signal is not altered, and the −20 dB signal is altered significantly.](image)

### 16.10.4 Waterproof Wireless Microphone Systems

Wireless microphones that are worn are very useful for coaching all forms of athletics including swimming and aquatic aerobics. If the instructor always stays on the pool deck, a weatherproof system might be adequate. If the instructor is in the water, a completely submersible and waterproof system will be required.

Hydrophonics assembles a completely waterproof and submersible wireless microphone system. Assembled with Telex components, the system includes a headset microphone with a special waterproof connector and a Telex VB12 waterproof beltpack transmitter. The transmitter can operate on a 9 V alkaline battery or a 9 V NiMH rechargeable battery. The rechargeable battery is recommended as it does not require removing the battery from the transmitter for recharging and therefore reduces the chance of water leaking into the transmitter housing. The receiver is a Telex VR12 for out-of-pool operation, and can be connected to any sound system the same way as any other wireless microphone.

An interesting thing about this system is you can dive into the water while wearing the system and come up and immediately talk as the water drains out of the windscreen rapidly.

The DPA Type 8011 hydrophone, Fig. 16-150, is a 48 V phantom powered waterproof microphone specially designed to handle the high sound pressure levels and the high static ambient pressure in water and
other fluids. The hydrophone uses a piezoelectric sensing element, which is frequency compensated to match the special acoustic conditions under water. A 10 m high-quality audio cable is vulcanized to the body of the hydrophone and fitted with a standard three-pin XLR connector. The output is electronically balanced and offers more than 100 dB dynamic range. The 8011 hydrophone is a good choice for professional sound recordings in water or under other extreme conditions where conventional microphones would be adversely affected.

16.11 Multichannel Wireless Microphone and Monitoring Systems

By Joe Ciaudelli and Volker Schmitt

16.11.1 Introduction

The use of wireless microphones and monitoring systems has proliferated in the past few years. This is due to advancements in technology, a trend towards greater mobility on stage, and the desire to control volume and equalization of individual performers. Consequently, installations in which a number of wireless microphones, referred to as channels, are being used simultaneously, have increased dramatically. Now theatres and studios with large multichannel systems, greater than thirty channels, are common. Systems of this magnitude are a difficult engineering challenge. Careful planning, installation, operation, and maintenance are required.

Wireless systems require a transmitter, transmit antenna, and receiver to process sound via radio frequency (RF) transmission. First, the transmitter processes the signal and superimposes it on a carrier through a process called modulation. The transmit antenna then acts as a launch pad for the modulated carrier and broadcasts the signal over the transfer medium: air. The signal must then travel a certain space or distance to reach the pickup element, which is the receiving antenna. Finishing up the process, the receiver—which selects the desired carrier—strips off the signal through demodulation, processes it, and finally reconstitutes the original signal. Each wireless channel needs to operate on a unique frequency.

16.11.2 Frequencies

 Manufacturers generally produce wireless microphones on ultrahigh frequencies (UHF) within the TV band with specifications outlined by government agencies such as the Federal Communications Commission (FCC). The wavelength is inversely proportional to the frequency. Higher frequencies have shorter wavelengths. UHF frequencies (450–960 MHz) have a wavelength of less than one meter. They have excellent reflective characteristics. They can travel through a long corridor, bouncing off the walls, losing very little energy. They also require less power to transmit the same distance compared to much higher frequencies, such as microwaves. These excellent wave propagation characteristics and low power requirements make UHF ideal for performance applications.

16.11.3 Spacing

In order to have a defined channel, without crosstalk, a minimum spacing of 300 KHz between carrier frequencies should be employed. A wider spacing is even more preferable since many receivers often exhibit desensitized input stages in the presence of closely spaced signals. However, caution should be used when linking receivers with widely spaced frequencies to a common set of antennae. The frequencies need to be within the bandwidth of the antennas.

16.11.4 Frequency Deviation

The modulation of the carrier frequency in an FM system greatly influences its audio quality. The greater the deviation, the better the high-frequency response and the dynamic range. The trade-off is that fewer channels can be used within a frequency range. However,
since audio quality is usually the priority, wide deviation is most desirable.

### 16.11.5 Frequency Coordination

Multichannel wireless microphone systems can be especially difficult to operate, as they present several special conditions. Multiple transmitters moving around a stage will result in wide variations of field strength seen at the receiver antenna system. This makes frequency selection to avoid interference from intermodulation (IM) products highly critical. This is even more challenging in a touring application since the RF conditions vary from venue to venue. In this case, the mix of frequencies is constantly changing. The daunting task to coax each of these variables to execute clear audio transmission can be achieved through careful frequency coordination.

Intermodulation is the result of two or more signals mixing together, producing harmonic distortion. It is a common misconception that intermodulation is produced by the carrier frequencies mixing within the air. Intermodulation occurs within active components, such as transistors, exposed to strong RF input signals. When two or more signals exceed a certain threshold, they drive the active component into a non-linear operating mode and intermodulation (IM) products are generated. This usually happens in the RF section of the receiver, in antenna amplifiers, or the output amplifier of a transmitter. In multichannel operation, when several RF input signals exceed a certain level the intermodulation products grow very quickly. There are different levels of intermodulations defined by the number of addition terms.

In any wireless system with three or more frequencies operating in the same range, frequency coordination is strongly advised.

It is necessary to consider possible IM frequencies that might cause problems for the audio transmission. The 3rd and 5th harmonics, in particular, might raise interference issues.

The following signals may be present at the output of a nonlinear stage:

- **Fundamentals**: F1 and F2
- **Second Order**: 2F1, 2F2, F1±F2, F2–F1
- **Third Order**: 3F1, 3F2, 2F1±F2, 2F2±F1
- **Fourth Order**: 4F1, 4F2, 2F1±2F2, 2F2±2F1
- **Fifth Order**: 5F1, 5F2, 3F1±2F2, 3F2±2F1
- **Additional higher orders**

As a result, the intermodulation frequencies should not be used, as those frequencies are virtual transmitters. The fundamental rule *never use two transmitters on the same frequency* is valid in this case. However, even-order products are far removed from the fundamental frequencies and, for simplicity, are therefore omitted from further considerations. Signal amplitude rapidly diminishes with higher-order IM products, and with contemporary equipment design, consideration of IM-products can be limited to 3rd and 5th order only.

For multichannel applications such as those on Broadway (i.e., 30+ channels), the intermodulation products can increase significantly and the calculation of intermodulation-free frequencies can be done by special software. By looking only at the third harmonic distortion in a multichannel system, the number of third-order IM products generated by multiple channels is:

- 2 channels result in 2.
- 3 channels result in 9.
- 4 channels result in 24.
- 5 channels result in 50.
- 6 channels result in 90.
- 7 channels result in 147.
- 8 channels result in 225.
- ....
- 32 channels result in 15,872 third-order IM-products.

Adding more wireless links to the system will increase the number of possible combinations with interference potential logarithmically: n channels will result in \((n^3 - n)/2\) third-order IM-products. Equal frequency spacing between RF carrier frequencies inevitably results in two- and three-signal intermodulation products and must be avoided!

The RF level and the proximity define the level of the intermodulation product. If two transmitters are close, the possibility of intermodulation will increase significantly. As soon as the distance between two transmitters is increased, the resulting intermodulation product decreases significantly. By taking this into consideration, the physical distance between two or more transmitters is important. If a performer needs to wear two bodypack transmitters, it is recommended to use two different frequency ranges and to wear one with the antenna pointing up and the other with it pointing down.

If the number of wireless channels increases, the required RF bandwidth increases significantly, Fig. 16-151.

External disturbing sources such as TV transmitters, taxi services, police services, digital equipment, etc., also have to be taken into consideration. Fortunately, the
screening effect of buildings is rather high (30–40 dB). For indoor applications, this effect keeps strong outside signals at low levels. A significant problem can occur when poorly screened digital equipment is working in the same room. These wideband disturbing sources are able to interfere with wireless audio equipment. The only solution to this problem is to replace the poorly screened piece of equipment with a better one.

Other RF-systems that have to be considered for compatibility are:

1. TV stations “On-Air.”
2. Wireless intercoms.
3. IFBs.
4. Wireless monitor systems.
5. Other wireless systems.

Compatibility between components of a system is achieved if the following requirements are met: each link in a multichannel wireless system functions equally well with all other links active and no single link—or any combination of multiple links—causes any interference.

If the transmitter of a wireless mic channel is switched off, its complementary receiver should also be switched off or muted at the mixing console. A receiver that does not see its transmitter will try to latch onto a nearby signal. That signal may be an intermodulation product. The receiver will then try to demodulate this signal and apply it to the speaker system.

Equipment can be designed to minimize intermodulation. A specification known as **intermodulation rejection** or **suppression** is a measure of the RF input threshold before intermodulation occurs. For a well designed receiver, this specification will be 60 dB or greater. An intermodulation rejection of 60 dB means that intermodulation products are generated at input levels of approximately 1 mV. The highest quality multichannel receivers currently available feature an intermodulation rejection of >80 dB. If high-quality components are used, having an intermodulation suppression of 60 dB or greater, only the third-order products need to be considered.

### 16.11.6 Transmitter Considerations

Transmitters are widely available as portable devices, such as handheld microphones, bodypacks, and plug-on transmitters and are produced in stationary form as stereo monitors. When transmitting signals for most wireless applications via air, FM modulation is generally used; in doing so, one must also improve the sound quality in a variety of ways.

An RF transmitter works like a miniature FM radio station. First, the audio signal of a microphone is subjected to some processing. Then the processed signal modulates an oscillator, from which the carrier frequency is derived. The modulated carrier is radiated via the transmitter’s antenna. This signal is picked up by a complementary receiver via its antenna system and is demodulated and processed back to the original audio signal.

#### 16.11.6.1 Range and RF Power

Transmitter power is a rating of its potential RF signal strength. This specification is measured at the antenna output. The range of a wireless transmission depends on several factors. RF power, the operating frequency, the setup of the transmitter and receiver antennas, environmental conditions, and how the transmitter is held or worn are all aspects that determine the overall coverage of the system. Therefore, power specifications are of only limited use in assessing a transmitter’s range, considering these variable conditions. Also, battery life is associated with RF output power. Increased power will reduce battery life with only a moderate increase in range.

Using RF wireless microphone transmitters with the right amount of RF output power is important to ensure total system reliability. There is a common misconception that higher power is better. However, in many applications high power can aggravate intermodulation (IM) distortion, resulting in audible noises.

First of all, the applied RF output power must fall within the limit allowed by each country’s legislation. In the United States, the maximum RF output power for wireless microphones is limited to 250 mW. In most of the countries in Europe this figure is 50 mW, while in Japan it is only 10 mW. Despite the 10 mW limitation, many multichannel wireless microphones are operating...
in Japan. This is achieved by careful attention to factors like antenna position, use of low loss RF cables and RF gain structure of the antenna distribution system.

There are indeed some applications in which more RF output power is an appropriate measure; a perfect example would be a golf tournament, as the wireless system needs to cover a wide area. There are usually only a few wireless microphones in use at this type of function, and those microphones are generally not in close proximity to each other.

If transmitters with high RF power are close together, intermodulation usually occurs. At the same time, the RF noise floor in the performance area is increased. As a matter of fact, a transmitter in close proximity to another transmitter will not only transmit its own signal, but it will also receive the signal and add this to the RF amplifier stage.

16.11.6.2 Dc-to-Dc Converter

Transmitters should be designed to provide constant RF output power and frequency deviation throughout the event being staged. This can be achieved through the use of a dc-to-dc converter circuit. Such a circuit takes the decaying battery voltage as its input and regulates it to have a constant voltage output. Once the voltage of the batteries drops below a minimum level, the dc-to-dc converter shuts off, almost instantaneously. The result is a transmitter that is essentially either off or on. While it is on, the RF output power, frequency deviation, and other relevant specifications remain the same. Transmitters without regulation circuits, once the battery voltage begins to drop, will experience reduced range and audio quality.

16.11.6.3 Audio Processing

To improve the audio quality, several measures are necessary because of the inherent noise of the RF link.

16.11.6.3.1 Pre- and De-Emphasis

This method is a static measure that is used in most of the FM transmissions. By increasing the level of the higher audio frequencies on the transmitter side, the signal-to-noise ratio is improved because the desired signal is above the inherent noise floor of the RF link.

16.11.6.2 Companding

The compander is a synonym for compressor on the transmitter side and for expander on the receiving end. The compressor raises low audio level above the RF noise floor. The expander does the mirror opposite and restores the audio signal. This measure increases the signal-to-noise ratio to CD quality level.

16.11.6.3.3 Spurious Emissions

Apart from the wanted carrier frequency, transmitters can also radiate some unwanted frequencies known as spurious emissions. For large multichannel systems these spurious frequencies cannot be ignored. They can be significantly reduced through elaborate filtering and contained by using a well-constructed, RF tight metal housing for the transmitter. Also, an RF tight transmitter is less susceptible to outside interference.

A metal housing is important not only for its shielding properties, but also its durability. These devices usually experience much more abuse by actors and other talent than anyone ever predicts.

16.11.6.4 Transmitter Antenna

Every wireless transmitter is equipped with an antenna, which is critically important to the performance of the wireless system. If this transmitter antenna comes in contact with the human body, the transmitted wireless energy is reduced and may cause audible noises known as drop-outs. This effect of detuning the antenna on contact is called body absorption.

For this reason, talent should not touch the antenna while using handheld microphones. Unfortunately, there is no guarantee that they will follow this recommendation. Taking this into account, optimized antenna setup at the receiver side and the overall RF gain structure of the system becomes critical.

This same effect can occur when using bodypack transmitters, especially if the talent is sweating. A sweaty shirt can act as a good conductive material to the skin. If the transmitter antenna touches it, reduced power and thus poor signal quality may result. In this case, a possible approach is to wear the bodypack upside down near or attached to the belt, with the antenna pointing down. Sometimes this measure does not work because the talent will sit on the antenna. In this case, a possible solution is keeping the transmitter in the normal position and fitting a thick-walled plastic tube over the antenna, such as the type that is used for aquarium filters.
16.11.7 Receiver Considerations

The receiver is a crucial component of wireless audio systems, as it is used to pick the desired signal and transfer its electrical information into an audio signal. Understanding basic receiver design, audio processing, squelch, and diversity operation can help ensure optimum performance of the system.

Virtually all modern receivers feature superheterodyne architecture, in which the desired carrier is filtered out from the multitude of signals picked up by the antenna, then amplified and mixed with a local oscillator frequency to generate the difference: intermediate frequency. This IF undergoes more controlled discrimination and amplification before the signal is demodulated and processed to restore the output with all the characteristics and qualities of the original.

Audio signal processing of a receiver is the mirror opposite of the transmitter. Processing done in the transmitters often include pre-emphasis (boosting high audio frequencies) as well as compression. These are reversed in the receiver by the de-emphasis and the expander circuit.

An inherent RF noise floor exists in the air. The squelch setting should be set above this noise level. This acts as a noise gate that mutes the audio output if the wanted RF signal falls below a threshold level. This prevents a blast of white noise through the PA if the RF signal is completely lost. If the squelch setting is too low, the receiver might pick the noise floor and this noise can be heard. If the squelch setting is too high the range of the wireless microphone is reduced.

16.11.7.1 RF Signal Level

Varying RF signal strength is mainly due to multi-path propagation, absorption and shadowing. These are familiar difficulties also experienced with car radios in cities.

Audible effects due to low RF signals, known as dropouts, can occur even at close range to the receiver due to multipath propagation. Some of the transmitted waves find a direct path to the receiver antenna and others are deflected off a wall or other object. The antenna detects the vector sum, magnitude and phase of direct and deflected waves it receives at any particular instant. A deflected wave can diminish a direct wave if it has different phase, resulting in an overall low signal. This difference in phase is due to the longer path a deflected wave travels between the transmitter and receiver antennae and any phase reversal occurring when it hits an object. This phenomenon needs to be addressed in an indoor application since the field strength variation inside a building with reflecting walls is 40 dB or more. It is less critical outside.

RF energy can be absorbed by nonmetallic objects resulting in low signal strength. As stated previously, the human body absorbs RF energy quite well. It is important to place antennas correctly to minimize this effect.

Shadowing occurs when a wave is blocked by a large obstacle between the transmitter and receiver antennas. This effect can be minimized by keeping the antennas high and distance of ½ wavelength away from any large or metallic objects.

These problems are addressed by a diversity receiver. A diversity system is recommended even if only one channel is in operation. Large multichannel systems are only possible with diversity operation.

There are different kinds of diversity concepts available. Antenna switching diversity uses two antennas and a single receiving circuit. If the level at one antenna falls below a certain threshold it switches to the other antenna. This is an economical architecture but it leaves the chance that the second antenna could be experiencing an even lower signal then the one that falls below the threshold level. Another approach is the switching of the audio signal of two independent receiver units where each receiver unit is connected to its own antenna. This is known as true diversity. This technique improves the effective RF receiving level by greater than 20 dB. Depending on the diversity concept, active switching between the two antennas is a desired result.

The minimum distance between the two diversity antennas is very often an issue of debate. A minimum of ¼ of a wavelength of the frequency wave seems to be a good approach. Depending on the frequency, 5–6 inches is the minimum distance. In general, a greater distance is preferred.

16.11.8 Antennas

The position of the antenna and the correct use of its related components—such as the RF cable, antenna boosters, antenna attenuators, and antenna distribution systems—are the key to trouble-free wireless transmission. The antennas act as the eyes of the receiver, so the best results can be achieved by forming a direct line of sight between the transmitter antenna and receiver antenna of the system.

Receiving and transmitting antennas are available as omnidirectional and directional variants.

For receiving, omnidirectional antennas are often recommended for indoor use because the RF signal is reflected off of the walls and ceiling. When working
outside, one should choose a directional antenna since there are usually little to no reflections outdoors, and this directivity will help to stabilize the signal. In general, it is wise to keep an antenna toolbox that contains both omnidirectional and directional antennas for use in critical RF situations, since they transmit and receive signals differently.

Omnidirectional antennas transmit or receive the signal by providing uniform radiation or response only in one reference plane, which is usually the horizontal one parallel to the earth’s surface. The omni-directional antenna has no preferred direction and cannot differentiate between a wanted and an unwanted signal. If a directional antenna is used, it will transmit or receive the signal in the path it is pointing toward. The most common types are the yagi antenna and the log-periodic antenna, which are often wide-range frequency antennas covering the whole UHF range. In an outdoor venue, the desired signal can be received and the unwanted signal from a TV station can be rejected to a certain degree by choosing the correct antenna position. A directional antenna also transmits or receives only in one plane, like an omnidirectional antenna.

Several types of omnidirectional and directional antennas also exist for specific conditions. The telescopic antenna is an omnidirectional antenna and often achieves a wide range (450–960 MHz). If telescopic antennas are in use they should be placed within the line of sight of the counterpart antenna. They should not, for example, be mounted inside a metal flight case with closed doors as this will reduce the RF field strength from the transmitter and compromise the audio quality.

System performance will be raised considerably when remote antennas are used. A remote antenna is one that is separated from the receiver or transmitter unit. These antennas can be placed on a stand such as that for a microphone. This will improve the RF performance significantly. However, when using remote antennas, some basic rules need to be considered. Once again, a clear line of sight should be established between the transmitter and receiver antenna, Fig. 16-152.

Placing antennas above the talent increases the possibility the transmitter and receiver remain within line of sight, ensuring trouble-free transmission.

If a directional antenna is used, the position of the antenna and the distance to the stage is important. One common setup is pointing both receiving antennas toward the center of the stage. Once again, a line of sight between the receiver and transmitter antennas is best for optimum transmission quality.

Directional and omnidirectional antennas do have a preferred plane, which is either the horizontal or vertical plane. If the polarization between the transmitter and receiver antenna is different, this will cause some significant loss of the RF level. Unfortunately, it is not possible to have the same polarization of the antennas all of the time. In a theatrical application, the antenna is in a vertical position when the actress or actor walks on the stage. The polarization of the transmitter may change to the horizontal position if a scene requires the talent to lie down or crawl across the stage. In this case, circular polarized antennas can help. These kinds of antennas can receive the RF signal in all planes with the same efficiency.

Because the polarization of the antenna is critical and telescopic antennas are often used, it is not recommended to use the receiver antennas strictly in a horizontal or vertical plane. Rather, angle the antennas slightly as this will minimize the possibility that polarization would be completely opposite between transmitter and receiver.

One last note: The plural form for the type of antenna discussed in this article is antennas. Antennae are found on insects and aliens.

16.11.8.1 Antenna Cables and Related Systems

Antenna cables are often an underestimated factor in the design of a wireless system. The designer must choose the best cable for practical application, depending on the cable run and the installation, Table 16-3. As the RF travels down the cable its amplitude is attenuated. The amount of this loss is dependent on the quality of the cable, its length and the RF frequency. The loss increases with longer cable and higher frequencies. Both of these effects must be considered for the design of a wireless microphone system.

RF cables with a better specification regarding RF loss are often thicker. These are highly recommended for fixed installations. In a touring application, in which
the cable must be stored away each day, these heavier cables can be very cumbersome.

Source: Belden Master Catalogue.

As any RF cable has some RF attenuation, cable length should be as short as possible without significantly increasing the distance between the transmitter and receiver antennas. This aspect is important for receiving applications but is even more critical for the transmission of a wireless monitor signal.

In a receiving application, it is important to consider losses from the cable as well as from any splitter in the antenna system during the design and concept stage of a wireless microphone system. If the losses in the system are small, an antenna booster should not be used. In this case, any drop-out is not related to the RF loss in the antenna system; instead, it is more often related to the antenna position and how the transmitter is used and worn during the performance. An antenna booster is recommended if the loss in the antenna system is greater than 6 dB.

If an antenna booster is necessary, it should be placed as close as possible to the receiving antenna. Antennas with a built-in booster are known as active antennas. Some of these have a built-in filter, only allowing the wanted frequency range to be amplified. This is recommended because it reduces the possibility of intermodulation.

Two antenna boosters should not be used back-to-back when the RF cable run is very long. The second antenna booster would be overloaded by the output of the first amplifier and would produce intermodulation.

Special care must be taken when using an antenna booster if the transmitter comes close to the receiver antenna. The resulting strong signal could drive the antenna booster past its linear operation range, thus producing intermodulation products. It is recommended to design and install a system such that the transmitter remains at least 10 feet from the receiver antenna at all times.

Another important factor is the filter at the input stage of the antenna booster. The approach is to reduce the amount of unwanted signals in the RF domain as much as possible. This is another measure to reduce the possibility of intermodulation of this amplifier.

Also, signals that come from a TV station—such as a digital television (DTV) signal—are unwanted signals and can be the reason for Intermodulation products in the first amplifier.

If the free TV channel between the DTV should be used for wireless microphone transmission, the DTV signals might cause the problems. To reduce the effect of DTV signals, a narrow input filter will help to overcome the possible effect of Intermodulation.

Often a narrower filter at the input stage of a wireless receiver is preferable. This will often work for fixed installations because there are decreased possibilities that the RF environment will change. This is especially the case when the RF environment is difficult and a lot of TV stations or other wireless systems are operating.

16.11.8.2 Splitter Systems

Antenna splitters allow multiple receivers to operate from a single pair of antennas. Active splitters should be used for systems greater than four channels so that the amplifiers can compensate for the splitter loss. Security from interference and intermodulation can be enhanced by filtering before any amplifier stage. As an example, a thirty-two-channel system could be divided into four subgroups of eight channels. The subgroups can be separated from each other by highly selective filters. The subgroups can then be considered independent of each other. In this way, frequency coordination only needs to be performed within each group. It is much easier to coordinate eight frequencies four times than to attempt to coordinate a single set of thirty-two frequencies, Fig. 16-153.
16.9 Wireless Monitor Systems

Wireless monitor systems are essential for stage-bound musical productions. Perhaps the biggest advantage of a wireless monitor system is the ability to use an individual monitor mix for each musician on stage. Furthermore, a wireless monitor system significantly reduces the amount of, or even eliminates, monitor speakers in the performance area. This results in lower risk of feedback and a more lightweight, compact monitor system.

Some special precautions must be taken before using wireless monitor systems. In most cases, this signal is a stereo signal. This multiplexed signal is more sensitive to dropouts and static and multipath situations. For long range applications, mono operation can improve system performance.

If wireless microphones and wireless monitor systems are used in parallel, those systems should be separated in a way that the frequencies are at least 8 MHz apart and that the physical distance between the transmitter and the receiver is maximized. This will reduce the risk of blocking—an effect that desensitizes a receiver and prevents the reception of the desired signal. Therefore, if a bodypack wireless mic transmitter and a wireless monitor receiver are both attached to the same talent, those devices should not be mounted directly beside each other.

When musicians use the same monitor mix, one transmitter can be used to provide the RF signal to more than one wireless monitor receiver. If individual mixes are desired, each mix requires its own transmitter operating on a unique frequency. To avoid intermodulation disturbances, the wireless monitor transmitters should be combined, and the combined signal should then be transmitted via one antenna. Active combiners are highly recommended. Passive combiners suffer from signal loss and high crosstalk. An active combiner isolates each transmitter by around 40 dB from the other and keeps the RF level the same (0 dB gain), thus minimizing intermodulation. Again, intermodulation is a major issue within the entire wireless concept. When using stereo transmission, it is even more critical.

When considering an external antenna, one important factor must be taken into consideration: the antenna cable should be as short as possible to avoid losses via the RF cable. A directional external antenna is recommended to reduce multipath situations from reflections, and it will have some additional passive gain that will increase the range of the system.

If remote antennas are used for the wireless monitor transmitters as well as wireless mic receivers, those antennas should be separated by at least 10–15 feet. Blocking of the receivers, as discussed above, is then avoided. Furthermore, the antennas should not come in direct contact with the metal of the lighting rig. This will detune the antenna and reduce the effective radiated wireless signal.

16.10 System Planning for Multichannel Wireless Systems

When putting together a multi-channel wireless microphone system, several items are essential for trouble-free operation. First, you must understand the environment in which the system will be used.

Location. The location of a venue can be determined by using mapping tools on the internet, such as Google Earth. If you figure out the coordinates of the venue, simply plug this information into the FCC homepage, http://www.fcc.gov/fcc-bin/audio/tvq.html. The result shows all transmitters licensed by the FCC in this area. This information will allow the designer of the wireless system to plan which vacant TV channels can be used for wireless audio devices. If there is a TV transmitter close to the location of the wireless microphone system (<70 miles), this TV channel should generally be avoided. Once one knows which TV channels may be used in the area, the designer can use another software tool that calculates the IM-free frequencies and displays possible setups.
Quantity and Frequency Coordination. Determine how many wireless microphones, wireless monitor systems, intercoms, etc. are required or in use for your job. With the information you gathered from step one, you can begin the system design. You now have the available TV channels and the number of wireless systems you want to use.

With this know-how you can start the frequency coordination of your system inside the vacant TV channels. This is supported by software that is available from various companies. The key here is to prevent intermodulation products (unwanted frequencies generated by harmonic distortion) from interfering with the wanted frequencies of your wireless systems.

A check in the venue is also necessary. If you have the chance, scout the location with a spectrum analyzer, Fig. 16-154. With this tool, you can verify that the information from the internet is correct. Alternately, you can scroll through the tunable frequencies of your wireless receivers to scan the RF activity in the venue. Many receivers also have an auto scan function to find open frequencies. This cross-check is necessary to find out whether other wireless devices are in use that you do not have on your list, which could interfere with your signal during operation.

Tune Your Components. Set your individual transmitters and corresponding receivers to their coordinated frequencies. Switch on all components and perform a final test of compatibility. Physically space the transmitters a couple feet apart and at least 10 feet from the receiving antenna. Listen for any interference. Compatibility between components of a system is achieved if the following requirements are met: each link in a multi-channel wireless system functions equally well with all other links active and no single link—or any combination of multiple links—causes interference.

16.11.11 Future Considerations: Digital Wireless Transmission

Digital is a buzz word that many presume solves all the technical issues we face today. More and more digital equipment, such as mixing consoles, audio signal processors, and the like, are used for several applications, as a digital audio signal chain offers many advantages. A digital signal on a wire (i.e., fiber optic cable) is easier to handle than on a copper wire because 48, 64, or more audio channels can be transported on one thin fiber optic cable. If an audio signal is already in the digital domain, it makes sense to keep it in this domain as long as possible.

As for digital wireless transmission, a digital wireless system is beneficial when the sound, occupied RF spectrum, and battery lifetime is as good or even better than an analog system. On top of this, latency (time delay between input and output) is always a very important topic to keep in mind.

16.11.11.1 Starting with Sound and the Related Data Rate

The best sound can be expected if there is no audio data compression used in the wireless system. This will lead to a very high data rate.

- Minimum for 20 kHz audio and approximately 110 dB dynamic range: 18 Bit × 48 kHz = 0.864 Mbit/s.
- Necessary overhead (framing, channel coding) leads to even higher data rate (factor approximately 1.5 [1.296 Mbit/s]).

When transmitting this high amount of data, it is no longer possible to use a simple and robust digital modulation scheme like FSK (frequency shift keying), ASK (amplitude shift keying), or PSK (phase shift keying), because these concepts will be not able to fulfill the spectrum mask, ≤ 200 kHz of occupied RF spectrum, defined by the FCC. Even if this constraint didn’t exist, greater occupied RF spectrum could inhibit large multi-channel systems.

To improve this, it is necessary to use a more complex modulation scheme with narrow filtering, Fig. 16-155.

The amplitude and the phase of the transmitted signal must be very precise when using this approach. Behind every point of the constellation diagram, a digital word is deposited, which the receiver has to pick up and transfer back into an audio signal.

This requires a very linear RF amplifier. This is a current-hungry device. The unwanted effect is reduced...
battery life of transmitters and portable receivers. By driving the RF amplifier with a better efficiency, the occupied RF spectrum will increase in an undesirable manner.

If the data rate described above can be reduced, the modulation scheme can be simplified and the amplified RF can be used in a more efficient way to conserve battery power and increase operational time.

To reduce the amount of digital data a compression algorithm has to be defined. This algorithm will add some latency to the whole data transmission process. Low latency is especially important during a live performance on stage. If the total latency in a PA system, including contributions from digital mixing consoles, effects, etc., is >10 ms, the timing of the band will be thrown off. Furthermore, if streaming video is projected to accommodate a large audience the picture and sound will be out of sync.

New audio data compression algorithms show good performance with a very low latency. However, audio compression would introduce the possibility of audible artifacts (at least with awkward signals).

As technology improves, there will be solutions to the obstacles described above and digital will become available for wireless transmission.

The key questions for a digital system at this time are:

• Is data compression used?
• What RF spectrum is necessary and how will this impact multichannel systems?

16.11.12 Conclusion

Large multichannel wireless systems demand excellent planning, especially in the initial phase, and good technical support. Observing all the above-mentioned items, perfect operation of a system can be guaranteed, even under difficult conditions.

16.12 Microphone Accessories

16.12.1 Inline Microphone Processors

The overall sound of a microphone can often benefit from signal processing, and most mixers provide some basic equalization as a tool for customizing the sound of the microphone. Digital mixers provide an even greater set of tools, including parametric EQ, compression, gain management, and other automated functions. Dedicated signal processing for each microphone in a system provides a real advantage for the user, and some manufacturers are offering this sort of custom processing on a per-microphone basis via processors that plug inline with the microphone. These include automatic gain control, automatic feedback control, control for plosives and the proximity effect, and integrated infrared gates that turn the microphone on and off based on the presence of a person near the microphone. These phantom-powered processors allow for targeted solutions to many problems caused by poor microphone technique.

16.12.1.1 Sabine Phantom Mic Rider Pro Series 3

The series 3 Mic Rider includes infrared gates that turn the microphone on and off based on the presence of a person. The heat-sensing IR module is mounted on the gooseneck or is built in on the handheld version. The IR sensor can be adjusted for both time to turn off of 5–15 s and for distances of 3–9 ft, Figs. 16-156 and 16-157.

16.12.1.2 Sabine Phantom Mic Rider Pro Series 2

The series 2 Mic Rider includes the adjustable IR Gate plus three audio processors: automatic gain control, proximity effect control for controlling increased bass due to the proximity effect, and plosive control for
reducing pops and bursts from certain consonant sounds in speech.

16.12.1.3 Sabine Phantom Mic Rider Series 1

The series 1 Mic Rider includes Sabine’s patented FBX Feedback Exterminator for maximizing gain before feedback plus the automatic gain control, proximity effect control, and plosive control. A nonadjustable IR gate is also included.

The Phantom Mic Rider works with 48 Vdc phantom power sources that conform to industry standards (DIN standard 45 596 or IEC standard 268-15A). Devices that do not conform can be modified to meet the standard, or external phantom power supplies can be used.

16.12.1.4 Lectrosonics UH400A Plug-On Transmitter

The design of this transmitter was introduced in 1988, in a VHF version aimed at broadcast ENG applications at a time when production crews were being downsized. Converting the popular dynamic microphones of the day to wireless operation eliminated the cable, which was very useful for the two-person production crews that had evolved. During the 20 years that followed, the design continued to evolve to address an ever-increasing variety of applications. The addition of selectable bias voltage allowed the transmitter to power electret microphones. The move to UHF frequencies and a dual-band compandor increased operating range and audio quality. Modifications to the design continued through the present day, leading to the current DSP-based model available in two versions for use with all types of microphones and modest line level signal sources.

The UH400A model has a 12 dB/octave low-frequency roll-off down 3 dB at 70 Hz. The UH400TM model offers an extended low frequency response down 3 dB at 35 Hz, Fig. 16-158. Fig. 16-159 is the block diagram of the transmitter.

The most common applications of this transmitter are eliminating the cable between a microphone and a sound or recording system. A prime example is acoustic analysis in a large auditorium or stadium where measurements must be made at multiple locations around the sound system coverage area and extremely long cable runs are not practical. In this case, the wireless not only speeds up the process of making measurements, but it also allows more measurements to be taken, which can improve the final sound system performance.

Digital Hybrid Wireless™ is a patented process that combines a 24 bit digital audio stream with wide deviation FM (U.S. Patent 7,225,135). The process elimi-
nates a compandor to increase audio quality and expand the applications to test and measurement and musical instrument applications.

Audio is sampled at 88.2 kHz and converted to a 24-bit digital stream. The DSP applies an encoding algorithm that creates what might be likened to an instruction set that is sent to the receiver via an FM carrier. The DSP in the receiver then applies an inverse of the encoding algorithm and regenerates the 24-bit digital audio stream.

An additional benefit of the FM radio link is the ability of the DSP to emulate a compandor for compatibility with analog receivers from Lectrosonics and two other manufacturers.

In the native hybrid mode, the FM deviation is ±75 kHz to provide a wide dynamic range. This wide deviation combined with 100 mW of output power provides a significant improvement in the audio SNR and the suppression of RF noise and interference.

Used with a microphone, the antenna is a dipole formed between the transmitter housing and the microphone body. When plugged into a console or mixer output, the housing of the transmitter is similar to the radiator of a ground plane antenna, with the console or mixer chassis functioning as the ground.

Phantom power can be set to 5, 15, or 48 V or turned off. The transmitter can provide up to 15 mA of current in 5 and 15 V settings, and up to 7 mA in the 48 V setting, allowing it to be used with any type of microphone, including high-end studio condenser models.

The transmitter is available on 9 different frequency blocks in the UHF band between 470 and 692 MHz. Each block provides 256 frequencies in 100 kHz steps.

16.12.1.5 MXL Mic Mate™ USB Adapter

The Mic Mate™, Fig. 16-160, is a USB adapter used to connect a microphone to a Macintosh or PC computer. It uses a 16-bit Delta Sigma A/D converter with $\text{THD} + \text{N} = 0.01\%$ at sampling rates of 44.1 and 48.0 kHz and includes a three-position analog gain control. It includes a studio-quality USB microphone preamp with a balanced low noise analog input, supplies 48 Vdc phantom power to the microphone, and includes MXL USB Recorder Software for two track recording. There are three different Mic Mates, one for condenser microphones, one for dynamic microphones, and one for news line feeds, video cameras, etc.

![Figure 16-159. Block diagram of the Lectrosonics UH400A transmitter. Courtesy Lectrosonics, Inc.](image1)

![Figure 16-160. MXL Mic Mate USB adapter. Courtesy Marshall Electronics.](image2)
16.12.2 Windscreens and Pop Filters

A windscreen is a device placed over the exterior of a microphone for the purpose of reducing the effects of breath noise and wind noise when recording outdoors or when panning or gunning a microphone. A windscreen’s effectiveness increases with its surface area and the surface characteristics. By creating innumerable miniature turbulences and averaging them over a large area, the sum approaches zero disturbance. It follows that no gain is derived from placing a small foam screen inside a larger blimp type, Fig. 16-161A, whereas a furry cover can bring 20 dB improvement, Fig. 16-161B. Most microphones made today have an integral windscreen/pop filter built in. In very windy conditions, these may not be enough; therefore, an external windscreen must be used.

With a properly designed windscreen, a reduction of 20–30 dB in wind noise can be expected, depending on the SPL at the time, wind velocity, and the frequency of the sound pickup. Windscreens may be used with any type microphone because they vary in their size and shape. Fig. 16-162 shows a windscreen produced by Shure employing a special type polyurethane foam. This material has little effect on the high-frequency response of the microphone because of its porous nature. Standard styrofoam is not satisfactory for windscreen construction because of its homogeneous nature.

A cross-sectional view of a windscreen employing a wire frame covered with nylon crepe for mounting on a 1 inch diameter microphone is shown in Fig. 16-163. The effectiveness of this screen as measured by Dr. V. Brüel of Brüel and Kjaer is given in Fig. 16-164.

16.12.2.1 Wind Noise Reduction Figures for Rycote Windsheilding Devices

Rycote has developed its own technique for measuring wind noise that uses real wind and a real time differential comparison. The technique compares the behavior of two microphones under identical conditions, one with a particular wind noise reduction device fitted and the other without, and produces a statistical curve of the result corrected for response and gain variations.

Fig. 16-165 is a Sennheiser MKH60 microphone—a representative short rifle microphone—without any low-frequency attenuation in a wideband (20 Hz–20 kHz) test rig.

When a wind noise reduction device is fitted, its effect on the audio response is a constant factor—if it causes some loss of high frequency, it will do it at all times. However, the amount it reduces wind noise depends on how hard the wind is blowing. If there is a flat calm it will have no beneficial effect and the result will be a degradation of the audio performance of the...

B&K model 4131 microphone (1 inch diameter)

Figure 16-163. Typical silk-covered windscreen and microphone. Courtesy B and K Technical Review.
Microphones

It is the effect of a shield at these lower frequencies that is most important. Cavity windshields inevitably produce a slight decrease in low-frequency response in directional microphones but this is not usually noticeable. Basket types have very little effect on high frequency. Fur coverings, while having a major effect in reducing low-frequency noise, will also attenuate some high frequency.

Adding the low-frequency attenuation available on many microphones or mixers (which is usually necessary to prevent infrasonic overload and handling noise when handholding or booming a microphone) may give extra wind noise reduction improvements of >10 dB at the cost of some low-frequency signal loss.

The standard (basket) windshield shows up to 25 dB wind noise attenuation at 35 Hz while giving almost no signal attenuation, Fig. 16-163.

The Softie Windshield is a slip-on open cell foam with an integral fitted fur cover. The Softie reduces wind noise and protects the microphone. It is the stan-

Figure 16-165. Wind noise reduction options for a Sennheiser MKH60 microphone under real wind conditions. Courtesy Rycote Microphone Windshields LTD

Figure 16-164. The effectiveness of the windscreen shown in Fig. 16-163. Courtesy B and K Technical Review.
standard worldwide in TV. A Softy attenuates the wind noise about 24 dB, Fig. 16-163B.

Adding a Windjammer (furry cover) to the basket windshield will give an improvement of about 10 dB at low frequency to −35 dB, Fig. 16-163C. The attenuation of the Windjammer is approximately 5 dB at frequencies above 6 kHz although this will increase if it is damp or the fur is allowed to get matted. Overall this combination gives the best performance of wideband wind noise reduction against signal attenuation. To determine the correct windscren for microphones of various manufacturers, go to www.microphone-data.com.

Pop protection is best appreciated when close-talking and explosive breath sounds are particularly bothersome. These explosive breath sounds are commonly produced when saying words involving P and T sounds. The phrase explosive breath sound is somewhat of a misnomer since these sounds, without amplification, are normally inaudible to a listener.15

The electrical output from the microphone is actually the transient microphone response to this low-velocity, high-pressure, pulse-type wavefront. The P and T sounds are projected in different directions and can be shown by saying the letters P and T while holding your hand about 3 inches (7.6 cm) in front of your mouth. Note that the T sound is felt at a considerable distance below the P sound.

For most microphones, pop output varies with distance between the source and microphone, reaching a peak at about 3 inches (7.6 cm). Also the worst angle of incidence for most microphones is about 45° to the microphone and for a glancing contact just at the edge of the microphone along a path parallel to the longitudinal axis.

sE Dual Pro Pop Filter. An interesting pop filter is shown in Fig. 16-166. The sE Dual Pro Pop pop screen is a two-filter device to suit vocal performances. The device has a strong gooseneck with both a standard fabric membrane and a pro metal pop shield on a hinge mechanism. They can be used separately or both simultaneously depending on the application.

In an emergency pop filters can be as simple as two wire-mesh screens treated with flocking material to create an acoustic resistance.

16.12.2.2 Reflexion Filter

The Reflexion Filter by sE Elecronics is used to isolate a microphone from room noises hitting it from unwanted directions, Fig. 16-167.

The reflexion filter has six main layers. The first layer is punched aluminum, which diffuses the sound waves as they pass through it to a layer of absorptive wool. The sound waves next hit a layer of aluminum foil, which helps dissipate energy and break up the lower frequency waveforms. From there they hit an air space kept open by rods passing through the various layers.

Next the waves hit an air space that acts as an acoustic barrier. The sound waves pass to another layer of wool and then through an outer, punched, aluminum wall that further serves to absorb and then diffuse the remaining acoustic energy.

The various layers both absorb and diffuse the sound waves hitting them, so progressively less of the original source acoustic energy passes through each layer, reducing the amount of energy hitting surfaces so less of the original source is reflected back as unwanted room ambience to the microphone. The Reflexion Filter also reduces reflected sound from reaching the back and sides of the microphone. The system only changes the microphone output by a maximum of 1 dB, mostly below 500 Hz.

The stand assembly comprises a mic stand clamp fitting, which attaches to both the Reflexion Filter and any standard fitting shock mount.

16.12.3 Shock Mounts

Shock mounts are used to eliminate noise from being transmitted to the microphone, usually from the floor or table.

Microphones are very much like an accelerometer in detecting vibrations hitting the microphone case. Shock
mount suspensions allow a microphone to stay still while the support moves.

Suspensions all use a springy arrangement that allows the microphone to be displaced and then exerts a restoring force to return it to the rest point. It will inevitably overshoot and bounce around, but the system should be damped to minimize this.

As frequency lowers, the displacement wavelength increases so the suspension has to move farther to do the job. For any particular mass of microphone and compliance (wobbliness) of suspension, there is a frequency at which resonance occurs. At this point the suspension amplifies movement rather than suppresses it. The system start to isolate properly at about three times the resonant frequency.

The microphone diaphragm is the most sensitive along the $Z$-axis to disturbances. Therefore the ideal suspensions are most compliant along the $Z$-axis, but should give firmer control on the horizontal ($X$) and vertical ($Y$) axes to stop the mic slopping around, Fig. 16-170.

**Suspension Compliance.** Diaphragm and so-called donut suspensions can work well, but tend to have acoustically solid structures that affect the microphone’s polar response. Silicone rubber bands, shock-cord cat’s cradles, and metal springs are thinner and more acoustically transparent but struggle to maintain a low tension, which creates a low resonant frequency, while at the same time providing good $X–Y$ control and reliable damping. The restraining force also rises very steeply with displacement, which limits low-frequency performance.

Shock mounts may be the type shown in Fig. 16-168. This microphone shock mount, a Shure A53M, mounts on a standard $3/8$ in – $27$ thread and reduces mechanical and vibration noises by more than $20$ dB. Because of its design, this shock mount can be used on a floor or table stand, hung from a boom, or used as a low-profile stand to place the microphone cartridge close to a surface such as a floor. The shock mount in Fig. 16-169 is designed to be used with the Shure SM89 shotgun microphone.

**Figure 16-167.** Reflexion Filter. Courtesy sE Electronics.

**Figure 16-168.** Shure A53M shock mount. Courtesy Shure Incorporated.

**Figure 16-169.** Shure A89SM shock mount for a shotgun microphone.Courtesy Shure Incorporated.

Shock mounts are designed to resonate at a frequency at least $2\frac{1}{2}$ times lower than the lowest frequency of the microphone. The goal is simple but
there are practical limitations. The resonant frequency \( f_n \) of a mechanical system can be computed from

\[
f_n = \frac{1}{2\pi} \sqrt{\frac{Kg}{w}}
\]  

(16-32)

where,

- \( K \) is the spring rate of the isolator,
- \( g \) is the acceleration due to gravity,
- \( w \) is the load.

A microphone shock-mount load is almost completely determined by the weight of the microphone. To obtain a low-resonant frequency, the spring rate or stiffness must be as low as possible; however, it must be able to support the microphone without too much sag and be effective in any position the microphone may be used.

The Rycote lyre webs rely primarily on their shape to give different performance on each axis. Typically, a 100 g force will barely move a microphone 1 mm along the (up and down) \( Y \)-axis, whereas it will move about four times that on the (sideways) \( X \)-axis. In the critical \( Z \)-axis, it will move almost ten times as far, Fig. 16-170.

With a very low inherent tension the resonant frequency can be very low, and the \( Z \) displacement can be vast. Even with small-mass compact microphones, a resonance of \(<8 \) Hz is possible, which means that microphones can be well isolated across almost their entire frequency range.

Damping has to be added to metal spring suspensions, and although integral to rubber band versions, is not very easy to control. With the lyre webs damping can be selected almost independently by choosing a suitable plastic. The Hytrel that Rycote uses not only damps smoothly but maintains its characteristics even down to arctic temperatures. It also has a shape memory that allows it to be tied in eye-watering knots without developing a permanent set—or snapping!

Most suspension systems are difficult to scale. Springs and elastic bands become thin and fragile, and the range of softness for rubber and foam is limited. However, this does not apply to lyre webs. The tiny InVision suspensions, which are visually unobtrusive, isolate compact and similar sized microphones down to \(<30 \) Hz, yet are tough enough to be dropped on the floor without risk. Fig. 16-171 shows the actual measured performance of the transfer function for a Schoeps CCM4 microphone being shaken with pink noise in an InVision mount. Trace A shows the output from the microphone with the shaker operating but not touching the mic, revealing the inherent coupling through air and the building itself. Trace B is with the shaker directly coupled to the microphone body to reveal the actual level of vibration input. Finally, the trace C shows the microphone’s output with the shaker knocking the bar of the mount, thus demonstrating the effectiveness of the suspension.
To determine the correct suspension systems for microphones of various manufacturers, go to www.microphone-data.com.

16.12.4 Stands and Booms

Microphones are mounted on microphone floor stands or table stands to place the microphone in front of the sound source. The floor stands are usually adjustable between 32 and 65 inches (0.8–1.6 m) and incorporate a 5/8 inch – 27 thread for mounting the microphone holder or shock mount. They normally have a heavy base or three widespread legs for stability.

The table stands are 6–8 inches (15–20 cm) high and often incorporate a shock mount and an on–off switch, as shown in Fig. 16-172.

Small booms, which are mounted on the standard microphone floor stand, are normally used to put the microphone in a place where it is difficult to reach with a floor stand, Fig. 16-173. They are also useful when micing from above the source. Combination booms and stands are often on wheels or flat tripod legs and adjustable from 60–90 inches (1.5–2.3 m) vertically and 90–110 inches (2.3–2.8 m) horizontally, Fig. 16-174.

It is important that the boom and/or microphone stand be easily adjusted and that the clutch/brake system has a positive lock. Better microphone stands incorporate a piston-type air suspension system for effortless height adjustment and microphone protection.

Large booms, as used in television and motion-picture sound stages, are motorized and often include a stage for the microphone sound person.

16.12.5 Attenuators and Equalizers

Attenuators, equalizers, and special devices from Electro-Voice, Shure, and others are available to reduce the microphone output level or shape the response to

Figure 16-172. Electro-Voice table microphone stand with push-to-talk switch. Courtesy Electro-Voice, Inc.

Figure 16-173. Atlas BB-44 microphone boom. Courtesy Atlas Sound.

Figure 16-174. Adjustable microphone stand/boom. Courtesy Atlas Sound.

16.12.5 Attenuators and Equalizers

Attenuators, equalizers, and special devices from Electro-Voice, Shure, and others are available to reduce the microphone output level or shape the response to
roll off the low or high end, increase the 3–5 kHz articulation region, or reverse polarity. These units normally have standard input and output male and female XLR or ¼ inch phone plug connectors. Attenuators are also available to be installed between the capacitor capsule and the condenser microphone electronics to eliminate overload from high-level sources.

16.13 Microphone Techniques

Micing is more of an art than a science. Therefore there is no one way to position a microphone for good recording. It is subjective and at the control of the engineer. The discussions of microphone placement in the following sections are only suggestions or the ideas of one engineer.

The quality of the reproduction can be greatly influenced by the position of a microphone in relation to the sound source. When only one microphone and one sound source are involved, this positioning is fairly straightforward: the closer the microphone, the more the direct sound will dominate over the reverberant sound. Except in an anechoic chamber, there will always be a certain amount of reflected sound present in the microphone output. This results from sound bouncing off boundaries such as the floor, ceiling, walls, and objects of significant proportions located in the area of the microphone. At a certain distance from the sound source, the amount of reflected sound will exceed the amount of the direct sound. The microphone is then said to be in the reverberant, or far, field. The effect is to make the acoustic environment (usually a room) more evident to the listener than would be the case with close micing (microphone in the near field).

The proper position of the microphone depends on the effect desired. Close micing produces a highly present, up-front sound, with little of the acoustic environment evident, whereas distant micing produces a more spacious sound with the room characteristics becoming very obvious. A close microphone position may not accurately reproduce the sound of the source, and equalization may be required to achieve a sound similar to the natural sound. If the room acoustics are not suited to the sound reproduction desired, a distant microphone position may produce an unpleasant or unintelligible result. The correct choice requires the engineer to choose the appropriate microphone position for the sound desired. A microphone placed an inch from a snare drum will produce an up-front, bigger-than-life sound, which could be appropriate for a modern rock recording but might be totally inappropriate for a jazz or big band recording. Distant micing of the snare drum could produce a powerful effect, in any kind of music, since the contribution of a good room might be important to the music.

It is rare that there is just one microphone and one sound source. Modern recording often requires the use of multiple microphones. Microphone placement then becomes more complicated, because as the microphone is moved farther from its intended source, more of the other sources will be picked up as well. No instrument is a point source, and there are different characteristic sounds emanating from various places on the instrument (i.e., a flute has vastly different sounds coming from the open end, the body of the flute, or the mouthpiece). Most instruments have complex directional characteristics, that vary from note to note. Even instruments of the same make and model can sound quite different from one another.

Whenever there is more than one microphone receiving sound from a single source, a problem of time and phase differences can become audible. This problem can have a major effect on the frequency response, presence, and clarity of the recording. The result for spaced microphones can be a comb filter effect, which will tend to reduce presence, upset the natural balance of various notes and overtones, and disturb localization of the source. In an extreme case, certain notes may be attenuated to inaudibility. In practice, the contribution of room reflections, pickup by other microphones, and intrinsic instrument imbalances may mask many of these effects.

Multitrack recording generally requires the engineer to isolate instruments so that only the intended source is recorded on each track. Sometimes this is simple because the track is being overdubbed and only that one instrument is in the studio. At the other extreme, an entire ensemble may be playing at once, yet the situation may require that all instruments be totally isolated on the tape tracks so that they can be individually mixed, processed, or even replaced with no effect on the other instruments. The latter requires very careful microphone choice and placement and/or the use of isolation booths for some troublesome instruments. If the musical balance is good in the room, the job is fairly simple. But if there are obviously incompatible instruments playing simultaneously (e.g., heavy drums versus a finger-picked acoustic guitar), isolation solely through microphone technique becomes next to impossible.

16.13.1 Stereo Micing Techniques

Modern recording practice often employs multiple microphones, each feeding a separate track of a multi-
track tape machine. Sound reinforcement practice usually requires good isolation of the various sound sources. In either case, the end result is a composite of a number of monaural sources, which are often placed in the stereo image with pan pots. This practice is not the same as true stereo recording, which can provide a sense of depth and realism unachievable with panned mono sources. It requires greater effort for superior results; a good acoustic environment is essential.

There are a number of stereophonic recording techniques available to the engineer. The simplest requires two microphones, often omnidirectional types, spaced apart by a distance ranging from several feet to more than 30 ft (9 m), Fig. 16-175. The spacing depends on the size of the sound source, the size of the room, and the effect desired. A broad source like an orchestra will require a wider spacing than a small source such as a single voice or instrument. If the microphones are too far apart, a hole in the middle of the stereo image will result, since the sound produced in the center of the stage will be too far from either microphone. When placed too closely together, a mono result will be obtained. When the spacing is comparable to the wavelength of the sound, phase cancellations may result (comb filters), which will destroy the monaural compatibility of the recording. The best spacing seems to be from 10–40 ft (3–12 m). Experimentation is necessary since every situation will be different. Needless to say, good monitoring is required; stereo headphones will not generally reveal defects evident on good monitor loudspeakers. A method of summing the two channels to mono is essential for testing compatibility.

Variations on the spaced microphone technique involve using bidirectional or unidirectional microphones, which may be helpful when the room character-istics are not perfect for the material being performed. Adding a microphone in the center, fed to both left and right channels (fill microphones), and combinations of spaced micing and other techniques might be required.

### 16.13.2 Microphone Choice

Every microphone type has certain characteristics. These characteristics must be taken into account when choosing a microphone for a specific application. Some of the factors to be considered are general type (condenser, moving coil dynamic, ribbon); directional pattern (omni-, bi-, or unidirectional); and specific microphone traits (bright, bassy, dull, presence peak, and so on).

Also, the susceptibility of the microphone to overload or its tendency to overload the associated preamplifier must be considered. The off-axis frequency response can have a large effect on the sound of a microphone in a particular application. Certain microphones may exhibit unusual traits that may make them more, or less, suitable for a certain application. For example, the design of the grille may have a major effect on the sound of a microphone when recording closely micing vocals.

Some of these characteristics can be inferred from the microphone specifications (i.e., frequency response, overload point, directional pattern—both on-and off-axis). Other characteristics are not as easy to measure or visualize, and experience and experimentation are necessary to make an intelligent choice.

### 16.13.3 Microphone Characteristics

There are many criteria used to judge the suitability of a microphone for a particular application—some are quite subjective. Frequency response is one obvious characteristic, distortion is another. The ability of a microphone to accurately translate waveforms into electrical signals is vital for good reproduction. Generally, the less massive the internal parts that must be moved by the sound pressure, the more accurate the reproduction, especially the reproduction of waveforms with steep leading edges and/or rapid level changes (e.g., percussive sounds). The condenser microphone has the lowest mass (only a thin plastic diaphragm with a very thin coating of metal must be moved by the sound pressure). The diaphragm and coil in the dynamic microphone have considerably more mass than the condenser diaphragm. The ribbon in a ribbon microphone has relatively low mass and is somewhere between the condenser and the dynamic microphone.
It would seem that the condenser microphone would always be the best choice, but other factors must be considered. Condenser microphones are generally less rugged than dynamic ones, and since they are usually more expensive, the decision to place a valuable microphone in a position where it could be hit or knocked over must be weighed against the possible benefit of improved sound. Also, condenser microphones contain internal active electronics, which can be overloaded by high sound levels. Many condenser microphones contain switchable or insertional pads, but long before the overload distortion becomes apparent, clipping of the transient peaks may muddy the sound in a subtle way.

Ribbon microphones are somewhat fragile. They can be especially vulnerable to blasts of air that can occur when closely micing vocals, inside a bass drum, or even when a door is slammed in an airtight studio.

In each type of microphone, there are many other factors that can affect the sound. The design of the mounting for the microphone components, the internal obstacles in the sound path, and the effect of the body of the microphone, all can have a major effect on the ultimate sound reproduction.

16.13.3.1 Directional Pattern

It might at first seem that the unidirectional microphone would be the universal choice for all applications, since picking up the intended source is the goal. It is true that unidirectional microphones (see Section 16.2.3) have the greatest application, but there are situations that require the use of omnidirectional microphones, which are designed to pick up sound from all directions as nearly equally as possible (see Section 16.2.1), or bidirectional microphones, which are sensitive to the front and back, but insensitive to the sides (see Section 16.2.2). But it is possible, in some situations, to obtain greater rejection of unwanted sound with an omni- or bidirectional microphone than would be possible with a unidirectional pattern.

Unidirectional and bidirectional microphones often exhibit a proximity effect, in which the response to lower frequencies (generally below 150 Hz) is emphasized when the microphone is placed close to the sound source (Section 16.2.3). Close may be a couple of inches or a couple of feet, depending on the microphone. Various designs have been developed to minimize or eliminate this effect. A switchable high-pass filter may be included on the microphone to roll off the bass in close micing positions. Proximity effect must be considered when choosing and placing a microphone. Sometimes the effect can be used to advantage (i.e., when additional bass response is desirable, perhaps on a snare drum or on certain vocals). But often the proximity effect emphasizes the (unrelated) tendency of some sound sources to sound more bassy when close mic'ed.

Directional microphones do not have the same frequency response off-axis as they do on-axis. This can cause increased apparent sound leakage from other sources, tonal aberrations of the reproduced sound, or unexpected phase cancellations. For example, many directional microphones exhibit less directionality at both higher frequencies and lower frequencies. If such a microphone were used to close mic a snare drum, the amount of pickup of the nearby bass drum and cymbals might be excessive.

16.13.4 Specific Micing Techniques

There are probably as many methods of using microphones as there are engineers. Contrary to popular opinion, there does not seem to be any special microphone or magical technique for recording any particular sound. What is right is what sounds best. The following discussion is merely a review of some common techniques widely employed and likely to work well in many circumstances.

16.13.4.1 Musicians

The first requirement for obtaining a good sound from any instrument is a superior player. An experienced studio musician can make almost any studio or engineer sound good. Unfortunately, the engineer usually has very little to say about the musicians who are hired for the session. When inexperienced players record, they may often expect to be made to sound like whoever their idols may be. They probably don’t want to know that their idol spent the last 10 years or more learning how to use the studio, and they may be likely to blame the engineer for their inability to play properly for recording. There isn’t much that can be done in such a circumstance.

16.13.4.2 Drums

Studios involved in music recording are more often judged by their drum sound than by anything else. It is true that much contemporary music relies heavily on drums and that getting the best possible sound is a goal worth pursing. There are any number of ways to record drums, but the most commonly used technique utilizes close micing.
Just as the musician is a vital element in obtaining a good sound, the drums themselves must be in good condition and properly tuned to obtain their best sound. The type of drum head used will have a major effect on the sound.

**Micing Each Drum.** A micing arrangement that is almost standardized requires the use of one microphone on each drum, Fig. 16-176. In addition, one or more microphones may be suspended over the drum set to pick up either an overall sound or primarily cymbals. How closely each microphone is placed depends on several factors: how tight a sound is required, which in turn is related to the relative liveness and character of the room; what isolation problems might exist, in terms of various drums leaking into other drum microphones and leakage from other instruments in the room; how dangerous it may be to place an expensive and fragile microphone in a position of possible destruction by an overly enthusiastic or inaccurate drummer; and whether the microphone and/or console can take the level produced without distortion.

**Above versus Underneath Micing.** Individual drums can be miced either from above or below, Fig. 16-177. The two positions will usually have vastly different sounds. If the sound is appropriate, the underneath position may be preferable if isolation is a problem.

When miced from above, microphones are commonly positioned at an angle to the drum head and near the edge of the drum. Seemingly minor changes in position can have a major effect on the sound, especially with some microphones.

**Bass Drum.** For recording, bass drums usually have only the beaten head, which is not to say that bass drums with both heads cannot be recorded, however. For some music, the use of both heads is preferable. In the single-head configuration, the usual microphone placement is within the shell of the drum, with the microphone aimed toward the beater, Fig. 16-178. Experimentation is required, however. Closer or farther distances, off-axis microphone positions, or even placement on the opposite side of the head may result in the desired sound.

**Tom-Tom Micing.** Tom-toms, too, often use only the top head. This facilitates underneath micing. In micing any drum, it is probable that simultaneous top and bottom micing will result in difficulty due to phase discrepancies. The use of phase-reversal switches at the board and minor position adjustment may be required.

**Cymbals.** The high hat and cymbals can be mic’ed from above or below, but the above position is more commonly used. Overhead microphones are often positioned above the entire drum set, usually as a stereo pair. How high they are set will depend on the effect desired; a relatively high placement will provide more of an overall drum sound, with more room characteristics than a closer position.

It is not unusual to pick up sufficient cymbals, or even excessive cymbals, from just the other drum...
microphones without the overhead microphones even being on. The amount of cymbal leakage will be determined mostly by the drummer’s technique and balance, with the room characteristics also being a factor.

**Other Drum Micing Techniques.** Close micing every drum is only one method. Another is to use relatively distant microphones to pick up an overall drum sound, Fig. 16-179. This, of course, results in much more room sound and possible leakage from other instruments. It also requires that the drummer play all the drums, and particularly the cymbals, in the proper balance. The engineer has much less control of the sound. This approach will not be successful in poor rooms, nor with drummers who do not correctly balance their various drums and cymbals. But in a good room, with a good drummer, the sound can be quite natural and often very powerful. A common technique is to use two overhead microphones, placed in such a way as to capture the natural sound and balance of the drum set. Some experimentation will be required to find the proper placement. Usually a separate bass drum microphone is used as well, to give the bass drum better definition and more punch.

16.13.4.3 Piano

Pianos are often recorded in stereo and can add width and a greater sense of space if done properly. Multiple microphones spread all over the sounding board may seem like an ideal way to pick up the full piano sound, but this procedure can lead to a very artificial and distant sound when heard in mono.

First, be certain that a stereo piano is really desirable. In multitrack recording, are there sufficient tracks available? And is the piano sound required to be so big? A mono piano can often have more punch and might be a better choice.

For a mono track, one microphone is usually all that is needed. For stereo, a pair of adjacent directional microphones will probably suffice. In micing either a
grand or upright piano, keep in mind that the sounding board and not the hammers and strings is the source of most of the sound. With a good piano, there may be surprisingly little difference in the sound picked up from various areas of the sounding board. A commonly mic’ed point is where the bass and treble strings cross, Fig. 16-180. Variations such as micing from beneath (or in the case of an upright, in back of) the sounding board, inserting microphones into the circular holes in the harp, or using various types of piano pickups can all be tried. Each piano is different, and each player will also have a large effect on the sound, so a variety of techniques should be tried.

The PZMicrophones can be used in recording piano. They can be placed on the inside of the piano lid and the lid closed for improved isolation.

As in all percussive instruments, the peak level produced by a piano can be far greater than the level shown on the volume unit (VU) meter. Peaks 20 dB above the meter reading are common. Since just about everybody knows what a piano sounds like, and since the instrument is so frequently featured in musical pieces, any distortion will be very obvious to the listener. Even a distortion that only occurs on the peaks can be evident as a dulling of the piano attack, a kind of audio blurriness. The peaks can really strain the dynamic range of microphones, preamps, and storage medium. If condenser microphones are used, be sure the pads are switched on even if the level seems moderate. Also, some engineers routinely record piano at a somewhat lower than normal level to avoid tape saturation.

Obtaining satisfactory isolation while still getting a good sound can be a problem with the piano. Isolation can be achieved with a booth, of course, but careful micing and some baffling can often work almost as well. One technique used in many studios is to place the microphone in the piano and then close the lid as much as possible. Often the short-stick position of the lid works well. Then carpeting or other dense, heavy, absorbent material is draped over the piano. With a good arrangement of other instruments and reasonably balanced volumes, very little leakage should exist. Another technique requires that microphones be mounted inside the piano, usually suspended from the lid, in such a way that the lid can be completely closed. The PZM type of microphone is particularly well suited for this approach.

Of course, a much better sound is obtained with the lid open and with perhaps a little more distance between the sounding board and the microphones. Sometimes removing the lid and suspending the microphones above the piano work well. (Most pianos have pins in the
16.13.4.4 Vocals

A single vocal, either speaking or singing, is usually recorded with one microphone placed within 2 ft (0.6 m) of the mouth. For popular music, it is common to have the singer very close to the microphone; in a recording of a classical singing voice, a greater distance is appropriate, even up to several feet may be used if the room acoustics permit. Speakers at a lectern usually are 1–2 ft (0.3–0.6 m) from the microphone.

16.13.4.5 Singers

Although vocals could be recorded in stereo, with any of the techniques previously described, it is customary to record the voice in mono. It is basically a point source, with little directional information. In a superior acoustic environment, such as a good concert hall, natural reverberation may be mixed in with additional microphones. But most often artificial reverb is added. It can be stereo and add considerable depth and width to the voice.

Condenser microphones, placed very close to the mouth, are the usual choice in the studio. A pop filter will be necessary for all but the most careful singers. This prevents explosive sounds from being produced when the vocalist sings a word containing Ps or other hard consonant sounds. It is important to remember that the output level of the microphone will adhere to the inverse square law, which states that if the distance from the source to the microphone is doubled, the level will be reduced to one-quarter. Experienced vocalists are well aware of this phenomenon and may even use it to obtain certain effects. The inexperienced or inattentive singer will probably require electronic processing (i.e., limiting) to obtain a satisfactory performance. This problem is further complicated by the trend toward mixing vocals quite low in the musical track and relying on processing to maintain intelligibility.

In the studio, it is often necessary to provide an acoustic environment less reverberant than normal for the recording of vocals. Cutting down on reverberation could be accomplished with a separate vocal booth with highly sound-absorbent surfaces, or it can be obtained by placing absorbent baffles around the singer and microphone in the studio, Fig. 16-181. On the other hand, it may sometimes be necessary to emphasize the reverberation for a special effect by distant micing or by mixing in another microphone placed some distance away.

Figure 16-181. Vocal mic’ing.

Proximity effect can be a problem with vocals. Many microphones have provision for a bass roll-off, which can be used to correct this deficiency. This approach is often superior to using equalization in the control room, especially if a limiter is used before the equalizer (the limiter would respond to the emphasized bass and thus not accurately track the vocal intensity). Some singers prefer the effect obtained from proximity, using the bass boost in their performance to emphasize certain words or phrases.

In a live performance, large studio condenser microphones would be inappropriate. With their suspensions and pop filters and the large microphone stand required, they would obscure the singer’s face. What is needed is a relatively small, rugged microphone that can be hand-held if desired. Although there are a number of condenser microphones that can be used this way, the usual choice is a compact dynamic microphone with built-in pop filters, integral shock mounting, and switchable bass roll-off.

Good directionality is required of a live performance microphone. The usual practice of providing the singer with a stage monitor loudspeaker, usually placed within a few feet of the microphone, requires good rejection of sound from off axis to minimize the possibility of feedback and reduce the degradation of the sound from the vocal microphone picking up the monitor’s reproduction of the other instruments and voices. Some microphones designed for live work have their direction of minimum sensitivity oriented toward the direction where the most unwanted sound would come from (i.e., not directly off the back of the microphone, but at some intermediate angle).
16.13.4.6 Group Vocals

A vocal group could consist of two singers or a chorus of several hundred. For a small group (less than eight), a single microphone with an omnidirectional pattern placed in the center of a circle of vocalists often works well, Fig. 16-182. This microphone arrangement requires that the singers achieve a proper balance of voices in the studio. The final balance can be fine tuned by having the necessary voices move closer to or farther from the microphone. If the singers are relatively close to the microphone (two feet or less), then their positions become more critical. A small change in position can have a major effect on the blend.

For stereo, the group could be divided into two circles, each with its own omnidirectional microphone in the center. Two bidirectional microphones, oriented at 90° to one another and placed one above the other, could be used to obtain a stereo omnidirectional recording when placed in the circle of vocalists, Fig. 16-183.

Whenever omnidirectional microphones are used, the room becomes more apparent in the recording than it would with unidirectional microphones. This effect must be considered when recording group vocals in this manner.

If greater presence is required (or less room sound) or if the balance must be controlled by the engineer for some reason, individual microphones could be used for each singer; however, this method has obvious practical limitations if the group is large. It also requires more set-up and balancing time, puts a musical burden on the recording personnel, and might have a disappointing result if lack of isolation creates phase problems when mixing the multiple microphones.

For really large groups, techniques similar to those described for string sections might be employed.

Typically, group vocals will be recorded as an overdub on a previously recorded musical track, requiring the vocalists to wear headphones. With a number of singers wearing headphones (which could be turned up quite loud) standing next to an omnidirectional microphone, a significant amount of leakage from the headphone mix is possible. This leakage from the headphone mix can become even more of a problem if one or more of the singers prefer to remove one side of the headphones from his or her ear in order to better hear their own voice and/or the blend of the other voices. Background vocals are often by nature relatively quiet parts requiring higher than normal gain on the microphone channel. All these factors can combine to degrade the entire recording seriously.

Solutions might be to use as low a headphone level as possible, have the singers sing as loudly as is appropriate for the part, turn the microphone off when the vocalists are not singing, or use a noise gate to do this automatically. In a really severe situation, the solution might be to use individual directional microphones.

16.13.4.7 Lectern Microphones

For redundancy, two or more microphones are often provided on a lectern. Only one should be active at a time, or phase cancellations can result. Often two microphones are arranged on opposite sides of the lectern, angled in toward the talker. The goal is satisfactory pickup as the speaker moves from side to side. This arrangement can cause serious phase cancellation problems because of the spacing (usually a couple of feet) resulting in feedback problems since the normal frequency response has been disturbed through the comb filter effect. A better arrangement places the two microphones in the coincident configuration as close
together as possible and angled toward opposite sides of the lectern, Fig. 16-184. The outputs can be summed with no phase problems. The angle between the microphones may be changed from the normal 90° if necessary to obtain proper coverage.

**Figure 16-184.** Lectern microphones for increased coverage pattern.

### 16.13.4.8 Strings

Although strings could be close miced, this approach usually results in an unnatural sound. Distant micing is more appropriate but puts a greater demand on the room acoustics. Obtaining a good string sound really requires a good room of considerable size.

A string quartet might sound fine recorded in a relatively small studio (2200 ft³ or 62 m³), but a large string section needs more volume. Not only will a larger room accommodate more players, but the microphone placement will also be simpler and the results will be closer to the actual sound of the section.

Each instrument could have a microphone, and this would give the mixer complete control of the balance of all the strings. But unless a great deal of time is available to obtain the proper balance, this approach is not cost effective when recording highly paid musicians. It does not guarantee the best results, either.

At the opposite extreme, a single microphone placed at a point determined to provide the best overall balance and sound could be a simple and quick way to get good results, Fig. 16-185. This placement works well if the engineer is familiar with the room and can rapidly duplicate a setup that has been successful in the past. A coincident pair can provide the same sound if stereo is required.

Another technique is to mic the ensemble in sections, Fig. 16-186, providing, for example, a single microphone for the first violins, another for the second violins, another for the violas, and so on. Cello and double bass often have microphones to pick them up individually in this type of setup.

It is also possible to set up microphones above each row of players, or above each two rows. This method is often used in conjunction with the single overall microphone.

In a practice session, Fig. 16-187, the setup is often a composite of all of these techniques: a single coincident pair at a distant point (perhaps 15–20 ft [5–6 m] from the first row, and up as high as practical in the room); a set of microphones over each section (one microphone for every two players, up above the space required for their bows and slightly in front of the instrument); and individual microphones for the cellos and basses (a foot or two in front of the instrument, opposite the F holes). At the start of the session, the overall microphone would first be monitored to determine what, if any, balance problems exist. If time permits, the overall microphone position might be changed to obtain a better balance. If the desired balance cannot be obtained with the single microphone,
the necessary individual section microphones may be brought into the mix. In many practically sized rooms, it is not possible to obtain a good balance of the near strings (usually violins) and the far strings (cello and bass). Careful use of the section microphones can correct this.

Since good high-frequency and transient response is required to reproduce the string section sound, condenser microphones are the most frequent types used for string recording.

16.13.4.9 Horns

In the recording world, horns are any brass instrument: trumpets, trombones, saxophones, and so on. Modern recording of popular music usually requires close micing of individual instruments, Fig. 16-188. Since many horns are capable of producing very high sound-pressure levels (as high as 130 dB), it is important to choose microphones that will not be overloaded by this close placement. Also, pads may be required to prevent overloading the mixer preamplifier or saturating an input transformer.

Condenser microphones are often used to pick up horns, but ribbon and dynamic types may also give good results.

It is important to remember that the sound produced by these instruments does not come entirely from the bell; this is particularly true of saxophones. Although the instrument output may be loudest at the bell, the contribution of the various other parts of the horn cannot be ignored. The microphone position is often a compromise between the presence of very close placement, the better tonality of a slightly greater microphone distance, the leakage from other instruments as the microphone distance is increased, and the degree of room contribution desired in the finished recording.

16.13.4.10 Woodwinds

Instruments like the oboe, flute, bassoon, clarinet, and their variations cannot generally have microphones placed too closely and still retain their character. In popular music they are often mic’ed individually at a distance of one to several feet, which is generally not far enough to provide a true sound, but the result is often acceptable—or even desirable—for compatibility with other instruments in the song.

Condenser or ribbon microphones are the usual choice. Most woodwinds tend to sound most natural when mic’ed from about 3 ft (1 m) away, with the microphone directed toward the middle of the instrument, or perhaps pointing slightly toward the bell or end of the instrument. Low placement, even on the floor...
with a PZMicrophone, tends to sound better than high placement.

For classical recording, a more distant pickup is necessary. A woodwind ensemble might be successfully recorded using the techniques described previously for string sections.

16.13.4.11 Electric Instruments

In this category are all instruments designed to be reproduced through amplifiers and loudspeakers. Electric guitar; electric bass; various synthesizer, organ, and other electronic keyboards; and acoustic instruments with attached microphones or pickups designed for amplification all fall into this category.

Generally, these instruments require microphone placement with the associated amplifier/loudspeaker combination. However, another technique is possible and in many cases preferable—that is, the direct recording of the instrument. Since most of these instruments produce a microphone-level high-impedance unbalanced output, all that is required in most cases is a high-quality transformer, providing the match between the instrument and the low-impedance balanced inputs of most mixers. Various direct boxes are available, some with active electronics to provide the required impedance transformation. Almost all provide an output to drive the instrument amplifier as well as the mixer, and most have a ground switch to select the grounding configuration with the least noise.

In many situations, the instrument and its amplifier constitute a system. The amplifier, which may contain loudspeakers or may be connected to a separate loudspeaker system, may have a major effect on the sound of the instrument. Taking a direct feed may result in a totally unnatural sound.

Mic’ing the instrument amplifier may seem simple, but often the cabinet contains several loudspeakers. These may be identical loudspeakers or separate drivers for various frequency ranges. A single close microphone may not provide the proper balance. Even in systems with identical loudspeakers, careless microphone placement may result in phase discrepancies producing a distant and/or colored sound. Two solutions are practicable: either give the microphone a more distant placement, far enough to be equidistant from all the loudspeakers, or position it very close, to pick up only one loudspeaker, Fig. 16-189.

Systems with multiple drivers for different frequency ranges will have to be mic’ed from far enough away that the various drivers are properly balanced. Although it may be possible to mic the individual drivers and mix them for the proper balance, this approach is more prone to error.

Distant micing is often desired, especially for an electric guitar. Naturally, the character of the room must be appropriate.

Often a combination of the direct and mic’ed sound is used. This combination can be effective, but the phase relationship between the two sources will be arbitrary, which can cause severe coloration of the sound. The tonal balance will change unpredictably as the ratio of direct and mic’ed sound changes. This change usually precludes any gain riding of the individual inputs. A phase reversal switch can sometimes be used to optimize the gross phasing between the two inputs.

Instruments like synthesizers or other electronic keyboards generally should be recorded directly. The sound of these instruments is usually not augmented by the addition of a musical instrument amplifier. There are exceptions, however, and the choice of technique depends on the effect desired—perhaps the limited frequency response and soft distortion of a tube-type amplifier is appropriate.

16.13.4.12 Percussion

The most common percussion instrument is the drum kit. Other percussion instruments, such as congas, tympani, handclaps, tambourines, timbales, wood blocks, claves, or maracas, etc., require care in micing due to the extreme levels encountered. It is not uncommon to have levels of +10 dBm and more (open circuit) on the output of a condenser microphone when placed close to a percussion instrument or a piano.

Such levels can be very demanding of microphone electronics, in the case of condenser microphones and the associated mixer. The use of internal microphone
pads is essential. Additional padding may be necessary between the microphone output and the mixer input.

The correct micing procedure for percussion instruments depends on the effect desired. A distant micing position is often justified when the sound of the room reverberation adds to the effectiveness of the instrument. Tambourine and handclaps often benefit from the sound of a good room. The resultant sense of space can produce better depth in the recording, and/or the explosive nature of a large, live room can add tremendous punch to the part.

On the other hand, the highly present sound of close micing might be more appropriate in another musical situation. Close, in this sense, might range from fractions of an inch to a couple of feet. Handheld instruments, like claves, must be played at a uniform distance from the microphone, which becomes more critical as the distance decreases.

16.13.5 Conclusion

It is important to remember that there is never only one way to position microphones. The techniques presented here are representative of the methods widely used in the recording and sound-reinforcement industries, but such practices have evolved over many years. Some are traditional; however, there may be better ways. Using the procedures outlined will result in reasonably accurate reproduction, or commercial reproduction as it applies to mainstream music recording. Since sound reproduction can be a creative endeavor, experimentation may yield new techniques. The exact reproduction of the original sound may not be the goal. Perhaps the engineer is attempting to obtain a previously unheard sound or effect. When the luxury of experimentation is available, the engineer may well use the time to pioneer new techniques that can supplement or even replace existing procedures.

17.1 Introduction

A loudspeaker is a device that converts electrical energy into acoustic energy (electroacoustic transducer), or more generally, a system consisting of one or more such devices. Loudspeakers are present in our daily lives to such an extent that, in most modern societies, one is in almost constant contact with them. From the time the speaker in our clock radio wakes us in the morning until we turn off the television before we go to bed at night, we encounter loudspeakers almost constantly. Even our computers have loudspeakers.

A general treatment of loudspeakers, including their history and design considerations, in order to fit within a single chapter of a book such as this, is limited to providing an overview of the subject rather than an in-depth treatment of design and theoretical considerations. We will touch on as many of the relevant areas as available space permits, while providing references for the reader who is interested in further study. This chapter may serve as an overview of the subject for end users and audio enthusiasts and as a guide to further study for those interested in performing loudspeaker design work themselves.

17.1.1 Uses of Loudspeakers

Even though there is a very wide range of applications for loudspeakers, they may be thought of as serving some combination of four primary purposes:

1. Communication.
2. Sound reinforcement.
3. Sound production.
4. Sound reproduction.

While there are common requirements for all of these uses, each one also imposes its own demands on loudspeaker attributes. In a given application, it is possible that more than one of these purposes must be served by a single loudspeaker. In such cases, the suitability of the loudspeaker for one or more of its uses may be compromised in order to facilitate others.

Communication. Ranging from intercom systems in offices and schools to radio communications systems for the space shuttle, voice communication systems make our everyday lives safer and more convenient. The first practical loudspeaker was in the earpiece of the original telephone. Since that time, loudspeakers have been an integral part of voice communication systems, from intercom systems to satellite-based telephone and conferencing systems.

Sound Reinforcement. In numerous situations involving public speaking and musical performance before audiences in halls, auditoriums, amphitheaters, and arenas, the sound created by the voices and/or musical instruments is not of sufficient loudness to be heard or understood satisfactorily by everyone present. In such situations, a sound reinforcement system can provide the acoustic gain required to overcome this deficiency.

Sound production. There are a number of subcategories of this type of loudspeaker usage. Perhaps the most readily recognizable is the use of amplification as an integral part of certain musical instruments—e.g., electric guitar, bass, and keyboards. Other examples include emergency warning and sonar systems. Loudspeaker characteristics may be very highly specialized when they are used as part of a sound production system, and loudspeakers optimized for this type of use are often not well suited to other uses.

Sound Reproduction. Playback of recorded music, motion picture soundtracks, and videotape requires a sound reproduction system. Almost every home in the United States has one or more sound reproduction systems. Movie theaters and recording studios also require sound reproduction systems. One of the author’s past design projects was a loudspeaker system for use in an international chain of large-screen specialty theaters.

17.1.2 Loudspeaker Components

It is useful to identify the component parts (or subsystems) of a loudspeaker for individual examination and analysis. For purposes of this chapter, the components of a loudspeaker are:

1. Transducer.
2. Radiator.
3. Enclosure.

We will examine various forms of each of these components in the sections that follow. Their interactions with each other within a loudspeaker will be discussed. We will also present concepts of loudspeaker performance characterization and an overview of electroacoustic models. The reader is encouraged to pursue the subject matter that is presented here through the references provided in the bibliography. The design and analysis of loudspeakers is a multidisciplinary field, incorporating elements of music, physics, electrical and mechanical engineering, and instrumentation. The individual subject areas are challenging and fascinating in
and of themselves, and their convergence in the field of loudspeaker design results in one of the most complex combinations of art and science that has ever existed.

17.2 Transducer Types

There are a number of ways in which electrical energy can be converted into acoustic energy. Of all the possibilities for carrying out this function, a relative few have become dominant in practical loudspeakers: electrodynamic, electrostatic, and piezoelectric. In general, an electroacoustic transducer contains three elements: motor, diaphragm, and suspension. The motor converts electrical energy into mechanical (motional) energy and the diaphragm converts mechanical energy into acoustic energy (vibration of the transmission medium, usually air). A suspension supports the diaphragm, allows it to move in an appropriately constrained fashion, exerts a restoring force proportional to displacement from its equilibrium position, and provides a damping force proportional to the velocity of motion that serves to prevent the diaphragm from oscillating in an undesired manner.

17.2.1 Electrodynamic Transducers

The most common type of transducer used in loudspeakers is the electrodynamic driver. In this type of transducer, a time-varying current passing through a conductive coil suspended in a time-invariant magnetic field creates a force on the coil and the parts to which it is attached. This force causes the parts to vibrate and to radiate sound.

There are a number of viable implementations of electrodynamic transducers. By far the most common is the cone driver. In a cone driver, a cone-shaped diaphragm is suspended at its outer periphery by a structure called a surround and (usually) near its center by a spider. The motor consists of a permanent magnet assembly that concentrates the magnetic field in an annular gap, in which is placed a voice coil that is attached to the center of the cone via a cylindrical coil former. An electrical signal is applied to the voice coil, and the current in the voice coil interacts with the magnetic field in the gap to create a time-varying force that vibrates the diaphragm. Fig. 17-1 shows a typical cone driver. The most commonly used magnetic material is ferrite, or ceramic. Other magnetic materials used in loudspeakers include aluminum/nickel/cobalt (alnico) and neodymium/iron/boron, (neodymium or neo). The magnet structure is typically held together with an anaerobic thermoset adhesive. Some loudspeakers are assembled with bolts through the magnet. In this case, stainless steel or brass screws must be used, so as not to magnetically short the top plate to the back plate. A rear cover may or may not be used. A vent through the pole piece may be provided. It serves to prevent the addition of a spring constant due to the small air cavity under the center cap (dust cover) and to reduce turbulence-induced noise due to pumping effects in the magnet gap.

17.2.2 Diaphragm Types

The most common direct-radiation device is the cylindrical voice coil–driven paper cone. The cheapest cone to make is the folded cone, which is cut from a sheet of paper, rolled, and bonded at the seam. A more expensive and difficult to make cone is the molded-paper cone. These are one piece, molded by straining a slurry of water and paper pulp through a strainer mold in the shape of the desired end product. The formed wet mat of pulp is then pressed and baked to remove residual moisture, bearing a dry, strong one-piece cone, free of joints. Ribs and concentric rings are sometimes molded into the cone, and the cones can be formed with straight or curved sides of varying depth. These are all available from suppliers of cones.

While most mathematical models of a direct radiator assume a rigid piston, in practice this is impossible to achieve. In some cases, diaphragm rigidity is intentionally reduced in order to produce specific desired behavior. Two examples involving a controlled breakup are shown in Figs. 17-2 and 17-3. The whizzer cone in Fig. 17-2 is intended to radiate high frequencies as the larger cone decouples from the motor. The Biflex principle, as popularized by Altec Lansing in the 1950s, is shown in Fig. 17-3. The inner cone is attached via a compliant element at A to the large outer cone in hopes of decoupling the outer cone at high frequencies.
Damping dope is applied to the coupling connection in an attempt to smooth the decoupling transition frequency response. While whizzer cones are still in use in some inexpensive ceiling speakers, there are at this time no devices similar to the Biflex on the market.

In addition to felted paper, a number of newer materials have found use in cone-type low- and medium-frequency loudspeakers. A variety of plastics have been used, the most popular being polypropylene and bextrene. The KEF Company introduced a composite aluminum-skinned foam-core sandwich cone. Community Professional Loudspeaker’s M4 compression midrange similarly uses a carbon fiber/epoxy composite diaphragm. Adamson Acoustics in Canada uses a Kevlar fabric resin-bonded diaphragm for the midrange driver. Mitsubishi Electric (Japan) introduced a studio monitor, which used cone woofers fabricated from a honeycomb core/carbon fiber skin composite.

In a loudspeaker with an alnico magnet, the magnet is directly under the pole piece (as opposed to being between the top and backplates), and the outside of the magnet structure is a cast iron return from the bottom of the magnet to the top plate. Venting may be accomplished via a hole covered with open wire mesh in the center dome. Other methods include a uniformly porous dome with no magnet vent, Fig. 17-4.

17.2.3 Suspension Methods

The suspension of a cone driver comprises two distinct components: the surround and the spider. The surround is attached to the periphery of the diaphragm or cone and is itself attached to the support structure (the basket in the case of a cone driver). The spider is attached to the voice coil former (or to the cone in the vicinity of the former) and is also attached to the basket on its periphery. Because they affect cabinet sealing, surrounds are designed to be nonporous. Surrounds and spiders both contribute to the damping of the motion of the diaphragm. The most popular surround construction is heat-formed, open-weave, resin-impregnated linen with formed-in convolutions and sealed with damping dope. Other surrounds are made of foam or butyl rubber formed in a half-roll. On some loudspeakers, a viscoelastic (never-drying) dope is applied to the surround.

Spiders are usually made of a heat-formed, open-weave, resin-impregnated cloth that is formed into convolutions. They are usually not treated with a sealing material (dope). The unsealed fabric is needed for venting, since the air beneath the spiders can otherwise be trapped. This also tends to damp the spider. An
early method of making porous spiders was to die-cut them from solid phenolic-impregnated linen sheet stock. The spider is not required to seal the edge of the cone to its enclosure as is the surround. In a typical cone driver, the spider contributes the majority of the stiffness in the suspension.

17.2.4 Mechanical Construction

The Peavey Black Widow bass drivers are unusual in that they have a streamlined magnet structure, called focused-field geometry, Fig. 17-5. It employs a magnetic circuit that has smoothly flowing flux lines, as might be intuitively preferred for a fluid flow channel. Other manufacturers have adopted similar approaches to magnet design. An added benefit of this approach is minimization of weight.

JBL ferrite-magnet drivers have symmetric field geometry. Fig. 17-6 shows the top plate configuration, which makes the magnetic leakage flux at the top and bottom of the gap symmetric, thereby, according to the manufacturer, reducing magnetic drive asymmetry and the resulting low-frequency distortion.

Another form of electrodynamic transducer is the dome radiator. Most commonly used for high frequencies, dome radiators have the advantages of compactness and predictability of acoustic behavior. Domes can be made from linen, impregnated phenolic fabric, Mylar™, paper, aluminum, titanium, beryllium, and composites such as carbon fiber/epoxy. Soft dome tweeters have been in widespread use for a number of years. Some of this popularity may be due to the fact that there is no abrupt transition from piston radiation to breakup. Instead, most of the radiation from a soft dome comes from the region immediately adjacent to the voice coil, making it function as a ring radiator.

Several flexible diaphragms have been used on magnetic drivers, all sharing the same basic construction: etched aluminum conductors on Mylar™ film. These are operated in various magnetic field configurations to produce sound. One of the earliest of these is the Magneplanar® loudspeaker, which consisted of an entire field of magnets over which the diaphragm conductor was mounted. Magneplanars are in the shape of large panels. The Heil high-frequency driver, used in systems manufactured by ESS, used direct radiators similar to Magneplanar® in that the voice coil was printed on Mylar™. The ESS-Heil unit, however, was corrugated, and the sound was produced by these vertical pleats moving open and closed, thereby squeezing air into radiated sound. An extension of this was used also by ESS in the Transar system, which used hollow spheres modulated by electromagnetically driven rods. Mitsubishi Electric (Japan) developed a printed conductor high-frequency device called the leaf tweeter, as shown in Fig. 17-7. The ribbon loudspeaker is the simplest and has excellent potential for good high-frequency response due to the fact that the diaphragm is the conductor. No extra diaphragm structure is used on the ribbon.

17.3 Compression Drivers

One means of improving the performance of an electrodynamic transducer that will be used to drive a horn is to create a compression driver. In a compression driver, the diaphragm radiates into a compression chamber and its output is typically directed through a phasing plug to the driver’s exit, which is attached to the throat of the horn.

The advantage of a compression driver is that relatively small diaphragm velocities are converted to larger particle velocities at the exit of the driver. The effect of this transformation is that less diaphragm excursion is required for a given acoustic power output. The tradeoffs
for this coupling include possible increases in certain distortion components and the requirement for a horn. Compression drivers are not used as direct radiators.

The purpose of the phasing plug is to equalize path lengths from the diaphragm surface to the exit. To the extent that this is accomplished, the useful bandwidth of the driver will be extended upward in frequency.

Fig. 17-8 is a cross-sectional view of a typical ceramic-magnet wide-range compression driver using a dome diaphragm. The case construction is unusual and peculiar to this design by Yamaha. The phase plug is also a bit unusual; however, it is still of the circumferential-slit variety on the phase plug (dome) surface. The diaphragm is aluminum and is supported by a typical Bakelite™ or plastic support frame. The back cap has sound-absorbing material inside to discourage interfering air resonances in the cap.

Fig. 17-9 shows a 2 inch throat JBL driver, model 2440, using an alnico magnet. The phase plug is more typical than that in Fig. 17-8, using more straight through circumferential slits. The JBL plug is made of cast Bakelite.

Fig. 17-10 shows another alnico driver, the 1 inch Altec 802/808. The 802 uses an all-aluminum diaphragm with tangential surround coupled via the phase plug and expanding throat section to a 1 inch diameter exit. The 808 is identical to the 802 in all respects except for the diaphragm. From left to right in the exploded view are the pot, the alnico magnet slug that fits under the pole piece, in which is mounted on a radial-slit tangerine phase plug. This unusual design is made from glass fiber–filled plastic and is bonded to the pole piece. Above this (to the right) is the ring that centers the pole piece in the air gap via the top plate. It is nonmagnetic (brass), and the holes provide a mechanical load on the voice coil, which affects response and distortion. Next are the diaphragm assembly and rear cap.

The preceding three examples are representative of dome diaphragm compression driver design practices, both in concept and in practical implementation.

A large number of variations exist in the art including a wide variety of suspension shapes and materials. Domes are made from aluminum, titanium, and beryllium. Yamaha International Corp. makes its suspension
out of stamped beryllium-copper cantilever fingers, and JBL and Ramsa stiffen their suspensions with rhombic and diamond patterns, respectively; this is actually a redistribution of diaphragm breakup resonances.

Midrange compression drivers are useful where there is a requirement to supply very high levels of acoustic power with low distortion. Community Professional Loudspeakers, M4 midrange driver is shown in Figs. 17-11 and 17-12. It is intended for use from 200 Hz to 2000 Hz. The diaphragm is approximately 7 inches in diameter. Originally it was fabricated from specially formed aluminum skins and a light, stiff foam core, about 0.090 inch thick. More recent versions had diaphragms made of a carbon fiber composite.

Another compression driver configuration is the screw-on driver. The University 7110XC (explosion proof) is shown in Fig. 17-13. This type of unit is often used on a reentrant horn in public address systems.

Throat diameter is usually ¾ inch. Diaphragms are most often made of phenolic resin-impregnated domes with integral convoluted suspensions. Voice coils are usually round copper wire.

17.4 Electrostatic Transducers

Electrostatic transducers make use of the fact that two static electrical charges placed at a distance from each other will experience a force directed along a line between them. The force is attractive if the charges have the opposite sign (positive and negative) and repulsive if the charges have the same sign (positive and positive or negative and negative). In practical loudspeaker designs, the forces are attractive, due to the complementary nature of the charge transfer from the amplifier output to the speaker plates. The magnitude of the force is inversely proportional to the distance between the charges and directly proportional to the magnitude of the charges.

A typical electrostatic loudspeaker consists of a diaphragm made of two pieces of metallic foil separated by a sheet of dielectric, or nonconductive, material. By itself, the application of a pure ac signal (i.e., one with no dc component) to an electrostatic loudspeaker would cause attractive forces for both positive- and negative-going signal excursions, since the induced charges are opposite in both cases. This would create a frequency-doubled signal containing extremely high levels of harmonic distortion.

For this reason, a dc polarizing voltage is applied to the foil diaphragms, maintaining a steady attraction between them. The audio (ac) signal is superimposed on this dc offset, modulating the attractive force. In
response to this modulated force, the diaphragms to move opposite (toward or away from) each other. The upper limit on the amplitude of the allowed signal voltage is then equal to half the polarization voltage. This arrangement is the basis of all modern electrostatic loudspeakers. The result is an acceptably low level of harmonic distortion, as long as variations in the distance between plates or the diaphragms are minimized. The movement of the foil diaphragms generates sound waves. The diaphragms produce equal acoustical power radiated in opposite directions. This set of characteristics defines a dipole radiator.

It is asserted by the designers of electrostatic loudspeakers that they overcome certain basic disadvantages of cone-type loudspeakers, particularly with respect to the propagation of acoustic energy at the high frequencies. Cone-type loudspeakers are driven by a voice coil that is attached to a relatively small portion of the total diaphragm area, and they do not behave as pistons at higher frequencies. Because the electrostatic loudspeaker has a diaphragm that is driven uniformly across its surface, breakup is said to be eliminated. Additionally, the diaphragm can have low mass compared to the air load on the diaphragm. This enhances high-frequency and transient response.

Electrostatic loudspeakers may be constructed in several different ways. Two of the most common construction types are:

1. Stretching the diaphragm between supports around its periphery and leaving an air gap between the diaphragm and two stationary electrodes, Fig. 17-14.

2. Using an inert diaphragm that is supported by a large number of tiny elements disposed across the entire surfaces of the two electrodes. These elements act as spacers to hold the diaphragm in the center between the electrodes, Fig. 17-15.

In the latter type of loudspeaker, the diaphragm is a thin sheet of plastic on which has been deposited a very thin layer of conductive material. It is supported by multiple small elastic elements that hold the diaphragm in place but permit it to follow audio-signal waveforms. The electrodes on each side of the diaphragm are acoustically transparent to avoid pressure effects from trapped air as well as to permit acoustic energy to propagate away from the diaphragm. This type of construction permits the diaphragm to be of arbitrary size. The performance per unit area is the same for any area of the diaphragm. The actual loudspeaker is a thin surface curved in the horizontal, forming a section of a cylinder.
by the stiffness of the diaphragm suspension. Measurements indicate that for a constant voltage applied to the electrodes, the acoustic response is uniform (flat) to well beyond the range of human hearing.

Output at low frequencies is limited by the maximum linear amplitude of the diaphragm motion, which is determined by spacing between the diaphragms and damping in the suspension. The maximum power output from an electrostatic loudspeaker of a given diaphragm area is determined by the strength of the electrostatic field that can be produced between the diaphragm and the electrodes.

An electrostatic loudspeaker is seen by an amplifier as a capacitor with a value on the order of 0.0025 μF from electrode to electrode. Thus, the magnitude of the impedance presented by the loudspeaker to the output of the amplifier falls off at 6 dB per octave as the frequency is increased. This presents some problems for driving electrostatics, as many amplifiers are not designed to drive purely capacitive loads.

Because electrostatic loudspeakers are relatively large in area compared to cones, their directivity is high in comparison to cone systems. Various schemes have been used by designers of electrostatics to address this issue. The Quad ESL63 is one example. Here, the diaphragm is broken into different regions for different frequency ranges, the smaller ones being used for higher frequencies, thereby making them wider in dispersion than a large single panel.

17.5 Piezoelectric Loudspeakers

Piezolectricity, or pressure electricity, was discovered in the 1880s by the Curies. It is today a feasible motor drive mechanism for loudspeakers. In a piezoelectric material, a voltage applied to the material will result in a mechanical strain or deflection. The reverse is also true, material (PZT) is now highly refined and exhibits the best properties of any piezo material for loudspeaker use.

Piezoelectricity came from Tamura and coworkers in their work on piezoelectric high-polymer films. This concept of a diaphragm possessing piezoelectric properties and thus coupling directly to the air without the use of any separate motor structure represents a substantial advancement toward the ideal acoustic transducer.

Another problem area in the development of the PZT loudspeaker was in the power-handling capability of the driver. The theoretical failure mode of a piezoelectric tweeter is the depolarizing of the driver through excessive drive level and/or high temperature. The Curie point (depolarizing temperature) of the PZT used here is above 150°C, and the depolarizing voltage is 10 V/25 μm thickness, or about 35 Vrms for the basic driver. These numbers describe a fairly impressive power-handling capability, but unfortunately one that is
reached only in theory. In reality, under continuous high drive levels, mechanical stress on the surface of the ceramic wafers generates cracks in the microstructure that eventually penetrate the entire wafer. This is especially severe around the area where solder connections are made to the wafers, since the soldering operation tends to prestress the material at this point. The net result is that the 35 V maximum drive level is an intermittent specification, with the continuous drive level recommended at a 15 V maximum up to 20 kHz. For use above that frequency, it has been recommended that the level be reduced further through the addition of a series attenuation resistor so as to safeguard the ceramic element from absorbing excessive high-frequency power. Here again, when using larger, thinner ceramic wafers, these problems are further aggravated. Using this ceramic is an area for future development.

Fig. 17-17 shows the Motorola KSN 1001A. Although Motorola manufactures a wide variety of other piezo-driven loudspeakers, the one illustrated here is the most widely used.

One near-optimal application of piezoelectric drive is underwater use. This is due to the excellent impedance match of the piezoelectric material to water via a waterproof barrier. Lubell Labs manufactures the underwater loudspeaker shown in Fig. 17-18. Although swimming pool loudspeakers using standard electromagnetic drivers are also available, the piezoelectric configuration is more efficient due to its mechanical impedance match to water. The loudspeaker is fixed to the side of the pool and driven like a conventional loudspeaker. Lubell Labs makes high-power arrays of these devices and a portable swim coach system with a noise-canceling microphone for underwater communications in various pool athletic events.

**17.6 Motor Design Considerations**

The most common means of coupling amplifier output to the diaphragm in an electrodynamic transducer is via a cylindrical voice coil. This configuration is used on all magnetic cone loudspeakers and compression drivers. This is commonly known as a linear motor. The coil, made of round or rectangular wire (edgewound), is wound around a hollow cylinder called a **former**. Formers may be made of paper, plastic (e.g., Kapton polymer, Mylar™), or aluminum. The voice coil assembly is bonded to the diaphragm. Fig. 17-19 shows the construction of a typical cone loudspeaker.

One novel approach to motor design involves printing or etching a conductor onto a thin sheet of Mylar™ (0.0005 inch) then folding it to produce and
pleated diaphragm that is forced in the magnetic field. In another implementation, continuous lengths of wire are bonded to a large panel of Mylar™, which is operated over a field of bar magnets. The leaf tweeter is similar, etching a conductor field on Mylar™. They are identical in principle to Fig. 17-19 and are discussed more thoroughly elsewhere in this text. The ribbon loudspeaker, Fig. 17-20, is a special case in which the voice coil serves as both conductor and diaphragm.

One notable departure from conventional linear motor design is the Servo-Drive loudspeaker. This patented drive system uses a rotary servomotor that drives a woofer cone and suspension assemblies via a pulley-belt mechanism, alternately pushing and pulling the diaphragms in response to the input signal. Two opposing diaphragms are driven in a push-pull arrangement so as to yield a balanced axial force on the drive mechanism. The motor is configured so that it presents a typical impedance load to an amplifier. SDL (for servo-drive loudspeakers) speakers come in a variety of sizes and power capacities, but typically they are in the form of low-frequency horns. Fig. 17-21 shows the mechanism employed to translate rotational motion of the servomotor to the linear motion needed to drive the opposing diaphragm assemblies. The opposing reinforced blastomeric belt mechanisms are used in the rotation-to-linear conversion, and the result is noiseless and free of slip. The opposing diaphragms drive the throats of conventional wood-fabricated folded bass horns. The positions of the diaphragms are shown in Fig. 17-22. Fig. 17-23 shows the positioning of the servo-driven diaphragms in a typical folded bass horn.

17.6.1 Output Limitations

The maximum usable output of an electromagnetic loudspeaker is a function of a number of parameters, including diaphragm displacement, heat transfer, sound quality (maximum acceptable nonlinearity), and/or wear life due to fatigue of moving parts.

There are two fundamental limitations on a magnetic driver, a displacement limit and a thermal limit. Displacement limits may be caused by either mechanical or electrical factors. Mechanical displacement limiting occurs when a moving part contacts a
stationary one or when a suspension element is made unacceptably nonlinear (either temporarily or permanently) by deformation beyond its design range. Electrical displacement limiting occurs when the motor is operated outside its range of linear travel. This is a function of the length of the windings on the voice coil and the thickness of the plates that form the magnet gap. Fig. 17-24 shows three typical voice coil configurations: equal length, overhung, and underhung coils.

When any of these coils reaches a displacement that causes a reduction in the current sensitivity of the motor, higher distortion will result.

It has been empirically determined that, due to a magnetic fringe or leakage field at the pole tips, an excursion of 15% farther than the gap length results in a reasonable distortion level (approximately 3% harmonic distortion at low frequencies). The equal length voice coil, Fig. 17-24C, has the greatest potential for motor-generated distortion. However, it also yields the highest motor strength (the greatest total conductive mass in the highest density magnetic field). The equal length voice coil is a common configuration for compression drivers, where maximum excursion is intrinsically low. The underhung coil, Fig. 17-24B, allows greater excursion but requires a larger magnet due to the longer gap. For moderate flux density levels (10,000 to 15,000 G), this design, as compared to the equal length design, requires approximately twice the magnet weight (twice the area and the same length) for a doubling of the gap length. This approximately doubles the excursion capacity, giving four times the acoustic power output capability (6 dB) for a doubling of magnetic weight (3 dB). The overhung coil, Fig. 17-24A, is capable of the greatest motor linearity, all else being equal. It is commonly seen on woofers used as direct radiators, where higher excursion is required. The major disadvantage here is that the coil that is not in the gap does not participate in transduction. The extra coil length does add both mass and dc resistance, however, reducing motor efficiency. In spite of this, there are numerous examples of successful commercial woofers using overhung coils. The transducer designer must take into account the often conflicting demands of high-efficiency, high-output, and low-frequency extension to arrive at an optimum design for a given range of applications.

The thermal limit of a magnetic loudspeaker motor is a function of the temperature limits of the materials used and heat transfer from the coil assembly to the outside world. Most adhesives used in the loudspeaker industry have an upper limit between 120°C and 177°C (250°F and 350°F). Some epoxy adhesives will tolerate higher temperatures, but they can require special curing processes and are therefore potentially more difficult to use. Wiring insulation may tolerate temperatures as high as 218°C (425°F). Anodized aluminum wire has the melting point of aluminum as a limit. Voice coils operated at high temperatures have higher resistance. A 1°C rise produces approximately a 0.4% rise in dc resistance in both copper and aluminum. Therefore, operating a voice coil 100°C above ambient (127°C or 261°F) will
cause the voice coil resistance to increase to 40% above its ambient value. The following equation give voice coil resistance at any temperature in degrees Celsius

\[ R_T = R_o + 0.004(T - T_o) \]  

(17-1)

where,

- \( R_T \) is the resistance at temperature \( T \) in ohms,
- \( R_o \) is the resistance at ambient temperature \( T_o \) in ohms,
- \( T \) and \( T_o \) have units of °C.

The operating temperature of the voice coil, \( T_{VC} \), is determined by ambient temperature, the amount of power being dissipated in the coil, and a parameter called thermal resistance, expressed in degrees Celsius per watt, °C/W. The thermal resistance is a measure of the ability of an object to transfer heat away from itself. The lower the value of the thermal resistance, the more effective the object is at this transfer. As power is doubled, final temperature rise above ambient is doubled. Heat transfer in a loudspeaker is a function of the air gap design, voice coil design, and the ability of the loudspeaker frame and magnet to dissipate heat to the surrounding or ambient air. Referring to Fig. 17-25, the thermal rise \( T_{VC} \) of a stationary voice coil in an air gap is

\[ \Delta T_{VC} = T_{VC} - T_s = \frac{QL}{A_TK} \]  

(17-2)

where,

- \( T_{VC} \) is the temperature of the voice coil in °C,
- \( T_s \) is the temperature of structure (magnet) in °C,
- \( Q \) is the electrical heating power \((IR)\) in watts,
- \( L \) is the effective air gap length in inches,
- \( A_T \) is the total gap area in square inches exposed to the voice coil,
- \( K \) is the conductivity of air or \( 7 \times 10^{-4} \) W/°C.

As the air gap length is decreased and the area increased, heat transfer increases (or, equivalently, thermal resistance decreases). Making the voice coil former of aluminum will increase effective heat transfer area; the thicker the aluminum, the greater the effect. Voice coils wound on aluminum formers with large diameters in magnets with large gap areas and very tight coil to gap tolerances are capable of handling high electrical power due to good heat transfer in the air gap. In short, large, accurately constructed loudspeakers can usually handle more power. As the loudspeaker moves, it may be able to pump the air in the gap to improve heat. The loudspeaker designer may be able to exploit this behavior. Given voice coils of the same length, the underhung and equal-length configurations will have greater heat transfer capacity. The overhung coil would only conduct heat well in the gap region, while the coil ends remaining out of the gap would be more likely to suffer damage at high power level because of relatively poor heat transfer. Typical thermal behavior for most coils is on the order of 0.5°C/W to 3°C/W input.

A heat-conducting magnetic liquid may be used to improve heat transfer. Known as ferrofluids, these fluids will be retained in a magnetic air gap due to magnetic attraction. Their thermal conductivity is seven to ten times higher than that of air. Since ferrofluid alters the mechanical damping of the moving assembly, its use has implications for the design of the motor assembly. There are also issues related to compatibility of ferrofluid with adhesives and materials used in the construction of a transducer. For these reasons, ferrofluids should generally be designed into a loudspeaker, rather than added on.

Temperature rise in voice coils is not instantaneous. It is directly related to mass. As one might suspect, light voice coils have short thermal rise times, and vice versa. The thermal time constant of a loudspeaker coil (the time required for the coil to reach 63% of its final value) is given by:

\[ t = MC \frac{\Delta T}{Q} = MC \frac{L}{A_TK} \]  

(17-3)

where,

- \( t \) is the time constant in seconds,
- \( M \) is the mass of the coil,
- \( C \) is the specific heat of voice coil material in joules per gram in degrees Celsius,
- \( \Delta T/Q \) is the thermal resistance in degrees Celsius per watt.
For example, a typical copper woofer voice coil has a mass of 24 g and a gap heat transfer coefficient (thermal resistance) of 1°C/W. Copper has a specific heat of 0.092 cal/g°C or 0.0220 J/g°C. Therefore, using Eq. 17-3, \( t = 0.528 \) s. This is a typical voice coil response time. An aluminum coil will typically have a shorter thermal time constant.

The time constant of the magnetic structure and frame can be on the order of hours. For this reason, long duration power tests are required to evaluate the maximum power tolerance of transducers. Initially, the voice coil might be at 280°F (137°C), but over the course of 2 hours, the mechanical structure (typical 1 to 3°C/W) could rise another 200°F to 300°F (100°C to 150°C), bringing the voice coil well over the thermal limit of its materials and adhesives. Heat transfer from the frame and magnet to the air is another important consideration. Although the rise time is large, the final temperature may vary greatly due to the enclosure. A vented enclosure with vents at the top and bottom with no fiberglass insulation might provide adequate ventilation for a hot loudspeaker. The same loudspeaker in a closed box stuffed with fiberglass might be subject to a dangerously high temperature rise. Attention to this final thermal path is warranted in applications that will demand maximum output from enclosed loudspeakers.

The efficiency of a loudspeaker has a direct bearing on the thermal load it must withstand for a given acoustic output level. The more efficient the loudspeaker, the lower the self-heating for a given output level; all else being equal, a loudspeaker with 3 dB higher overall sensitivity for a given impedance will experience one-half the thermal load for a desired output level.

In concert touring use, loudspeakers are routinely operated at and even beyond their design limits. Given that a loudspeaker that operates at twice its voice coil resistance due to heating will be 6 dB less sensitive, sound quality can vary greatly over the course of a performance. In failure situations, the nature of the input signal will usually determine the type of failure mode. Thermal failure can be precipitated by compressed high-frequency content material (low dynamic range). Mechanical failure is often due to dynamic, percussive material, such as might occur in a recording studio with drum channels set to solo, as well as other signals that do not limit dynamic range. Another cause of mechanical failure, most often in high-frequency transducers, is the application of a highly clipped signal that has been passed through a high-pass filter. Such a signal will contain a peak-to-peak voltage that is twice that of the input signal. This phenomenon is illustrated in the section on crossovers.

### 17.6.2 Heat Transfer Designs for High-Power Woofers

Of all the components in a sound reinforcement system, more heat is generated in low-frequency devices than in any other. While high-frequency horn driver combinations deliver 110–117 dB/1 W/1 m and midrange devices deliver 100–110 dB, woofers rarely exceed 100 dB. A typical woofer in a vented enclosure is in the 94–97 dB/1 W/1 m range. These devices are typically 2–8% efficient. The remaining 92–93% of the power goes directly into producing heat. Adding to the problem is the fact that much modern program material is bass-heavy.

As understanding of heat transfer mechanisms in loudspeakers grew, designs appeared that improved heat transfer from the voice coil and gave improved thermal power handling ratings, Fig. 17-26.

The heat transfer methods discussed here are simply methods to transfer heat away from the voice coil. If there were no heat transfer paths out of the magnetic circuit, the speaker’s temperature would continue to rise without limit. In the cases of drivers on exposed horns, natural convection transfers sufficient thermal energy to prevent overheating. The thermal resistance of the direct convection transfer path is on the order of 1–2°C/W. In the case of a woofer in a fiberglass-lined enclosure, this resistance may be five times greater. Heat buildup can be substantial. This mechanism is often ignored. Several proprietary loudspeaker systems have been developed in an attempt to address this problem, but most sound reinforcement systems still provide no designed-in mechanism for transferring heat out of the enclosures.

### 17.7 Radiator Types

In addition to converting electrical energy to mechanical energy, a loudspeaker must include a means for converting mechanical energy (e.g., the motion of a diaphragm) into acoustic energy. For purposes of this chapter, the various means for accomplishing this final conversion are referred to as radiators. While there is overlap in our definition of the terms transducer and radiator, it is extremely useful in understanding loudspeakers to consider the function of acoustic radiation as a separate subject from electroacoustic conversion. In general, there are two broad types of radiators: direct radiators and horn radiators.
17.7.1 Direct Radiators

The simplest form of radiator is the direct radiator, in which the diaphragm is directly coupled to the air. Most hi-fi loudspeakers consist of combinations of different sizes of direct radiators. Various forms of direct radiators were described in the previous section. In this section, we will outline their acoustic attributes.

17.7.2 Cone Radiators

In a cone radiator, the diaphragm is in the shape of a truncated cone. The concave surface of the cone is usually, but not always, the one which radiates sound. The cone shape is partially dictated by expediency: it allows the magnet structure to reside at the rear of the transducer assembly, while at the same time allowing for the use of a spider and a surround to suspend the diaphragm. This dual-element suspension provides positive centering of the voice coil in the magnet gap, and it helps constrain the motion of the cone to the desired linear path.

The above notwithstanding, there are also acoustic motivations tend to favor the cone shape. At first glance, one might expect a flat piston to offer superior on-axis response and directivity to a cone. A cone shape is generally preferable, however, when the excitation will be applied near the center of the diaphragm. Due to the fact that sound propagates at a finite velocity in a solid, the motion of the outer portion of the diaphragm will follow the initial excitation by some amount of time. If the diaphragm were flat, radiation from the outer portions of its surface would arrive at an on-axis observation point at later times than radiation from the center. The cone shape reduces the distance must be traveled by sound radiated from the outer portions to on-axis listening positions. Since the velocity of sound in the cone material is typically greater than the velocity of sound in air, a cone shape having the optimum included angle will tend to synchronize on-axis radiation from the outer portions of the diaphragm with that from near the center. Given a judicious choice of angle, the useful range of response of a cone transducer can be extended to a significantly higher frequency than would otherwise have been the case.

17.7.3 Dome Radiators

Another variant on the direct radiator theme is the dome radiator. Most often, this radiator takes the form of a convex dome driven and suspended at its periphery. The material used to form the dome may be soft, as is the

Figure 17-26. Various coil/gap geometries showing the evolution of heat transfer designs in modern woofers.
case with coated synthetic textiles, or hard, in the case of metals or composite materials (e.g., carbon fiber/epoxy). Dome radiators are most popular for high-frequency elements, although a number of dome-shaped midrange elements are also available. As with the cone radiator, the convex shape of the typical dome radiator has acoustic motivations. Since the excitation is at the edge, the dome’s mechanical motion will propagate inward. As a result, if the shape were flat, radiation from the inner portion would arrive at an on-axis observation point later than radiation from the edge. The convex shape helps deliver a more coherent wavefront to an on-axis listening position. It is common practice to suspend a small round cover just in front of the center of the dome.

17.7.4 Ring Radiators

Yet another form of direct radiator is the ring radiator. In a typical ring radiator, a flexible ring-shaped diaphragm is rigidly captured along its inner and outer circumferences and driven along a concentric circular line between those two circles. There is, then, no distinction between the diaphragm and the suspension, as a single part fills both functions. A dome tweeter with a cover over the center of the dome functions as a ring radiator. Ring radiators can also be used to drive short horns. The JBL 075 Bullet is an example of a ring radiator. Intended for use above 7 kHz, the diaphragm is a V-shaped ring of aluminum attached to a voice coil and former.

Fig. 17-27 shows a ceramic version of the ring, which is made by Yamaha. The phase plug is a simple slit ending in a large enough mouth to project the desired low end of the driver. The suspension is the diaphragm itself, and it is quite stiff. Ring radiators are typically operated in or above the principal resonance frequency of the diaphragm assembly.

17.7.5 Panel Radiators

Both electrostatic and planar electrodynamic speakers fall into this category. As with the ring radiator, there is a mixing of functionality between the diaphragm and the suspension. The acoustic advantage, at least in principle, of a panel radiator, is that the driving force is applied uniformly over a large portion of the diaphragm. For this reason, diaphragm rigidity is not an essential design element, as is the case with cone radiators. An interesting characteristic of a large panel radiator is that it will essentially project a shadow of its shape as a listening pattern; this shadow of the speaker’s radiation pattern will take up a large part of a typical listening area, particularly at close listening distances. This is claimed to produce a wider “sweet spot” compared to conventional cone systems.

17.7.6 Horns

Horns are used to increase the efficiency of a transducer and to control the directivity of the sound that is radiated. Horns are characterized by a number of parameters. The earliest approach to a predictive model, and the one still employed in acoustics texts, is characterization by the rate of increase of cross-sectional area with longitudinal position in the horn. Other means of characterization are related to the shapes formed by the horn walls.

Of all possible expansion (or flare) rates, a relative few have found use in horn design and analysis. Those most commonly encountered are exponential, hyperbolic, conic, and catenary. In general, the change of cross-sectional area with position in a horn can be expressed as

$$ A(x) = F(x) $$  \hspace{1cm} (17-4)

where,

- \( A(x) \) is the cross-sectional area at a point \( x \) along the axis of the horn, 
- \( F(x) \) is some function of \( x \).

For example, in an exponential horn,

$$ A(x) = A_0 e^{mx} $$  \hspace{1cm} (17-5)

where

- \( A_0 \) is the area of the horn at its throat or entry, 
- \( m \) is a constant called the flare rate.
Much more detailed information is available on the subject of the acoustic characteristics resulting from different rates of expansion from the sources cited in the Bibliography. The models are useful in analyzing the propagation of acoustic energy within a horn, but other considerations become dominant in determining the nature of the radiated sound beyond a horn’s mouth.

For this reason, practical horns have come to be known more by salient details of their sidewall shapes than by their flare rates. The more common types are described below.

17.7.6.1 Radial Horns

Radial (or sectoral) horns were claimed to allow a natural radial expansion of the sound wave from the driver, while maintaining an exponential expansion rate. Typically, a radial horn has straight horizontal sides and top and bottom walls that are in the form of spherical sectors. The design approach employed for a radial horn involves positioning the sides at approximately the desired angle for horizontal coverage. Given the area expansion desired, the top and bottom surfaces are then derived mathematically. The most popular materials used in making radial horns are cast aluminum (now relatively uncommon), molded plastic, laminated glass fiber, and polyester resin. This type of horn was in widespread use from the 1930s until approximately the mid-1980s, by which time constant directivity types had become more popular.

Fig. 17-28 is an Altec 311-60; it has a 60° horizontal coverage and is intended for use above 300 Hz, using a 1.4 inch driver. Altec was well known for this design, with its characteristic vertical vanes at the mouth of the horn.

17.7.6.2 Multicell Horns

Multicell horns were the first horns to be employed specifically for their directivity control attributes. The design approach was straightforward — several small horns were affixed together in an array, with each horn to supply a portion of the total coverage angle. These small horns were connected to a common manifold so that a single driver could power them, Fig. 17-29. Multicell horns first came into use in the late 1930s. They were originally made of sheet metal soldered together and either filled on the outside with sand or covered with a mechanical damping material.

17.7.6.3 Controlled Directivity Horns

The first constant directivity type of horn appeared in 1975. Developed by Electro-Voice, they employed a hyperbolic-flare throat section coupled to a conical radial bell section, as shown in Fig. 17-30. This horn shape yielded good low-frequency loading and relatively constant angular beamwidth in both vertical and horizontal directions over a wide frequency range. At the time, its design represented a major departure from previous thinking. Don Keele, the designer of the horns, presented an AES paper (“What’s So Sacred about Exponential Horns”). In the paper, he disclosed several empirically developed relationships between mouth size, frequency, and maintenance of coverage angle. The concept of a waveguide as applied to an acoustic...
radiator was used as the basis for predicting and controlling the directivity of a horn.

Keele’s paper and horn designs provided impetus for further empirical investigations of controlled directivity horns. Altec Lansing, at that time a competitor of Electro-Voice, introduced a family of horns using a narrow, vertical diffraction slot located at an intermediate point in the horn. With the appropriate choice of location for this slot, it is possible to make a horn with any desired combination of sidewall angles and aspect ratio (relationship between the height and width of the mouth).

This family of devices was dubbed “Manta-Ray,” and a number of designs based on this thinking were introduced over the ensuing years, Fig. 17-31.

Another approach to achieving the goal of frequency-independent directivity was represented in the JBL biradial family of horn designs. Also developed by Don Keele, who had by then taken an engineering position with JBL, the biradial shape employs continuously varying flanges in both directions, ending in a continuous horn. The vertical diffraction slot was retained. An exponential expansion rate was part of the design, and vertical and horizontal radial bell shapes (thus the term biradial) were employed. Three biradial horns are shown in Fig. 17-32. They are fabricated from cast aluminum (throat section) and molded fiberglass (bell section) and fit 2 inch exit drivers.

17.7.6.4 Voice Warning Horns

Fig. 17-33 shows another variety of controlled directivity horn, designed by Bruce Howze of Community Professional Loudspeakers, and originally built for Whelen Engineering. The horn used a slightly different directivity control philosophy: a controlled horizontal pattern (45° and a narrow vertical pattern), due to the

17.7.6.5 Asymmetric Directivity Horns

As the ability to determine the optimum loudspeaker directivity requirements for specific applications was refined, it became apparent that the required directivity was usually not symmetrical about a horizontal plane through the axis of the horn. From the point of view of
the loudspeaker, it is most common for the required horizontal coverage to be relatively narrow at the greatest distance from the source and to become successively wider at closer distances. In addition, it is desirable for the vertical angle of greatest intensity to be as large as possible — i.e., for greater energy to be directed to the seats at the greatest distance from the loudspeaker in order to produce similar SPL values throughout the audience. One early attempt to address this requirement was the JBL 4660, shown in Fig. 17-34.

Another design, developed for a specific application, is the IMAX® PPS (Proportional Point Source) loudspeaker, developed by the author. Fig. 17-35 is the high-frequency horn used in this loudspeaker, and Figure 17-36 is its 4 kHz isobar.

Dave Gunness, chief engineer at Electro-Voice at the time, developed a family of asymmetric directivity horns in the late 1980s and early 1990s. These were known as Vari-Intense devices.

Optimized (asymmetric) directivity is an attractive engineering goal, but there are a number of obstacles to its widespread acceptance:

1. Computer-based sound system prediction software is required in order to visualize its effectiveness and optimize aiming and device placement,

2. Exactly what constitutes ideal directivity is a strong function of the space in which the device is to be used. The ideal directivity will vary, for example, for different loudspeaker elevations within the same space.

3. With the exception of the proprietary IMAX loudspeaker, there are currently only high-frequency devices available with this type of directivity. Achieving uniform sound pressure levels throughout the seating, but at high frequencies only, is of limited value.

17.7.6.6 Acoustic Lenses

Although an acoustic lens is not generally regarded as a directivity control device, it can function as a directivity alteration device. While acoustic lenses are used to widen a pattern, they can also be used to narrow a horn’s directivity. An acoustic lens is usually formed with parallel plates of strategically chosen shapes placed at an angle to the direction of sound propagation. Differing path lengths through different portions of the lens create arrival time relationships for the associated components of the wave that generate specific directivity characteristics.

The slant-plate lens assembly, shown mounted on a JBL studio monitor in Fig. 17-37, is one notable implementation of an acoustic lens. Note that the device has concave openings in the plate array. As the wave leaves the horn and progresses through the lens plate array, the center of the wave reaches the air on the outside first, due to the shorter path through the lens. The outer portions of the wave travel through longer paths within the lens and are therefore delayed in time relative to the portions that came from the center. The net effect is to produce arrivals that are better synchronized—and therefore stronger—at positions that are off axis in the horizontal, thus widening the polar pattern in that direction. The vertical pattern would ideally be unaltered. Lenses have the undesirable property of causing relatively strong reflections back into the horn.

17.7.6.7 Folded Horns

One of the practical drawbacks of horns, particularly those intended for use at low frequencies, is their physical size. Folded horns were developed in response to this problem and have been in use in various forms for more than half a century. A folded horn is produced by truncating the shape at point, providing a reflecting surface to change the direction of the outgoing wave, and continuing the horn’s expansion in another direction,
usually opposite the prior one. Successive horn sections are typically positioned outside their predecessors. As many reversals are generated as are necessary to create the desired path length and mouth size. There are, as with other horn types, many variations on folded horns.

Fig. 17-38 shows a University Sound GH directional trumpet cross section and how the area expands by making two 180° turns. The design was introduced in the 1940s. Another University folded public address horn design is the cast zinc Cobreflex, shown disassembled in Fig. 17-39. This horn expands into a double mouth.

One of the most recognizable low-frequency horns is the Klipschorn, shown in Fig. 17-40. It was named for its inventor, Paul Klipsch, who was one of the pioneers in horn loudspeaker design. The Klipschorn uses a single 15 inch loudspeaker in a relatively compact package. It is designed for placement in a corner of the room, with the room’s walls forming an extension of the horn shape.

The Cerwin-Vega E horn is another form of folded bass horn. An 18 inch low-frequency driver sits between the upper and lower mouths and faces to the
rear in a compression chamber. The E horn makes one 180° fold that opens to the double mouths. The horn is intended for use with additional mouth extensions and in multiples for low-frequency coupling.

The W horn is another folded bass horn design. The best-known example is the RCA theater horn, which uses two 15 inch drivers. The W uses forward-facing drivers, and the horn flare is designed as a W-shaped double fold, expanding to twin mouths.

The Altec 31A uses a single 90° fold. This allows for a short front-to-back dimension. Additionally, the driver is mounted facing downward, making it rain and dust resistant. This horn uses a 120° mouth and is used above
The obvious advantage of a folded horn is the reduced package size for a given horn length. This advantage is offset by the fact that, for each reversal fold in the horn’s shape, a reflection is generated inward, opposite the desired direction of wave propagation. These reverse waves are reflected again in a forward (outgoing) direction when they reach the horn’s driver area, generating late signal arrivals that cause significant deviations from ideal in the horn’s response. For this reason, folded horns generally find use in applications that are relatively undemanding of fidelity.

17.7.6.8 Special Considerations for Low-Frequency Horns

Over the years, a number of horns have been developed specifically to radiate low frequencies. In the past, the primary motivation for the use of a horn to reproduce low frequencies was improved efficiency as compared to a direct radiator. The current availability of power amplifiers with extremely high output capacities and woofers that are capable of utilizing that power has rendered the issue of efficiency less important than that of size. As a result, there are fewer low-frequency horns on the market today than in the past.

The most common difference between bass horns and those intended for mid- and high-frequency use, aside from the bass horns’ larger size, is that low-frequency horns typically do not employ compression drivers. Instead, a cone transducer is mounted directly in the throat of the horn.

A potential issue in low-frequency horn design and operation is the transitional behavior of the horn. It is common practice to use a bass horn/driver combination to a sufficiently low frequency that the horn is too small to provide substantial acoustic loading in the lower portion of the bandwidth of use. In this frequency range, the driver must operate as a direct radiator, with correspondingly lower sensitivity. Although it has been asserted that this discrepancy, which can exceed 10 dB, may be overcome through the use of ports, in actuality the only means of leveling the device’s response between the two regimes of operation is with equalization of the input signal. Given proper equalization, a bass horn may be used in this fashion with excellent results.

17.8 Loudspeaker Systems

Most practical loudspeakers are systems comprising multiple transducer/radiator subsystems, each of which radiates a portion of the audio-frequency spectrum. This area of loudspeaker design has a major impact on a loudspeaker’s ultimate performance, yet this portion of the design process is frequently shortchanged. In this section we will discuss some considerations for loudspeaker system design and performance and provides some illustrative examples.

The desirability of dividing the audible frequency range into multiple bands is taken for granted in most loudspeaker applications. The most compelling reasons for dividing the spectrum among multiple components are:

1. By itself, the bandwidth of a practical transducer/radiator is inadequate to meet the bandwidth requirements for a complete loudspeaker.
2. The directivity of a single transducer/radiator will not be sufficiently consistent with frequency to meet reasonable goals for the directivity of a full range loudspeaker.
3. The maximum available acoustic output of a single transducer is inadequate. Sharing the output demand among a number of band-specific components enables a loudspeaker to produce greater total acoustic power.

In designing a loudspeaker system, one should, at the very least, have a working knowledge of the disciplines...
involved in the design of the component parts. The system designer’s challenge is to make a collection of individual components function as a cohesive whole while meeting the cost, size, and aesthetic requirements of the loudspeaker’s intended applications. The design of a successful loudspeaker system involves much more than simply selecting a group of components and building a box to house them.

It is axiomatic that, in addition to the required technical expertise, a loudspeaker designer should have the capability of subjectively evaluating a loudspeaker’s performance—critical listening—and that the final determinant of a loudspeaker’s success will almost always be subjective acceptance. It is equally true that there are always objectively observable phenomena that correlate with subjective preferences. The difficulty in reconciling the two is a direct result of the very large number of objective elements that must be accounted for in order to fully characterize the performance of a loudspeaker. This subject is covered in greater depth in the “Loudspeaker Characterization” section of this chapter.

Loudspeaker systems are often categorized by the number of spectral divisions made in the system, as in two-way or three-way systems. Generally speaking, a loudspeaker system consists of two or more transducer/radiator combinations, a crossover network, and an enclosure that houses everything. In addition to providing a convenient package for the components, the enclosure serves structural, acoustic, and aesthetic purposes. The sections on acoustic boundaries and electroacoustic models provide information about some of the acoustic effects of enclosure design.

17.8.1 Configuration Choices

A number of decisions about a loudspeaker’s configuration are typically made early in the design process. These include:

1. The number of spectral bands, or divisions.
2. The type of radiator to be used for each band.
3. The location and orientation of the individual components within the system housing.

In determining the number of frequency bands to be used in a loudspeaker, several conflicting demands must be reconciled. Choosing a greater number of divisions creates the possibility of greater broadband acoustic output and more optimal radiator configurations for each band. On the other hand, each added band adds to the size, complexity, cost, and more often than not, to non-ideal aspects of the acoustic behavior of the finished design.

The type of radiator chosen for each band is often a matter of custom or convention rather than of engineering. Where possible, it is generally desirable to match efficiencies and directivities of adjacent bands over a range of frequencies centered about their crossover point. This is most readily accomplished when similar types of radiators are used for both of the bands in question.

The location and orientation of individual components is an area worthy of careful attention. It is common practice to place all of the transducers on a flat panel (a baffle), displaced from each other in vertical and/or horizontal directions. In the case of loudspeakers designed for stereo reproduction, it is also common practice to make pairs of speakers in a mirror-image layout.

The aforementioned common practices have developed over many years, with the primary motivation being cost and ease of manufacture. Another approach to loudspeaker system design is the coaxial layout. First employed in the earlier part of the 20th century, this practice involves locating two or more bands of a loudspeaker along a common axis. While the coaxial approach is typically more difficult to implement, it has some advantages over more conventional layouts.

17.8.2 Types of Loudspeaker Systems

The simplest form of loudspeaker employs a single full-range transducer to reproduce all frequencies. The most common applications for this type of device are limited-bandwidth (e.g., speech) systems and inexpensive music reproduction systems.

For residential music systems, one of the more common configurations is a two-way system utilizing a small (typically 6 or 8 inch) woofer and a dome tweeter. Fig. 17-41 is one such system. More elaborate (and costly) systems are also employed for residential use, some employing line arrays (see Section 17.8.4) of transducers for one or more of their bands. As is the case with professional loudspeakers, visual aesthetics can play as important a role as performance in setting design requirements.

One of the more common types of loudspeakers for general sound reinforcement use is a two-way system consisting of a direct radiator woofer and a horn/compression driver high-frequency subsystem, with the components being located one above the other on the front face of the enclosure. The typical package for this type of loudspeaker is a trapezoidal enclosure.
The trapezoid designation describes the plan view of the enclosure, and the shape allows multiple loudspeakers to be arrayed in the shape of an arc segment, with the included angle between adjacent loudspeakers being equal to twice the sidewall angle. A large number of manufacturers offer loudspeakers that fit this description. Typical sidewall angles range from 12° to 15°, while the horizontal coverage angle (the angle at which the output has fallen to 6 dB below the level on axis) of the high-frequency horns used in such devices is typically either 60° or 90°, and the coverage of the woofer is entirely uncontrolled.

### 17.8.3 Performance Issues in Multiway Systems

Before trying one’s hand at designing a multiway loudspeaker, it is a good idea to develop a familiarity with the complete audio signal chain and to understand the implications each decision will have on the acoustic signal that will reach the listener’s ear. Fig. 17-42 is a functional diagram of the electrical and acoustic signal paths from the source (electrical input signal) to the observation (listening) point.

In the above representation,

\[
F_T(S, x, y, z) = \sum_N [F_n(S)G_n(S, x, y, z)]
\]

where,

- \(F_T\) is the total electroacoustic transfer function,
- \(F_n\) is the (electrical) transfer function of the \(n\)th crossover filter,
- \(S\) is the Laplace complex frequency variable,
- \(G_n\) is electroacoustic transfer function of the \(n\)th radiator in the system,
- \(x, y,\) and \(z\) are Cartesian spatial coordinates.

The concept is general and will accommodate an arbitrary number of spectral divisions.

It should be noted that, although this diagram depicts a loudspeaker with a passive crossover, it might also be used to represent an active system simply by including gain in the transfer functions of the crossover blocks. An active loudspeaker simplifies the task of crossover design. Since the power amplifier serves as a buffer between the crossover and the transducers, the frequency-dependent impedance behavior of the transducers becomes a very small factor in the design process. Note that the crossover filters are in cascade with the transducers, while the acoustic outputs of the devices are summed acoustically at the listening position. The nature of such a multipath system is complex, and detailed prediction of its response at every likely listening position is a nontrivial task.

Note also that the transfer functions \(G_n\) are functions of the spatial coordinates \(x, y,\) and \(z\) as well as of the complex frequency variable \(S\). This spatial dependency includes the effects of source directivity, propagation delay, and the inverse square law. If the system is not coaxial (and sometimes even if it is), then the lengths of the paths from each transducer to a given listening position will not generally be the same. The most common practice is to choose an axis along which one will attempt to equalize these acoustic path lengths and then to optimize the speaker’s behavior on this axis. In the case of a two-way loudspeaker with the transducers displaced along a line in the plane of the baffle, it is possible to make path lengths equal at every point in a plane. Once more than two spectral divisions are present, even this limited goal is no longer possible. It may well be the case that, in a three- or four-way system, there is no point for which all acoustic path lengths from the transducers to a listener’s ears will be equal.

The effect of unequal acoustic path lengths is that signals from different radiators will reach the listener at different times, even though they originated simultaneously. This timing discrepancy is not generally suffi-
cient to be recognized by a listener as comprising distinct multiple events, but it is enough to have audible and undesirable effects on a loudspeaker’s amplitude response, as well as on its ability to reproduce transient signals. Even when an axis or plane exists in which signal synchronization has been achieved, positions off the axis or outside of the plane will not receive the benefits of such synchronization.

The subject of complex addition of time-varying signals is beyond the scope of this chapter, but it is dealt with in many introductory circuit analysis texts. Additional effects of signal synchronization, and the lack thereof, on loudspeaker response are illustrated in the section on crossovers.

There are a number of ways in which the problems caused by noncoincident transducer locations may be addressed by a loudspeaker designer. One common approach is simply to assert that the response anomalies caused by this configuration are not audibly significant and to accept (or avoid acknowledging) their presence. Another is to employ crossover filters with very steep slopes so as to minimize the frequency range over which anomalies due to path length differences will be present. As will be shown in the crossover section, the latter technique has its own set of drawbacks and may in some cases create more serious problems than it solves.

One means of addressing the synchronization issue is with a coaxial loudspeaker. This type of loudspeaker is most often two-way, although it is possible to design a three- or four-way coaxial system. There are benefits in making the midrange and high-frequency components of a three-way system coaxial, while leaving the low-frequency portion displaced in the more conventional manner.

A coaxial loudspeaker will always possess symmetrical response behavior, Fig. 17-43. That is, the response at a given angle from its axis will be mirrored at the same angle in the opposite direction. Additionally, if the acoustic path lengths from transducer to listener are equal on the system’s axis, it is possible to preserve this synchronization at all listening positions with a coaxial design. Even though it is possible to achieve signal synchronization over a wide angular range with a coaxial loudspeaker, this possibility is not always realized in practice. When a coaxial loudspeaker fails to achieve coincident performance (i.e., it fails to behave as a single full range radiator), its sole distinction as compared to more conventional configurations is that frequency-dependent anomalies related to crossover interactions will be symmetrically located about the loudspeaker’s axis.

17.8.4 Line Arrays

Another type of loudspeaker system is a line array. Although line arrays have much in common with other types of loudspeaker systems, they have some attributes that are unique enough to justify their separate treatment. A line array may form a complete full-range loudspeaker or one or more bands thereof. In a line array, individual radiators are arranged in a straight line or an arc segment. It is also possible for a number of complete loudspeaker systems to be configured as a line array. It is this configuration that has come into fashion in recent years. In the simplest form of line array, each of the elements—usually a small cone transducer—is supplied an identical full-range signal. This type of array, also called a sound column, was popular in this
country through much of the 1970s and is still in common use in installed sound systems.

Recent developments in DSP technology, combined with the constant pressure on the touring concert reinforcement industry to minimize weight, blockage of audience sight lines by speakers, and truck space, have resulted in a resurgence of interest in line arrays. As attractive as some of their perceived performance characteristics may be, they have inherent limitations. First, the directivity attributes associated with line arrays are present in the vertical plane (along the length of the array) only. The horizontal directivity is only as good as the horizontal performance of the individual devices used to form the array. Secondly, line arrays invariably comprise discrete elements, as opposed to a continuous line source. This periodicity exacerbates problems with

Figure 17-44. Generic two-way loudspeaker directivity balloon and polar pattern in the crossover region.

Figure 17-45. Coaxial two-way loudspeaker directivity balloon and polar pattern in the crossover region.
nulls and lobes, and it causes the off-axis impulse response of a line array to contain multiple discrete arrivals.

It is often incorrectly asserted that a line array behaves, or can behave, as a line source. A line source is largely a theoretical construct. It consists of a long, narrow radiator that radiates sound with perfect uniformity at every point on its surface. This assumption of perfect uniformity, while impossible to achieve in practice, simplifies the mathematics required to model the behavior of a line source. When used for illustrative purposes in texts, line sources may additionally be assumed to have infinite length, making possible even further simplification of the mathematical model. The same model has been employed in texts on electromagnetic theory, for the same reasons.

The two assumptions—continuous radiation and infinite length—lead to two interesting results. First, due to symmetry, the frequency response of an infinitely long, continuous line source is not a function of observation position along the line. For example, if the line is assumed to be coincident with the Z-axis in a cylindrical polar coordinate system, then its response will not vary with changes in the Z-coordinate of an observation position (i.e., for movement in a direction that is parallel to the line). Second, due to the infinite length of the source, the wavefront (a collection of isophase points) will form a cylindrical, rather than a spherical, shape. For this reason, the intensity of radiation in the outward direction falls off as the inverse of the first, rather than the second, power of the distance from the line.

As interesting and attractive as the two above results may be, they are not achievable in any physically realizable array. The effects of radiation that is neither continuous nor uniform, and of finite array length, cannot be neglected in discussing the behavior of real-world systems. Unfortunately, these issues have been glossed over or completely ignored in the information that is provided regarding the performance of commercially available line array products.

Full-range line arrays characteristically have relatively narrow vertical radiation patterns. The details of these radiation patterns vary widely with frequency and typically contain undesirable off-axis nulls (deep response notches) and lobes (response peaks). The same phenomena that produce off-axis response variations in a noneoaxial, multiway loudspeaker—interference caused by variations in the relative distances between multiple sources and the listener—create this directivity. At high frequencies, the angular separation between the first two nulls—and therefore the useful coverage angle—may be on the order of 5° or less.

A number of remedies to the problem associated with line arrays have been implemented over the past 50 years. There are two primary areas in which the line array intrinsically poses challenges to the designer: total array length and individual device spacing. Both must be addressed in order to produce a well-behaved system.

One means to address the issue of total array length is to implement a tapered array. In this type of array, only the innermost elements carry the highest frequencies. The signals applied to the more outwardly placed elements in the array are low-pass filtered at successively lower frequencies. The goal of this approach is to make the effective length of the line array become shorter at higher frequencies. An alternative way of stating this goal is that one desires the ratio between the effective length of the array and the wavelength of sound to be invariant. With the ability via DSP processing to create filters of essentially arbitrary amplitude and phase response, it has become relatively straightforward to create tapered arrays. Additionally, the availability of frequency-independent delay makes lobe steering possible.

The matter of device spacing poses another set of challenges. The smaller the spacing can be made relative to wavelength, the better a line array can approximate the behavior of a continuous radiator. When device spacing becomes large relative to a wavelength—roughly in the range of a full wavelength—the off-axis response of the array will contain many lobes and nulls. It is likely that one or more of these off-axis lobes will approach the level of the on-axis radiation. When one considers the small wavelengths of the higher audible frequencies—the wavelength of 10 kHz is 34.4 mm (1.35 inch)—the challenge of achieving optimal device spacing for higher frequencies becomes apparent. The continued reduction in size of motor assemblies through the use of high-powered magnetic materials has been helpful in addressing this issue.

### 17.8.5 Crossovers

Multiway loudspeakers incorporate a crossover network. A crossover network is a collection of electrical filters, each of which allows a specific portion of the frequency spectrum to pass through it. The filtered signal is then applied to one of the bands in the loudspeaker. The types of electrical filters used to execute the crossover function are low pass, high pass, and bandpass.

The simplest crossover network consists of a low pass and a high-pass filter for use in a two-way loudspeaker. Choices that must be made regarding the filters in this crossover are:
1. Crossover frequency: below this frequency, output from the low-frequency section (woofer) is dominant, and above it the high-frequency section (tweeter) dominates.

2. Filter slopes: analog filters have characteristic stop-band, or rolloff, slopes, which are integer multiples of 6 dB/octave (or equivalently 10 dB/decade). The simplest type of filter is the first order, or 6 dB/octave filter. In passive loudspeakers, the highest order filters in common use are third-order (18 dB/octave), whereas fourth-order (24 dB/octave) Linkwitz-Reilly filters are popular in active crossover implementations.

17.8.5.1 Effect on Maximum Output

The choice of filter slopes used in a crossover has a number of implications for the performance of the loudspeaker system. Generally speaking, crossover filter characteristics will affect a loudspeaker’s maximum output capacity, amplitude and phase response, and directivity.

Since all transducers have a maximum excursion beyond which their output is no longer linear (or permanent damage occurs), and since the required excursion for a given acoustic output level increases with decreasing frequency, the characteristics of the high-pass filter(s) in a crossover have a direct bearing on a loudspeaker’s maximum available acoustic output: in general, selecting a higher cutoff frequency will reduce the excursion required of the high-frequency transducer(s), as will employing steeper filter slopes. For a given high-frequency transducer, increasing the crossover frequency reduces the displacement required of that transducer. The demand made of the woofer as a result of the increase is strictly thermal, since the lower end of its band of use is not affected by such a change. This benefit has to be balanced against the possible inability of the woofer to effectively radiate higher frequencies over a large angle.

In addition to excursion limiting, the bandwidth of the signal applied to a given transducer determines the thermal load the transducer will see in operation. For this reason, dividing the spectrum into a greater number of bands—thereby reducing the total power that is applied to any single band—can also increase the available acoustic output of a loudspeaker. One must consider, however, that very seldom will the signal applied to a loudspeaker contain a constant broadband spectrum. At times, much of the energy applied to a loudspeaker may be confined to a relatively narrow range of frequencies. In such cases, the advantage of having a greater number of loudspeaker bands is substantially reduced.

17.8.5.2 Effect on Loudspeaker Response

The choice of filter slopes and alignments has major implications for the response of a multiway loudspeaker. Even though these effects have been examined and published for decades, they are often either misunderstood or simply ignored by loudspeaker designers.

It is a good idea to state as simply as possible the ideal functional requirements that should be met by a crossover network: a crossover should enable the acoustic sum of the individual transducers’ outputs to be an accurate replica of the system input signal.

The response of a loudspeaker, for purposes of this chapter, is defined as its pressure response at a particular point in space. Even though the above criterion is simple to state, there are many design constraints that lead to tradeoffs in a loudspeaker’s accuracy. For example, prevention of damage to transducers is often an overriding consideration in the design of a crossover. This may motivate the designer to consider steeper filter slopes. In some loudspeaker configurations, off-axis response anomalies are intrinsic to the design. The designer may wish to make off-axis anomalies in amplitude response as geometrically symmetrical and as narrowband as possible. The Linkwitz-Reilly filter family is sometimes employed in pursuit of these goals.

The simplest crossover is a first-order filter pair. In a two-way loudspeaker, the first-order transfer functions for low-pass and high-pass functions are:

\[ F_1 = \frac{\omega_0}{S + \omega_0} \]  \hspace{1cm} (17-7)

and

\[ F_h = \frac{S}{S + \omega_0} \]  \hspace{1cm} (17-8)

where,

- \( F_1 \) is the low-pass transfer function,
- \( \omega_0 = 2\pi f_0 \) is the angular cutoff (–3dB) frequency,
- \( S \) is the Laplace complex frequency variable,
- \( F_h \) is the high-pass transfer function.

If we add the two electrical transfer functions, we get

\[ T_t = \frac{S + \omega_0}{S + \omega_0} \]  \hspace{1cm} (17-9)

\[ = 1 \]
The two transfer functions add up to a constant, independent of frequency. This is a desirable result, since the outputs of the radiators in a multiway loudspeaker are ultimately recombined by (acoustic) addition. The transfer function of our electrical sum implies that, in a two-way loudspeaker with ideal, perfectly coincident transducers and a first-order crossover, the system transfer function would not depend on frequency. We could, with some additional effort, engage in the same exercise with higher-order transfer functions. If we did so, we would find that, of all symmetrical (identical low-pass and high-pass slope and alignment class) filters, only the first-order pair does not introduce phase or amplitude error or both to the loudspeaker’s transfer function. The interested reader will find detailed mathematical analyses of the various crossover topologies in the references cited at the end of this chapter.

One way of examining the effects of crossover filters on loudspeaker response is to use circuit simulations to model various aspects of the system’s behavior. This method has the advantage of presenting a simple graphic representation of the values being modeled without requiring extensive mathematical skills for comprehension.

17.8.5.3 Two-Way Crossovers

For simplicity, we will examine several aspects of crossover performance in two-way systems. Then we will point out some of the elements that must be altered when three- or four-way systems are contemplated.

The chart in Fig. 17-46 is the impulse response of a first-order crossover, including the input signal, low-pass, high-pass, and summed signals. For simplicity, the crossover frequency has been set at 1 kHz. The choice of crossover frequency causes no loss of generality.

Note that, although low-pass filter has obvious delay and the high-pass filter overshoots the input signal’s return to zero, these effects perfectly cancel each other, rendering the input and the summed signals identical. This characteristic is unique to a family of crossovers identified by Richard Small as “constant voltage crossovers.” The first-order filter set is the only symmetric low-pass/high-pass filter pair that falls into this class.

By contrast, the summed second-order impulse response shown in Fig. 17-47 contains significant deviations from ideal.

Note that, in the summed signal (output) there is overshoot on the return to zero, followed by a delayed reaction due to the low-pass filter’s delay characteristics. Viewed in the frequency domain, the second-order summed low-pass and high-pass response has a perfect null—i.e., a notch that is infinitely deep on a decibel scale—at the crossover frequency. Its phase response goes through a wrap of 360° centered at the crossover frequency.

Fig. 17-48 shows the impulse response family of a fourth-order Linkwitz-Reilly filter pair. It should be evident from this series of graphs that the impulse response of a loudspeaker may be compromised by the designer’s choice of crossover filter topologies. Viewed in the frequency domain, the Linkwitz-Reilly filter pair exhibits ideal amplitude response (i.e., perfectly flat) through the crossover range and elsewhere, but its phase...
response goes through a 720° wrap through the crossover region. From what we have observed so far, it is evident that higher-order symmetric filters can introduce nonideal transient response behavior when used as crossover filters. Based on observations of the delaying effect of the low-pass filters, one might be tempted to introduce electrical delay into the high-frequency signal in an attempt to better synchronize low- and high-frequency signals. In the case of the LR filter family, such attempts will only serve to compromise the amplitude response of the loudspeaker while offering minimal improvement in the impulse response. As with crossover-frequency anomalies caused by noncoincident transducers, one way of addressing the nonideal behavior of higher-order symmetric filters is to assert that the problems are not audible. It is also possible to address transient response issues and at the same time retain a steep filter slope for one of each pair of neighboring bands in a multiway loudspeaker. Crossovers of this type are termed constant voltage crossovers and are discussed in Section 17.8.5.3. The simulations above are based on ideal filter behavior and ideal transducers. As one makes the simulation more realistic, accounting for the bandpass behavior of real-world transducers, the performance of all of the modeled crossovers will deteriorate, but the relative attributes of constant voltage filters remain.

Figure 17-48. Impulse response family of fourth Linkwitz-Reilly filters.

17.8.5.4 Beyond Two-Way Systems

As the number of spectral bands in a loudspeaker increases, the issues that must be dealt with in crossover design multiply. In a system with three or more bands, at least one of the crossover filters is a bandpass, usually formed by cascading low-pass and high-pass filters of the desired characteristics. The low-pass portion of the arrangement will introduce delay in its passband, which can create misalignment between the band in question and its lower neighbor. In addition to this issue, there is also the possibility of interactions between transducers that are not neighbors in the audio spectrum (e.g., the woofer in a three-way system can contribute enough energy in the high-frequency horn’s passband to make its presence known). This type of interaction is often undesirable, as it has generally deleterious effects on the response and directivity of the system.

17.8.5.5 Passive versus Active Crossovers

When designing a passive crossover—one that receives the power amplifier’s output and applies appropriately filtered signals to each transducer—the designer must account for the frequency dependence of the impedances of each transducer in the system. In the case of most cone transducers, the impedance curve has a peak at the resonant frequency, above which it decreases to a minimum and then rises with frequency in similar fashion to the impedance of an inductor. This variation of impedance with frequency is often minimized through the use of a parallel, or shunt, network. Once the device’s impedance has been stabilized in this manner, the actual crossover filter may be designed to drive a purely resistive load with excellent results. Active crossovers—those that divide the spectrum at line level and apply the band signals to the inputs of power amplifiers—have the advantage of the buffering effect provided by the power amplifier. Impedance-related issues are far less significant in this case, and active filters—particularly DSP-based ones—offer a number of options not readily available in passive versions. These include frequency-independent delay, all-pass filters, and dynamics processing (compression/limiting). The price that is paid in an active system is in additional channels of power amplification and wiring.

17.8.6 Acoustic Boundaries

Generally, one considers that acoustic boundaries are part of the space into which a loudspeaker is radiating. The field of architectural acoustics is largely concerned with the acoustic behaviors such boundaries cause. However, every loudspeaker has a collection of acoustic boundaries independent of the external environment in which it is operated, and these boundaries make a surprisingly large contribution to the loudspeaker’s response and directivity. Most of the boundaries associated with loudspeakers constitute reflective surfaces: enclosure walls are designed to be rigid and generally have hard
surfaces. The same is true for horn surfaces. Phenomena associated with this type of surface fall into two broad categories: reflection and diffraction.

In the simplified textbook models such as a piston radiating into a half space, the infinitely large baffle on which the loudspeaker is mounted is assumed to be perfectly reflective. All of the reflections that occur at this surface will add coherently to the outgoing wave, since the source is in the same plane as the baffle. The only interfering radiation present in this model is that which is caused by the source itself, and it is this simplicity that allows a closed form solution—the piston directivity function—to yield an accurate prediction of the device’s behavior.

If a hard surface is present on the front of the baffle and at right angles to it—as would be the case with room walls, for example—the wave’s outgoing motion can continue no farther past this surface. Its direction is reversed due to reflection.

In a typical direct radiator loudspeaker, the wave created by a transducer expands along the front surface of the cabinet until it reaches the edges. At these edges, the support provided by the enclosure’s front surface for forward motion of the wave abruptly collapses as the wave is allowed to expand rearward as well as forward. The propagation of the sound wave past this point is altered by diffraction.

Loudspeaker cabinet diffraction has not been a well-understood phenomenon until relatively recent work. The model developed by Vanderkooy shows that diffraction at an edge has strong dependence on the observation angle and that forward diffraction (in the same direction as the original outgoing wave) is inverted in polarity, whereas diffraction at angles greater than 180° (to the rear of the loudspeaker) is of the same polarity. The reader is encouraged to study Vanderkooy’s work, as well as the other references, for mathematical treatments of this phenomenon.

The net effect of this diffracted energy is to introduce a set of acoustic arrivals at an observation point that follow the direct arrival in time and are reversed in polarity for positions in front of the loudspeaker. These arrivals interfere with the direct signal, with the specific effect of the interference depending on frequency, baffle size, and transducer positioning on the baffle. The result is a series of peaks and dips in the loudspeaker’s response due entirely to the baffle itself.

Some effects of diffraction from panel edges are illustrated in the following graphs. On-axis response measurements were performed on a 1 inch soft dome tweeter with a 3.75 inches (95 mm) square mounting panel. Fig. 17-49 is a response measurement of the tweeter alone, suspended from a microphone stand. Fig. 17-50 is the same tweeter mounted on a thin panel approximately 19 inches (483 mm) square.

![Figure 17-49. Dome tweeter on axis with no baffle.](image)

![Figure 17-50. Dome tweeter on axis with 19 inch square baffle.](image)

Note the relatively wide depression in the tweeter’s response in Fig. 17-49. The center of the depression is approximately at 6.5 kHz. A diffracted arrival at a one-wavelength distance will interfere destructively with the primary wave. At 6.5 kHz, this distance is approximately 2.1 inches. This is consistent with the average distance from the center of the tweeter mounting flange to its edge. A tweeter with a round mounting flange could be expected to have a deeper, narrower notch due to reduced time smear in the diffracted arrival.

The same characteristic notch is present in Fig. 17-50, but at a much lower frequency. This is also consistent with the model of reversed-polarity forward diffraction: The notch is now centered at 1220 Hz, which has a wavelength of approximately 11 inches. The average distance from the center of the 19 inch panel to its edge matches this dimension very closely.

Fig. 17-51 is the same configuration as in Fig. 17-50, with the addition of a layer of ¾ inches (19 mm) thick foam attached at the edges of the panel. This material is
relatively absorptive above 1 kHz. Its effect on the tweeter’s response is most evident between 1 kHz and 3 kHz. The graphs in Figs. 17-50 and 17-51 display loudspeaker response differences that are due entirely to the boundaries formed by the speaker’s baffle. The same transducer was used in each measurement.

This brief examination of some acoustic effects due to loudspeaker boundaries is intended to provide a starting point for further study and investigation. A number of implications for loudspeaker design should be readily apparent.

Transitional points in a loudspeaker’s shape (e.g., edges, slots) behave as acoustic sources. Energy arrivals from these features always follow the primary wave in time. Additionally, they can be reversed in polarity. Acoustic absorption is a useful diagnostic tool as well as a powerful design element for the loudspeaker engineer.

17.8.7 Conclusion

Loudspeaker system performance is a function of several elements, including transducer design, crossover topology, component location and orientation, and the acoustic boundaries formed by the loudspeaker’s housing. Each of these elements has a major effect on the final result, and the most effective loudspeaker designs successfully address all of these areas.

17.9 Characterization of Loudspeaker Performance

17.9.1 Motivation

In considering the behavior of a loudspeaker, it stands to reason that we need performance parameters with which we can evaluate the effectiveness of a specific device for an envisioned use. There are many performance areas in which loudspeakers differ in significant ways, including on-axis response, bandwidth, directivity, distortion, and maximum acoustic output. Unfortunately, there are a number of different formats for presentation of loudspeaker performance data. Before attempting to interpret such data, it behooves us to develop some general concepts of loudspeaker performance.

The picture is made much more complicated by the fact that we hear not only the direct sound produced by a loudspeaker, but also the reflections caused by interactions between the loudspeaker and the acoustic environment in which we are listening. Different loudspeakers interact in different ways with acoustic environments, with certain types and degrees of interaction being preferable to others. For this reason, it is useful to develop a concept of loudspeaker performance that will provide a means for understanding (and, hopefully, predicting) these interactions.

17.9.2 Efficiency and Sensitivity

Since a loudspeaker converts electrical energy into acoustic energy, the concept of efficiency is relevant. As we will see, this conceptual construct, while it is a good starting point for study, has limitations in the characterization of loudspeaker performance.

Efficiency is defined as the ratio of power provided by the system output divided by the power applied to the input. As a result of conservation of energy, the efficiency of a loudspeaker (or any energy-conversion device) is always less than one. Most often, efficiency is expressed as a percentage. Typical loudspeaker efficiencies range from less than 1% in the case of some hi-fi products to approximately 25% for limited-bandwidth horn-loaded devices.

Since a loudspeaker’s efficiency varies with frequency, a single number for efficiency does not generally provide adequate information for discriminating one device from another. Also, since human hearing responds to changes in acoustic pressure, the total power radiated into an acoustic space may or may not be a good indicator of what the human ear–brain perceives. Furthermore, the devices that drive loudspeakers—incorrectly called power amplifiers—are designed to control the voltage applied to a loudspeaker. For these reasons, the concept of a loudspeaker’s functional efficiency needs to be expanded.

The parameter most often used to characterize a loudspeaker’s ability to produce acoustic output is called sensitivity. A loudspeaker’s sensitivity is the sound pressure level (SPL) produced at a reference
distance with a reference electrical input signal. The most common standard is dB-SPL at 1 meter with a 1-watt input. Since a loudspeaker’s impedance varies with frequency, and since a power amplifier is actually a voltage-controlled voltage source, the 1 watt figure is usually translated into an rms voltage (e.g., 2.83 Vrms into 8 Ω = 1 W). Also noteworthy is the fact that the actual measurement will generally not be accurate if it is actually carried out at a 1-meter distance, since it will not be in the loudspeaker’s farfield. Instead, the testing is done at a greater distance and the results normalized to the 1-meter reference distance. The discussion that follows is based on the premise that we are interested in knowing the acoustic output characteristics of a loudspeaker with known voltages applied to its input.

17.9.3 Network Transfer Function

The performance characterization of electrical circuits is a well-developed realm and is employed as the basis for much data presented in regard to loudspeaker behavior. The impulse response, \( H(t) \), and Laplace transfer function, \( L(H(t)) = F(s) \), of an electrical circuit are widely used models for the linear portion of a circuit’s behavior. A large body of practical mathematics has been developed to aid in manipulating transfer functions of circuits, and the subject is covered at the undergraduate level in almost every engineering discipline.

A necessary item in applying these concepts to an electrical network is a definition of which terminals constitute the input and which will be considered the output. Using these definitions, the performance of the circuit may be modeled and/or measured and the resulting data used to evaluate the suitability of the circuit for an intended use.

17.9.4 Loudspeaker Transfer Function

Before developing these concepts further, we should recognize the importance of the correlation between the response behavior of a loudspeaker and its audible (i.e., subjectively evident) performance. The inevitable limitations in the resolution of measured loudspeaker data should ideally be determined with the capabilities and limitations of human hearing in mind. Data that is too highly resolved will reveal a number of details, or artifacts, that are not likely to be audibly significant, while insufficiently resolved data will tend to smooth over relatively serious imperfections that may easily be heard. With respect to frequency resolution, constant percentage octave (log frequency) resolution would appear to correlate best with the capabilities of human hearing. If measurements are taken so as to yield 1/6-octave resolution above 100 Hz, it is unlikely that greater resolution would reveal additional features that can be distinguished by human hearing.

The concept of frequency response (more appropriately, amplitude response) is a direct consequence of the transfer function model. This is the most familiar of the many possible ways of graphically representing portions of a transfer function. It is widely assumed that a loudspeaker may be characterized by one frequency response, usually measured at a point defined to be on axis of the loudspeaker. This assumption is incomplete: a loudspeaker has infinity of transfer functions (or, interchangeably, impulse responses), one for each point in 3D space. In the interest of compactness, we could say equivalently that a loudspeaker has a transfer function with four independent variables instead of one: where \( F(s) \) is sufficient for electrical circuits, for loudspeakers the equivalent expression (in Cartesian coordinates) will be \( F(x,y,z) \).

When we consider loudspeakers, the analogy with electrical networks is incomplete due to the nature of the device’s output. Whereas a two-port electrical network has a single output, a loudspeaker radiates energy into free space in all directions. If only one listener were present, and if there were also no reflections in the acoustic environment, then the loudspeaker’s response at a single point—the listening location—would be sufficient to characterize what that listener would hear. If multiple listeners and reflections are present, it is no longer sufficient to consider only the single transfer function: we need much more information.

If we limit our consideration to the far field (i.e., distances many times greater than the largest dimension of the loudspeaker), then the dependence of the transfer function on distance will be reduced, in most practical cases, to a characteristic delay of

\[
\tau = \frac{r}{c} \quad (17-10)
\]

where,

- \( r \) is the distance from the source to the observation point,
- \( c \) the phase velocity of sound in air, plus a change in acoustic pressure that is inversely proportional to distance from the source due to the inverse square law.

Both of these quantities may be assumed to be frequency-independent, although there are some exceptions.
Given this simplification, the extended transfer function of a loudspeaker may be characterized on the surface of a sphere of some arbitrarily chosen radius with the source at its center. The number of independent variables is then reduced to two, yielding a transfer function that may be represented as a function of $S$ and two angles —i.e., $F(s, \theta, \psi)$. Even with this simplification, the number of single-point transfer functions remains uncountably infinite. Clearly, further simplification will be required if the task of measuring and describing a loudspeaker’s performance is to be made practically realizable.

Currently available software for the simulation of sound system performance requires data to be presented with a fixed angular resolution. The polar coordinate system that has been adopted for this purpose is most easily described as that of a globe with the loudspeaker’s axis aimed at the North pole. Typically, the plane of horizontal coverage is defined as $0^\circ$ rotation angle, with the lines of constant rotation equivalent to longitude and radius angles analogous to latitude. One advantage of this approach is that data points are at maximum density near the on-axis position. There is still debate regarding the angular resolution required to show relevant details of device performance. Increments as fine as $1^\circ$ have been suggested. Practically speaking, even with $10^\circ$ increments, a complete set of measurements on a device with mirror-image symmetry (i.e., requiring measurements in only one quadrant) requires 172 response measurements of the device. An asymmetric device (e.g., Altec VIR, IMAX PPS, requiring two quadrants of measurement) requires 325 measurements to characterize with $10^\circ$ resolution.

One possible compromise is to use one angular increment for measurements taken within the intended coverage pattern of the loudspeaker and another, broader, one for other measurements. This has the advantage of providing greater detail in the angular area in which the loudspeaker’s response has the greatest audible effect. It would, however, complicate the process of interpolation that is required to approximate the response of a speaker at angles that fall between the angles at which measurements were taken. This variable resolution is unavailable in currently array prediction software.

Due to the large amount of measured data that is required to meaningfully characterize the performance of a loudspeaker, it is highly impractical, if not altogether impossible, to provide the data in a hardcopy format. In order to conveniently view loudspeaker data of this complexity, one must employ a computer program. For many years, the only available programs for this purpose were those that were primarily designed for sound system modeling and prediction. These programs have capabilities that go far beyond the display of loudspeaker data, are not optimized for that use, and are typically quite costly.

Recently, a format specifically for presentation of loudspeaker performance data, called the common loudspeaker format, or CLF, has been developed. This format is supported by a consortium of loudspeaker manufacturers. Due to the amount of data accommodated by the format, it is optimized for electronic, rather than hardcopy, presentation of data. It requires a data viewer program, which is available for download free at http://clfgroup.org. The displays in the CLF viewer include 3D amplitude balloons, traditional polar plots, normalized off-axis response plots, impedance versus frequency, as well as other data. Figs. 17-52 and 17-53 are screen captures of a CLF display.

### 17.9.5 Impedance

The impedance of a loudspeaker is very seldom constant with respect to frequency. For this reason, the nominal impedance provided in the specification sheet—typically 4 Ω, 8 Ω, or 16 Ω—is often useless as a figure of merit. Because power amplifiers have limited ability to drive excessively low impedances and because loudspeaker cabling may have nonnegligible series resistance, it behooves the prospective purchaser of a loudspeaker to examine its impedance versus frequency curve. Of greatest interest is the minimum impedance seen in the device’s bandwidth and, to a lesser extent, the frequencies and magnitudes of any peaks in the curve.

### 17.9.6 Distortion

The concept of a transfer function assumes a linear system. In a linear system excited by a single frequency, the output will contain only that frequency, possibly changed in amplitude and/or phase. By extension, the output of a linear system excited by a signal containing multiple frequencies will contain only those frequencies present in the original signal.

There are a number of nonlinear mechanisms in any loudspeaker. These include nonlinearities in the motor, suspension, and air (e.g., in a phasing plug or the throat of a horn). For this reason, all practical loudspeakers have nonnegligible levels of harmonic and intermodulation distortion. By comparison with modern electronic signal processing devices and amplification, loud-
speakers have orders of magnitude higher levels of distortion.

The degree to which loudspeaker distortion constitutes an audible problem is a matter of some controversy. Indeed, some of the more popular devices have distortion levels that are quite high, even by loudspeaker standards. Various studies over the years have established the audibility of simple harmonic distortion at levels above approximately 2%, but it is not clear that all of these studies fully accounted for the distortion present in the loudspeakers required to perform the testing. The continuing popularity of tube amplifiers among the audiophile community would tend to indicate that at least some forms of distortion are perceived as pleasing. In terms of simple harmonic distortion, it is often asserted that even-order distortion products have a
more musical relationship to the fundamental, going upward in frequency in successive octave steps. Because of this, it may be true that even-order distortion products are more readily tolerated (or even preferred) by many listeners.

Because of the relatively high levels of distortion in all loudspeakers and the wide variety of ways in which a signal can be distorted, there is no consensus in the industry as to the best means for characterizing the distortion performance of a loudspeaker. The audible significance of the nonlinear distortion caused by a loudspeaker is best judged in person, and the results may or may not correlate well with commonly measured data.

17.9.7 Characterization for Design Purposes

Prior to beginning work on a new design, the designer will (or should) develop a set of performance criteria for a loudspeaker. Parameters typically considered are bandwidth, available acoustic output, directivity, and efficiency. Often, the designer must interpret subjective information provided by others and translate it into performance specifications.

The more complete the data regarding target performance, the more satisfactory the finished loudspeaker is likely to be. For this reason, targeted applications for a new design should be well understood and well defined. Possible performance definitions include characteristic isobars, lower and upper cutoff frequencies, tolerance for nonideal amplitude response (off-axis as well as on-axis), maximum acoustic output, maximum distortion level relative to fundamental, and phase versus frequency criteria. A reasonably good idea of minimum acceptable performance is also useful for purposes of cost engineering. Once the overall loudspeaker performance envelope is finalized, requirements for individual component performance can be established.

The specific measurements that should be performed on an individual component will depend on the transducer or radiator in question and on the nature of the loudspeaker of which it will become a part. Impedance versus frequency measurements are always essential. For woofers, this will allow determination of the parameters necessary for the design of an appropriate enclosure. For horn/driver combinations, the designer needs to know the frequency of mechanical resonance. It is also possible to identify internal horn reflections and diaphragm breakup problems in an impedance curve. Finally, the behavior of the component as an electrical load is required for the design of passive crossovers.

Measuring a representative set of transfer functions is an essential part of the component characterization process. What constitutes a representative set will depend on the component. A woofer will need comparatively few measurements if it is well behaved and to be used only at low frequencies, a horn will need a significantly larger number of measurements, and an array of two or more components operating over the same range of frequencies will require still more measurements. Some devices cannot be suitably characterized by a reasonable number of measurements. The measurement process will determine if a component is usable in the intended application and will aid in early prediction of the ultimate performance of the completed loudspeaker.

The extent of testing needed to evaluate the most complex component is likely to be required for the complete system. The degree to which target performance objectives have been met should be established at the prototype stage. Any necessary modifications may then be made and the system retested. This process may continue through as many iterations as necessary for the loudspeaker to perform as desired.

17.9.8 Characterization for the User

Once a loudspeaker is in production, performance data will be required for (a) giving potential buyers information for comparative purposes, and (b) use in the design of sound systems. Loudspeaker performance data provided to the sound system designer should be sufficiently comprehensive for acceptably accurate prediction of the performance of a sound system. Unfortunately, the volume of data required to fully characterize a loudspeaker is, as we have discussed, quite large. If hard copy were generated with all pertinent information, most loudspeakers intended for professional use would require a small book.

There are many ways to provide transfer function information about a loudspeaker. Keeping in mind that our extended definition of transfer function for a loudspeaker intrinsically includes directivity information, possible formats include:

1. Amplitude response curves calibrated to a constant level reference (e.g., dB-SPL) with a specified signal input (e.g., 2.83 Vrms) at a variety of angles. This format has the advantage of explicitly showing the direct-field response that listeners in various locations relative to the loudspeaker will hear, Fig. 17-54.
2. Amplitude response measurements as above but normalized to the response at a particular angle,
usually on axis. This is the equivalent of assuming that the on-axis response will be equalized flat, which is not always a good idea. The caveat: anomalous narrowband behavior on axis (i.e., a notch) that disappears off axis will create features (peaks) in the normalized curves that are unrepresentative of what would occur in actual use.

3. On-axis amplitude response, accompanied by polar plots at various frequencies. The common usage of only vertical and horizontal polar curves is problematic. The omission of polar curves at angles between 0° and 90° rotation leaves a lot of a loudspeaker’s performance to speculation, Fig. 17-55.

4. On-axis amplitude response, accompanied by isobars at various frequencies. This format is useful for showing overall coverage behavior of a loudspeaker. Lobes, where present, are not generally revealed in isobar plots.

5. Directivity data for use with sound system modeling software. The format of this data will be dictated by the requirements of the predictive program. Some standards for the presentation of this are being discussed, but there is not yet an industry-wide consensus on a final standard, Figs. 17-56 and 17-57.

Of course, various combinations of the above can be provided. The formats available for the presentation of loudspeaker data continue to evolve. The availability of inexpensive mass data storage media and ever more sophisticated acoustic modeling software will continue to make the presentation of loudspeaker response and directivity information more effective and intuitive.

17.10 Direct Radiation of Sound

The physics and mathematics of loudspeaker behavior are diverse and complex. In order to account for the conversion of an electrical signal to sound, one must develop both acoustic and electromechanical models. Several of these models, which are developed and presented in almost every introductory text on acoustics, are presented here without proof. The interested reader is encouraged to study the references.
17.10.1 Acoustics of Radiators

An understanding of direct sound radiation from a piston in space, a baffle, or a box can be approached by analyzing two distinct but directly related quantities, radiation resistance and directivity. Radiation resistance is the measurement of the capacity of an acoustic radiator to convert vibratory motion into sound energy. It is the ratio of pressure to the volume velocity due to the piston’s motion. At high frequencies, all pistons have the same capacity per unit surface area to produce acoustic power. However, as the size of the wavelength of sound being produced approaches the size of the piston, the radiation resistance decreases as the square of frequency, i.e., at approximately 12 dB/octave.

17.10.1.1 Piston in an Infinite Baffle

A piston in a wall of infinite extent (half space) is the model most commonly employed to develop predictive equations. Even though this model is not representative of the majority of actual loudspeakers, its simplicity and mathematical manageability make it useful for instructional and comparative purposes.

A piston in an infinite baffle will see an acoustic load that depends on its size relative to a wavelength of sound at the frequency of interest. The radiation resistance, which is the part of the acoustic impedance that accounts for transmission of sound energy, is given by

\[ R_f = \rho_0 c \pi a^2 [R_1(2ka)] \]

where,
\[ R_1(2ka) \]

\[ R_1[2ka] \] is the piston resistance function, given by

\[ R_1(x) = \frac{x^2}{2 \cdot 4} - \frac{x^4}{2 \cdot 4^2 \cdot 6} + \frac{x^6}{2 \cdot 4^2 \cdot 6^2 \cdot 8} - \ldots \]

(17-12)

The value of the piston resistance function approaches unity for values of \( 2ka \) above 6. For example, in the case of a piston with an effective radius of 6 inches, the radiation resistance will be approximately constant above 1100 Hz.

The acoustic power radiated by a flat piston is given by

\[ W = \frac{R_f U_0^2}{2} \]

\[ = \frac{U_0^2 \rho_0 c \pi a^2 R_1[2ka]}{2} \]

\[ = U_0^2 \rho_0 c S R_1[2ka] \]

(17-13)

where,
\[ U_0 \] is the amplitude of the piston’s velocity.

Two regimes of interest may be derived from the above equation. If we first consider \( 2ka < 1 \)—i.e., a small piston and/or low frequency—we can neglect the higher-order terms in the expression for the piston resistance function

\[ R_1(x) \approx \frac{x^2}{8} \]

(17-14)

and the power radiated by a flat piston becomes

\[ W = \frac{\rho_0 c k^2}{4\pi} (S^2 U_0^2) \]

(17-15)

Note that, for constant velocity amplitude, the acoustic power rises as the square of the frequency. Clearly, there must be a compensating mechanism, as a typical cone transducer has relatively flat amplitude.
response over this range of frequencies. This mechanism is the mechanical impedance due to the moving mass of the piston, which rises with the square of frequency. Therefore, a piston excited by a force that does not vary with frequency responds with a velocity that falls off as the square of frequency. But, in the low-frequency region, the acoustic impedance rises with the square of frequency, so the two effects effectively cancel each other over a significant range of frequencies. It is this serendipitous balance between key mechanical and acoustic parameters that makes the cone transducer an effective acoustic radiator.

The second regime is the region for which \(ka \gg 1\) (high frequencies and/or a large piston). In this case, because the piston resistance function approaches unity, we get

\[
W \approx \frac{1}{2} \rho_0 c \pi a^2 U_0^2 \\
= \frac{1}{2} \rho_0 c S U_0^2. \tag{17-16}
\]

Note that there is no frequency dependency in the above expression: the radiation resistance of a piston approaches a constant at high frequencies. Given velocity amplitude that falls off as the square of frequency, it is clear that, in the high-frequency regime, the acoustic power radiated by a typical transducer could be expected to decrease as the fourth power of the frequency. Note also that, in the low-frequency limit, for constant velocity amplitude, radiated power goes as the square of the surface area of the piston. In the high-frequency limit, however, it goes as only the first power of the area. Therefore, all else being equal, increasing the size of the piston has a greater effect on its low-frequency output than on its capacity to radiate higher frequencies.

### 17.10.1.2 Piston Directivity

So far, we have examined expressions for the total power radiated by a piston. If a piston radiated identically in all directions, no further acoustic information would be needed. Since this is not the case, it is also worthwhile to consider the nature of this directivity.

The mathematical technique for deriving the piston directivity function is to consider the piston as being made up of infinitesimal differential elements, each of which contributes to the observed radiation at a point in space. These individual contributions are combined via integration to yield a value for each specific point in space.

In coming up with a manageable expression for piston directivity, one assumption must be made: the distance from the piston to the observation point is much greater than the piston’s radius. The result for the pressure amplitude is

\[
\rho = \frac{\rho_0 c k a U_0}{2r} \left[ \frac{2J_1(ka \sin \theta)}{ka \sin \theta} \right] \tag{17-17}
\]

The first term in the above relationship contains the dependency of the pressure on velocity amplitude, piston size, and distance from the source. The second term, called the piston directivity function, is derived from a Bessel function, \(J_1(x)\). The value of this function is graphed in Fig. 17-58. Note that, up to \(ka = 3.83\), the value of the piston directivity function is uniformly positive. The radiation pattern of the piston will have only a single lobe under these conditions. If \(ka = 3.83\), the pattern will have a null at 90° off-axis. For higher values of \(ka\), this null will occur at successively smaller angles. Additionally, secondary lobes will appear outside of the main lobe, although these lobes are smaller in magnitude than the primary one. These lobes will alternate in sign: the first set will be negative, the second positive, etc.

**Figure 17-58.** Piston directivity function.

The directivity of a real loudspeaker differs from that predicted for a rigid piston due to the fact that several of the basic assumptions in the preceding model are not fully satisfied. First, no real loudspeaker has a perfectly rigid cone or diaphragm. In the case of a cone transducer, the diaphragm is excited at its center. The excitation travels outward from the voice coil as an acoustic disturbance in the cone material. The velocity of propagation of this disturbance is always finite. At lower frequencies, this effect is negligible, but at higher frequencies not all portions of the diaphragm will vibrate in phase.
A second difference between real loudspeakers and our theoretical piston is that practical diaphragms are very seldom flat. Most often, they are in the shape of a concave cone, but convex dome shapes are also employed. In many instances, the shape of the diaphragm is chosen so as to minimize the effect of finite-velocity wave propagation in the diaphragm material on the device’s on-axis response.

Generally speaking, the directivity of real-world cone or dome transducers is qualitatively similar to that of a rigid, flat piston. The nonideal behavior of real transducers can actually create beneficial effects in that the frequency at which secondary lobes appear can be higher than the theory predicts.

17.10.2 Direct Radiator Enclosure Design

A woofer is not effective as a freestanding radiator. If it were to be employed in this fashion, radiation from the rear of the diaphragm, which is out of phase with that from the front, would cause cancellation, particularly at low frequencies. Consequently, woofers are always housed. Two types of enclosures are widely used: sealed and vented.

17.10.2.1 Sealed-Box Systems

The low-frequency response of a sealed-box system may be modeled as a second-order high-pass filter. The effect of the enclosure is to add stiffness to the woofer suspension, which will modify the free-air resonant frequency of the woofer. The contribution made by the air in the enclosure to the stiffness of the diaphragm is given by

\[ k_b = \frac{\rho_0 c^2 S_D^2}{V_B} \]  \hspace{1cm} (17-18)

where
- \( k_b \) is the box effective spring constant,
- \( \rho_0 \) is the equilibrium density of air,
- \( c \) is the speed of sound in air,
- \( S_D \) is the diaphragm area,
- \( V_B \) is the enclosure volume.

The spring constant of the enclosure simply adds to that of the woofer suspension, so

\[ k' = k_d + k_B \]  \hspace{1cm} (17-19)

The air mass that effectively adds to the moving mass of the diaphragm is given by

\[ \frac{m_a}{3\pi} = \frac{\rho_0 8 S a}{3\pi} \]  \hspace{1cm} (17-20)

where,
- \( S \) is the surface area of diaphragm,
- \( a \) is the radius of diaphragm.

Again, this mass is additive, so

\[ m' = m_d + m_a. \]  \hspace{1cm} (17-21)

Note the dependence of the enclosure spring constant and the effective mass on two properties of air: its equilibrium density and the speed of sound. Both of these quantities are subject to significant variations with atmospheric conditions, so the degree of accuracy with which one can predict the response of an enclosure/transducer combination in actual use is intrinsically limited.

The resonant frequency of the woofer/enclosure system is given by

\[ \omega_0 = \frac{k'}{\eta m'} \]  \hspace{1cm} (17-22)

where,
- \( \omega_0 = 2\pi f \) is the angular resonant frequency.

The expression for the low-frequency farfield pressure response of a sealed-box woofer when driven by a constant-voltage source may be written as

\[ p = \frac{\frac{E_m B l \rho_0 S_d}{2\pi R_c m' r}}{1 + \frac{j\omega}{Q_\omega} \left( \frac{\omega_0^2}{\omega_0^2} - \frac{\omega^2}{\omega_0^2} \right)} \]  \hspace{1cm} (17-23)

where:
- \( E_m \) is the amplitude of the applied voltage,
- \( R_c \) is the dc resistance of the voice coil,
- \( B \) is the flux density in the magnet gap,
- \( l \) is the length of the voice coil conductor in the gap, and
- \( r \) is the distance from the source to the observation point.

\( Q_\omega \) is given by

\[ Q_\omega = \frac{\sqrt{k' m'}}{R_m + \frac{\beta^2 l^2}{R_e}} \]  \hspace{1cm} (17-24)

where,
- \( R_m \) is the woofer mechanical resistance (damping).
Note the separation of right side of the equation for pressure response into two parts. The first contains amplitude information resulting from the driving voltage, woofer parameters, and distance from the source, and the second provides frequency response information. A voltage excitation of the form of \( E = E_m e^{j\omega t} \) is assumed.

From the first term in the equation, we can see several ways in which the system’s output can be increased for a given distance and driving voltage:

1. Increase the flux density, \( B \). Increasing magnet size will accomplish this up to the point at which the pole piece is saturated.
2. Increase the length \( l \) of the conductor in the gap. This will increase \( R_e \), however, if all we do is to add turns to the voice coil.
3. Increase the diaphragm surface area, \( S_d \). Doing so without changing the density of the material will also increase \( m \), however.

Changing any of the above will potentially have an effect on the value of \( Q_t \). If the total system \( Q \) has a value of 0.707, the response of the system will be maximally flat, also known as a Butterworth alignment. If the \( Q \) is higher than this, there will be a peak in the response just above the cutoff frequency.

If total \( Q \) is lower than 0.707, the response will fall off, or sag, in the region above cutoff, Fig. 17-59.

### 17.10.2.2 Vented Boxes

Prior to the existence of analytical models for a vented-box woofer, it was understood that an opening could be cut in a low-frequency enclosure, creating a Helmholtz resonance. The vent itself functions as an additional radiator in this case, and its radiation can add constructively to that of the woofer over a limited range of frequencies. A. N. Thiele developed the original published analytical model for vented box radiators, and his work was later supplemented by that of Richard Small.

The effect of the enclosure on the spring constant of the woofer is the same as in a sealed enclosure. The vent functions as a passive radiator coupled to the woofer cone via the air in the enclosure. In modeling the response of a vented enclosure woofer, we must account for the motion, and therefore the acoustic radiation, of the vent. The air in the vent is assumed to move as a unit to allow the mathematics to remain manageable. The following expression gives the farfield half-space acoustic pressure from a vented enclosure at low frequencies:

\[
p = \left[ \frac{E_m B l \rho_0 S_d}{2 \pi R e m^*} \right] \times \frac{\left( \frac{\omega}{\omega_0} \right)^4}{\frac{\omega}{\omega_0} + \frac{1}{Q_t \omega_0} + \frac{1}{Q_t \omega_0^2} + \frac{1}{Q_t \omega_0^3} + \frac{1}{Q_t \omega_0^4}}
\]

where,
\( \omega = 2\pi f \),
\( \omega_0 = \sqrt{\rho_0 c \omega_v} \),
\( \omega_v = \sqrt{k_v / m_v} \).

The first portion of the right side is identical to its counterpart in the sealed-box equation. The second part describes a fourth-order high-pass filter. There are three general alignment classes for such filters: Butterworth, or maximally flat, Chebychev, or peaked; and Bessel, or maximally flat group delay.

A comparison of the attributes of sealed and vented enclosures is in order. The sealed system has the advantage of an intrinsic excursion-limiting mechanism—the addition to the woofer’s spring constant due to the air in the chamber—for frequencies below the system cutoff. The vented system, on the other hand, can allow excessive woofer excursion if excited with out-of-band signals, so an electrical high-pass filter is a desirable protective element. The higher-order nature of the vented system renders it more susceptible to misalignments caused by production variations in woofer parameters and changes in atmospheric conditions, but it has the advantage of
requiring less woofer excursion for a given acoustic output in the lowest portion of its usable bandwidth. In general, a sealed system will have more highly damped low-frequency transient response when compared to a vented system with the same cutoff frequency. This effect is most noticeable for frequencies in the neighborhood of the system lower cutoff frequency.

The design and modeling of vented and sealed woofer enclosures has been greatly simplified in recent years due to the ready availability of computer software developed specifically for the purpose. The following Thiele-Small (in honor of A. N. Thiele and Richard Small) loudspeaker parameters are required as minimum input to an enclosure design program:

1. \( Q_T \) is the total loudspeaker \( Q \).
2. \( F_S \) is the free-air cone resonance of the loudspeaker.
3. \( V_{AS} \) is the equivalent volume compliance of the suspension.
4. \( X_{max} \) is the maximum linear excursion.
5. \( P_{max} \) is the maximum thermal power handling.

Most manufacturers provide the above parameters as per Audio Engineering Society (AES) recommended practice on loudspeaker specifications.

Loudspeaker enclosures can have resonances, or standing waves, caused by internal reflections. The characteristic frequencies (\( f_n \)) of these standing waves are given by:

\[
 f_n = \frac{c}{2} \sqrt{\left( \frac{n_x}{l_x} \right)^2 + \left( \frac{n_y}{l_y} \right)^2 + \left( \frac{n_z}{l_z} \right)^2}
\]

(17-26)

where,

\( x, y, \) and \( z \) are the three box dimensions,

\( l \) is the designated dimension of the box,

\( n \) takes on all possible integer values \( (n = 0, 1, 2, 3, \ldots) \).

If the lowest modal frequency found by setting \( n = 0 \) for all but the longest box dimension is above the band of use, there will be no standing waves inside the enclosure. In the more common case of a woofer being used above the first mode frequency, acoustic absorption can be added to damp these unwanted resonances. It should be understood that the addition of large amounts of damping material can have an adverse effect on the box/port tuning, so a balance must often be struck between control of standing waves and optimal low frequency response alignment.

### 17.10.2.3 Measurement of Thiele-Small Parameters

The most accurate way of determining \( f_S \) is by observation of a Lissajous pattern on an oscilloscope of voltage versus current with the speaker in free air. When the pattern collapses to a straight diagonal line, the phase of the impedance is zero, which indicates resonance. Once this condition has been achieved, the frequency should be measured with a frequency counter that is accurate to 0.1 Hz or better.

\( V_{AS} \) may be determined with the loudspeaker suspended in free air as follows:

1. Find total moving mass \( (m) \) by attaching an extra mass \( (M_X) \) to the cone (as close to the voice coil as possible) and observing the new resonant frequency, \( f_{SX} \). \( M_X \) can be putty or clay; measure \( m_X \) accurately. The total mass can then be found by the equation

\[
 m' = \frac{M_X}{\left( \frac{f_S}{f_{SX}} \right)^2 - 1}
\]

(17-27)

2. The suspension spring constant is then

\[
 k = (2 \pi f_s)^2 m'
\]

(17-28)

3. From the effective diaphragm area of the loudspeaker, \( S_D \), \( V_{AS} \) is given by

\[
 V_{AS} = \frac{p_0 c^2 S_D^2}{k}
\]

(17-29)

One means for determining the effective diaphragm area is to excite the woofer near its resonant frequency and observe its motion using a strobe light tuned almost, but not exactly, to the frequency of excitation. The resulting apparent slow motion of the woofer will allow an accurate determination of the portion of the cone that is moving.

\( Q_T \) may be found using the following procedure:

1. Determine the impedance of the woofer, \( Z_{max} \), at its resonant frequency. This is simply the applied voltage divided by the current in the coil.
2. Identify the frequencies, \( f_+ \) and \( f_- \), above and below \( f_s \), respectively, at which the magnitude of the applied voltage divided by the magnitude of the current in the coil is equal to.
3. Mechanical \( Q \) is given by

\[
 Q_m = \left( \frac{f_0}{f_+ - f_-} \right) \sqrt{\frac{Z_{max}}{R_e}}
\]

(17-30)

4. The total \( Q \) is then
17.10.3 Horns

Although there are numerous mathematical treatments of horns in the texts on acoustics, they all suffer from a common set of inadequacies: the models developed in the literature account for energy transmission inside the horn, but there are no closed-form solutions to the problem of horn directivity—i.e., the behavior of a horn’s radiation outside the boundaries of the horn walls, where listeners are located. Modern horn designers have been far less concerned with optimizing acoustic loading than with creating desirable directivity characteristics, and the designs have without exception been derived empirically rather than analytically.

In an exponential horn, the cross-sectional area is given by

\[ S = S_0 e^{mx} \]  

(17-32)

where,

- \( S_0 \) is the cross-sectional area at the horn’s throat, or entry,
- \( m \) is called the flare constant.

The radiation impedance of an exponential horn, assumed to be infinitely long for our purposes, is

\[ Z_r = \frac{\rho_0 c}{S_0} \left[ \frac{1}{N} - \frac{m^2 c^2}{4\omega^2} + j\frac{mc}{2\omega} \right]. \]  

(17-33)

The first term in the brackets is the radiation resistance, and the second is the radiation reactance. Of interest is the frequency at which the value of expression inside the square root becomes zero

\[ \omega_c = \frac{mc}{2} \]  

(17-34)

or

\[ f_c = \frac{mc}{4\pi} \]  

(17-35)

This is known as the horn cutoff frequency. The above theory predicts that no sound will be transmitted through the horn below this frequency. Clearly, this is not the case with real horns, so the theory contains one or more assumptions that are not met in practice. Note also that the second term in the brackets, the radiation reactance, goes to zero in the high-frequency limit.

17.11 Loudspeaker Testing and Measurement

As with most other devices that transmit or process a signal containing information, measurement techniques have been developed specifically for the testing and evaluation of loudspeakers. Before the early 1980s, accurate, comprehensive testing of loudspeakers generally required expensive anechoic chambers or large outdoor spaces. Since that time, the advent of computer-based time-windowed measurements has revolutionized the field of acoustic instrumentation, particularly as regards the testing of loudspeakers.

17.11.1 Linear Transfer Function

One objective in testing a loudspeaker is to determine the linear portion of its characteristic transfer function (or, equivalently, impulse response). The most common means for acquiring this data is a spectrum analyzer. A spectrum analyzer applies a signal with known spectral content to the input of a system and processes the signal that appears at the output of the device to acquire the system’s transfer function.

17.11.1.1 Spectrum Analysis Concepts

All spectrum analysis techniques are subject to a set of general constraints imposed by the mathematical relationship between time and frequency. It is useful to have a feeling for these constraints when gathering or evaluating loudspeaker data. Time and frequency are the mathematical inverses of each other. A signal that has only one frequency must exist for all time and, conversely, a signal that exists for a finite amount of time must contain multiple frequencies. A signal that exists only within a known time interval—i.e., at all times before time \( t_0 \) the value of the signal is zero and at all times after time \( t_1 \) the value is zero—can only contain frequencies given by the expression:

\[ f = N \frac{1}{(t_1 - t_0)} \]  

(17-36)

where,

- \( N \) is an integer.

The frequency corresponding to \( N = 1 \) gives the best (lowest) frequency resolution that is possible in a test conducted for that precise time interval. All other
frequencies will be integer multiples of this frequency. In order to have infinitesimally small frequency resolution (i.e., perfectly resolved frequency data), a test would have to be conducted for an infinite amount of time. It follows that all realizable response tests have a limit on their frequency resolution.

The effect of frequency resolution on a transfer function measurement is to smooth the appearance of a plot of the results, thereby possibly obscuring some of the details of the transfer function. This smoothing is present to some degree in all transfer function measurements. In the case of electronic devices, transfer functions are typically well behaved enough that the frequency resolution of a response test does not cause meaningful loss of detail. With loudspeakers, the opposite is often true: a loudspeaker’s transfer function often has so much fine structure that a practical test will noticeably smooth out the peaks and dips in the speaker’s response. The degree to which this fine structure is audibly significant is a matter of some controversy. As a result, there is no widespread agreement in the industry on the minimum desirable frequency resolution in testing loudspeakers.

17.11.2 Chart Recorders

Prior to the advent of computer-based measurement systems, the most commonly employed loudspeaker measurement instrumentation comprised a strip chart recorder and a signal sweep generator. The two devices are synchronized such that, for a given frequency in the sweep, the pen on the recorder is in the appropriate x (frequency) position on preprinted graph paper. The pen’s y position would correspond to the amplitude of the signal received from the test microphone, and therefore, hopefully, to the amplitude response of the speaker at that frequency.

If the y amplifier is logarithmic, then the amplitude will be expressed in decibels. As common as the strip-chart measurement technique was prior to the 1980s, it had several prominent disadvantages:

1. There is no means of measuring a loudspeaker’s phase response with this technique.
2. The measurement is incapable of discriminating between direct sound from the device under test and sound that is reflected from surfaces in the test environment. This necessitated the construction of very costly anechoic chambers. Even in such a chamber, the inclusion of some reflected sound in a strip-chart type measurement is unavoidable.
3. The measurement technique does not isolate the linear portion of a loudspeaker’s transfer function. Distortion products are simply added to the amplitude of the loudspeaker’s transfer function at the fundamental frequency that excites them.
4. There is no direct, accurate way to determine or control the frequency resolution of a strip chart measurement. Reducing pen speed and/or increasing chart (and sweep) speed have the effect of reducing frequency resolution, or smoothing, the data, but the degree to which this has taken place is not always apparent.
5. Data from this form of measurement is only generated in hard copy format.
6. This measurement technique provides no ready means to compensate for propagation delay: the time required for sound to travel from the loudspeaker to the test microphone.
7. Since there is no means for distinguishing between the output signal from the loudspeaker and ambient noise, the test environment must be quiet.

17.11.3 Real Time Analyzers

Although initially developed to measure the response of sound systems in their operating environments, real-time analysis has also been used to measure loudspeaker response in controlled environments. With this testing technique, a pink noise signal is applied to the loudspeaker. Pink noise is a random signal that contains equal energy for each unit of logarithmic frequency—e.g., for each octave or fraction thereof. The signal from the test microphone is applied to a series of bandpass filters of constant percent-octave bandwidth, each of which is tuned to a different band center, and the averaged output level of each filter is displayed, either on a CRT, LCD, or LED display. The display represents, within the limitations due to the measurement technique and the test environment, the amplitude response of the loudspeaker. Because the frequency content of a random signal has small fluctuations over time, the display may be averaged, or integrated, to produce a stable graph. Real time analysis suffers from the same general disadvantages as the chart recorder method of measurement.

17.11.4 Time-Windowed Measurements

The development of inexpensive computers has literally revolutionized the field of acoustic instrumentation. This is largely the result of the computer’s ability to process and store large amounts of signal data. With a
computer-based measurement system, processing and display of the data can be accomplished at any time after the raw data has been taken.

The effects of time windowing are present in any signal measurement, since the measurement must be initiated and completed in a finite amount of time (window). In digital measurement systems, however, the exact size of the time window, and therefore the resultant tradeoffs in resolution, are more directly controllable. There are two general approaches to acquiring a loudspeaker’s transfer function via time-windowed measurements: measurement of the device’s impulse response (time-domain measurement) or acquisition of the device’s transfer function in the frequency domain.

17.11.4.1 Measurement of the Impulse Response

One form of input signal that is highly useful as an excitation for test and analysis purposes is an impulse. Mathematically, the signal is described by a Dirac delta function. Descriptively, an impulse is a voltage “spike” of very short duration and relatively large amplitude. An interesting property of an impulse is that it contains all frequencies at the same level. The impulse response of a loudspeaker, via the Fourier transform (or fast Fourier transform, FFT, as implemented in computer-based instruments), gives the speaker’s transfer function. It is this equivalency via transform of the impulse response and transfer function that allows us to fully characterize a two-port device through measurement taken in only one domain or the other (time or frequency).
